OXFORD LIBRARY OF PSYCHOLOGY

The *Oxford Library of Psychology*, a landmark series of handbooks, is published by Oxford University Press, one of the world's oldest and most highly respected publishers, with a tradition of publishing significant books in psychology. The ambitious goal of the *Oxford Library of Psychology* is nothing less than to span a vibrant, wide-ranging field and, in so doing, to fill a clear market need.

Encompassing a comprehensive set of handbooks, organized hierarchically, the *Library* incorporates volumes at different levels, each designed to meet a distinct need. At one level are a set of handbooks designed broadly to survey the major subfields of psychology; at another are numerous handbooks that cover important current focal research and scholarly areas of psychology in depth and detail. Planned as a reflection of the dynamism of psychology, the *Library* will grow and expand as psychology itself develops, thereby highlighting significant new research that will impact on the field. Adding to its accessibility and ease of use, the *Library* will be published in print and, later on, electronically.

The *Library* surveys psychology's principal subfields with a set of handbooks that capture the current status and future prospects of those major subdisciplines. This initial set includes handbooks of social and personality psychology, clinical psychology, counseling psychology, school psychology, educational psychology, industrial and organizational psychology, cognitive psychology, cognitive neuroscience, methods and measurements, history, neuropsychology, personality assessment, developmental psychology, and more. Each handbook undertakes to review one of psychology's major subdisciplines with breadth, comprehensiveness, and exemplary scholarship. In addition to these broadly conceived volumes, the *Library* also includes a large number of handbooks designed to explore in depth more specialized areas of scholarship and research, such as stress, health and coping, anxiety and related disorders, cognitive development, or child and adolescent assessment. In contrast to the broad coverage of the subfield handbooks, each of these latter volumes focuses on an especially productive, more highly focused line of scholarship and research. Whether at the broadest or most specific level, however, all of the *Library* handbooks offer synthetic coverage that reviews and evaluates the relevant past and present research and anticipates research in the future. Each handbook in the *Library* includes introductory and concluding chapters written by its editor to provide a roadmap to the handbook's table of contents and to offer informed anticipations of significant future developments in that field.

An undertaking of this scope calls for handbook editors and chapter authors who are established scholars in the areas about which they write. Many of the nation's and world's most productive and best-respected psychologists have

agreed to edit *Library* handbooks or write authoritative chapters in their areas of expertise.

For whom has the *Oxford Library of Psychology* been written? Because of its breadth, depth, and accessibility, the *Library* serves a diverse audience, including graduate students in psychology and their faculty mentors, scholars, researchers, and practitioners in psychology and related fields. These individuals will find in the *Library* the information they seek on the subfield or focal area of psychology in which they work or are interested.

Befitting its commitment to accessibility, each handbook includes a comprehensive index, as well as extensive references to help guide research. And because the *Library* was designed from its inception as an online as well as a print resource, its structure and contents will be readily and rationally searchable online. Furthermore, once the *Library* is released online, the handbooks will be regularly and thoroughly updated.

In summary, the *Oxford Library of Psychology* will grow organically to provide a thoroughly informed perspective on the field of psychology, one that reflects both psychology's dynamism and its increasing interdisciplinarity. Once published electronically, the *Library* is also destined to become a uniquely valuable interactive tool, with extended search and browsing capabilities. As you begin to consult this handbook, we sincerely hope you will share our enthusiasm for the more than 500-year tradition of Oxford University Press for excellence, innovation, and quality, as exemplified by the *Oxford Library of Psychology*.

ABOUT THE EDITORS

Keith J. Holyoak

Keith J. Holyoak, Ph.D., Distinguished Professor of Psychology at the University of California, Los Angeles, is a leading researcher in human thinking and reasoning. He received his B.A. from the University of British Columbia in 1971 and his Ph.D. from Stanford University in 1976. Dr. Holyoak was on the faculty of the University of Michigan from 1976–1986 and then joined the Department of Psychology at UCLA. His work combines behavioral studies with both cognitive neuroscience and computational modeling. Dr. Holyoak has published over 180 scientific articles, and is the co-author or editor of numerous books, including *Induction: Processes of Inference, Learning and Discovery* (MIT Press, 1986), *Mental Leaps: Analogy in Creative Thought* (MIT Press, 1995), and the *Cambridge Handbook of Thinking and Reasoning* (Cambridge University Press, 2005). In a parallel career as a poet he has published *Facing the Moon: Poems of Li Bai and Du Fu* (Oyster River Press, 2007), *My Minotaur: Selected Poems 1998–2006* (Dos Madres Press, 2010), and *Foreigner: New English Poems in Chinese Old Style* (Dos Madres Press, 2012).

Robert G. Morrison

Robert G. Morrison, Ph.D., Assistant Professor of Psychology and Neuroscience at Loyola University Chicago, uses behavioral, computational, and neuroimaging methods to investigate memory and reasoning throughout the lifespan. After receiving his B.S. from Wheaton College, Morrison worked both as a scientist and a conceptual artist. He discovered cognitive science at the interface of these worlds and studied Cognitive Neuroscience at UCLA, where he received his Ph.D. in 2004. After co-founding Xunesis (xunesis.org) and completing a National Institute of Aging post-doctoral fellowship at Northwestern University, Morrison joined the Department of Psychology and the Neuroscience Institute at Loyola in 2009. Dr. Morrison has published numerous scientific articles and chapters and has edited the *Cambridge Handbook of Thinking and Reasoning* (Cambridge University Press, 2005). Dr. Morrison's research has been funded by the National Institute of Mental Health, the Office of Naval Research, the American Federation of Aging Research, and the Illinois Department of Public Health. In a parallel career as an artist he has exhibited his painting, sculpture and photography in galleries and museums throughout the United States.

PREFACE

A few decades ago, when the science of cognition was in its infancy, the early textbooks on cognition began with perception and attention and ended with memory. So-called higher-level cognition—the mysterious, complicated realm of thinking and reasoning—was simply left out. Things changed—any good cognitive text (and there are many) devotes several chapters to topics such as categorization, various types of reasoning, judgment and decision making, and problem solving. As the new century began, we noticed that unlike fields such as perception or memory, the field of thinking and reasoning lacked a true Handbook—a book meant to be kept close “at hand” by those involved in the field, particularly those new to it. In response, we edited the *Cambridge Handbook of Thinking and Reasoning* (2005). Our aim was to bring together top researchers to write chapters each of which summarized the basic concepts and findings for a major topic, sketch its history, and give a sense of the directions in which research is currently heading. The *Handbook* provided quick overviews for experts in each topic area, and more important for experts in allied topic areas (as few researchers can keep up with the scientific literature over the full breadth of the field of thinking and reasoning). Even more crucially, this *Handbook* was meant to provide an entry point into the field for the next generation of researchers, by providing a text for use in classes on thinking and reasoning designed for graduate students and upper-level undergraduates.

The first *Handbook* achieved these aims. However, a fast-moving scientific field has a way of quickly rendering the “state of the art” the “state of yesterday.” By the time the book appeared, new developments that our book had barely touched on were already generating excitement among researchers. These new themes included advances in Bayesian modeling, which helped to understand the rational foundations of thinking and reasoning, and advances in cognitive neuroscience, which began to link higher order cognition to its neural and even genetic substrate. In addition, new topics such as moral reasoning became active. After a few years, we decided the field of thinking and reasoning was ripe for a new comprehensive overview. This is it. Our aim is to provide comprehensive and authoritative reviews of all the core topics of the field of thinking and reasoning, with many pointers for further reading. Doubtless we still have omissions, but we have included as much as could realistically fit in a single volume. Our focus is on research from cognitive psychology, cognitive science, and cognitive neuroscience, but we also include work related to developmental, social and clinical psychology, philosophy, economics, artificial intelligence, linguistics, education, law, business,

and medicine. We hope that scholars and students in all these fields and others will find this to be a valuable collection.

We have many to thank for their help in bringing this endeavor to fruition. The editors at Oxford University Press, Catherine Carlin and more recently Joan Bossert, were instrumental in initiating and nurturing the project. We find it fitting that our new *Oxford Handbook of Thinking and Reasoning* should bear the imprint and indeed the name of this illustrious press, with its long history reaching back to the origins of scientific inquiry and its unparalleled list in the field of psychology. The entire staff at Oxford, especially Chad Zimmerman, provided us with close support throughout the arduous process of editing 40 chapters with 76 authors. During this period our own efforts were supported by grants from the Office of Naval Research (N000140810126), the Air Force Office of Scientific Research (FA9550-08-1-0489), and the Institute of Education Sciences (R305C080015) (KJH); and from the National Institute of Aging (T32AG020506), the Illinois Department of Public Health Alzheimer's Disease Research Fund, American Federation of Aging/Rosalinde and Arthur Gilbert Foundation, and the Loyola University Chicago Deans of Arts and Sciences and the Graduate School (RGM).

And then there are the authors. (It would seem a bit presumptuous to call them “our” authors!) People working on tough intellectual problems sometimes experience a moment of insight (see Chapter 24), a sense that although many laborious steps may lay ahead, the basic elements of a solution are already in place. Such fortunate people work on happily, confident that ultimate success is assured. In preparing this *Handbook*, we also had our moment of “insight.” It came when all these outstanding researchers had agreed to join our project. Before the first chapter was drafted, we knew the volume was going to be of the highest quality. Along the way, our distinguished authors graciously served as each other’s reviewers as we passed drafts around, nurturing each other’s chapters and adding in pointers from one to another. Then the authors all changed hats again and went back to work revising their own chapters in light of the feedback their peers had provided. We thank you all for making our own small labors a great pleasure.

Thinking and Reasoning: A Reader's Guide

Keith J. Holyoak and Robert G. Morrison

“*Cogito, ergo sum*,” the French philosopher René Descartes famously declared, “I think, therefore I am.” Every fully functioning human adult shares a sense that the ability to think, to reason, is a part of one’s fundamental identity. A person may be struck blind or deaf yet still recognize his or her core cognitive capacities as intact. Even loss of language, the gift often claimed as the *sine qua non* of *Homo sapiens*, does not take away a person’s essential humanness. Perhaps thinking, not language, lies closest to both the core of our individual identity and to what is special about our species (see Penn & Povinelli, Chapter 27; Gleitman & Papafragou, Chapter 28). A person who loses language but can still make intelligent decisions, as demonstrated by actions, is viewed as mentally competent. In contrast, the kinds of brain damage that rob an individual of the capacity to think and reason are considered the harshest blows that can be struck against a sense of personhood (see Morrison & Knowlton, Chapter 6).

Cogito, ergo sum.

What Is Thinking?

We can start to answer this question by looking at the various ways the word *thinking* is used in everyday language. “I think that water is necessary for life” and “Keith and Bob think George was a fascist” both express *beliefs* (of varying degrees of apparent plausibility)—explicit claims of what someone takes to be a truth about the world. “Ann is sure to think of a solution” carries us into the realm of problem solving, the mental construction of an action plan to achieve a goal. The complaint, “Why didn’t you think before you went ahead with your half-baked scheme?” emphasizes that thinking can be a kind of *foresight*, a way of “seeing” the possible future.¹ “What do you think about it?” calls

for a *judgment*, an assessment of the desirability of an option. “Genocide is evil” takes judgment into the *moral* domain. And then there’s “Albert is lost in thought,” where thinking becomes some sort of mental meadow through which a person might meander on a rainy afternoon, oblivious to the world outside.

Rips and Conrad (1989) elicited judgments from college students about how various mentalistic terms relate to one another. Using statistical techniques, the investigators were able to summarize these relationships in two diagrams, shown in Figure 1.1. Figure 1.1A is a hierarchy of *kinds*, or categories. Roughly, people think planning is a kind of deciding, which is a kind of reasoning, which is a kind of conceptualizing, which is a kind of thinking. People also think (that verb again!) that thinking is *part of* conceptualizing, which is part of remembering, which is part of reasoning, and so on (Fig. 1.1B). The kinds ordering and the parts ordering are quite similar; most strikingly, *thinking* is the most general term in both orderings—the grand superordinate of mental activities, which permeates all the others.

Cogito, ergo sum.

It is not easy to make the move from the free flow of everyday speech to scientific definitions of mental terms, but let us nonetheless offer a preliminary definition of thinking to suggest what this book is about:

Thinking is the systematic transformation of mental representations of knowledge to characterize actual or possible states of the world, often in service of goals.

Obviously our definition introduces a plethora of terms with meanings that beg to be unpacked, but at which we can only hint. A *mental representation* of knowledge is an internal description that

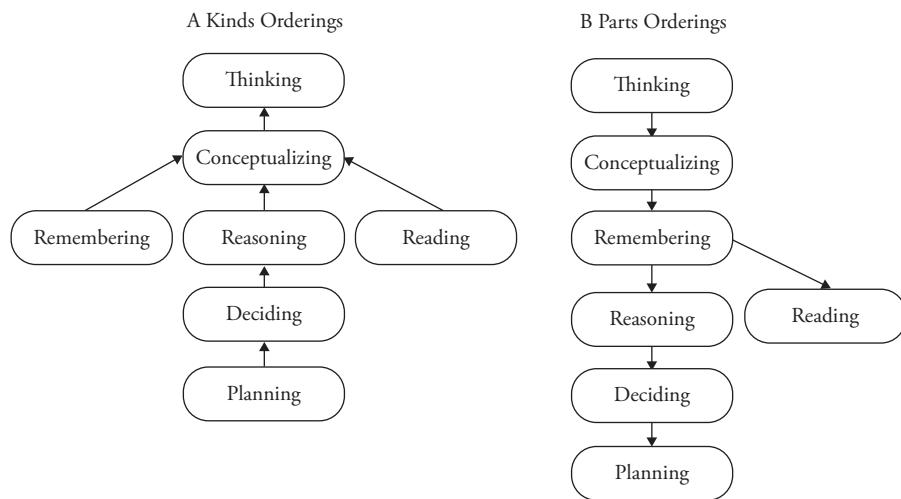

Fig. 1.1 People's conceptions of the relationships among terms for mental activities. (A) Ordering of "kinds." (B) Ordering of "parts." (Adapted from Rips & Conrad, 1989, with permission.)

can be manipulated to form other descriptions (see Markman, Chapter 4). To count as thinking, the manipulations must be *systematic* transformations that may be described computationally (see Doumas & Hummel, Chapter 5), governed by certain constraints. Whether a logical deduction (see Evans, Chapter 8) or a creative leap (see Smith & Ward, Chapter 23), what we mean by thinking is more than unconstrained associations (with the caveat that thinking may indeed be disordered; see Bachman & Cannon, Chapter 34). The internal representations created by thinking describe states of some external world (a world that may include the thinker as an object of self-reflection; see Gelman & Frazier, Chapter 26); that world might be our everyday one or perhaps some imaginary construction obeying the "laws" of magical realism. And often (not always—the daydreamer, and indeed the night dreamer, is also a thinker), thinking is directed toward achieving some desired state of affairs, some goal that motivates the thinker to do mental work (see Molden & Higgins, Chapter 20).

Our definition thus includes quite a few stipulations, but notice also what is left out. We do not claim that thinking necessarily requires a human or even a sentient being. Nonetheless, our focus in this book is on thinking by hominids with electrochemically powered brains constrained by their genes. Thinking often seems to be a conscious activity, of which the thinker is aware (*cogito, ergo sum*); but consciousness is a thorny philosophical puzzle, and some mental activities seem pretty

much like thinking except for being implicit rather than explicit (see Evans, Chapter 8). Finally, we do not claim that thinking is inherently rational, or optimal, or desirable, or even smart (see Stanovich, Chapter 22). A thorough history of human thinking will include quite a few chapters on stupidity; but at its pinnacle, thinking can be sheer genius (see Simonton, Chapter 25).

The study of thinking includes several interrelated subfields, which reflect slightly different perspectives on thinking. *Reasoning*, which has a long tradition that springs from philosophy and logic, places emphasis on the process of drawing inferences (*conclusions*) from some initial information (*premises*). In standard logic, an inference is *deductive* if the truth of the premises guarantees the truth of the conclusion by virtue of the argument form. If the truth of the premises renders the truth of the conclusion more credible, but does not bestow certainty, the inference is called *inductive*.² *Judgment and decision making* involve assessment of the value of an option or the probability that it will yield a certain payoff (judgment), coupled with choice among alternatives (decision making). *Problem solving* involves the construction of a course of action that can achieve a goal.

Although these distinct perspectives on thinking are useful in organizing the field (and this volume), these aspects of thinking overlap in every conceivable way. To solve a problem, one is likely to reason about the consequences of possible actions and to make decisions to select among alternative actions.

A logic problem, as the name implies, is a problem to be solved (with the goal of deriving or evaluating a possible conclusion). Making a decision is often a problem that requires reasoning. And so on. These subdivisions of the field, like our preliminary definition of thinking, should be treated as guideposts, not destinations.

A Capsule History

Thinking and reasoning, long the academic province of philosophy, have over the past century emerged as core topics of empirical investigation and theoretical analysis in the modern fields known as cognitive psychology, cognitive science, and cognitive neuroscience. Before psychology was founded, the 18th-century philosophers Immanuel Kant (in Germany) and David Hume (in Scotland) laid the foundations for all subsequent work on the origins of causal knowledge, perhaps the most central problem in the study of thinking (see Cheng & Buehner, Chapter 12). And if we were to choose one phrase to set the stage for modern views of thinking, it would be an observation of the British philosopher Thomas Hobbes, who in 1651 in his treatise *Leviathan* proposed “Reasoning is but reckoning.” *Reckoning* is an odd term today, but in the 17th century it meant “computation,” as in arithmetic calculations.³

It was not until the 20th century that the psychology of thinking became a scientific endeavor. The first half of the century gave rise to many important pioneers who in very different ways laid the foundations for the emergence of the modern field of thinking and reasoning. Foremost were the Gestalt psychologists of Germany, who provided deep insights into the nature of problem solving (see Bassok & Novick, Chapter 21; van Steenburgh et al., Chapter 24). Most notable of the Gestaltists were Karl Duncker and Max Wertheimer, students of human problem solving, and Wolfgang Köhler, a keen observer of problem solving by great apes.

The pioneers of the early 20th century also include Sigmund Freud, whose complex and ever-controversial legacy includes the notions that forms of thought can be unconscious, and that “cold” cognition is tangled up with “hot” emotion (see Molden & Higgins, Chapter 20). As the founder of clinical psychology, Freud’s legacy also includes the ongoing integration of research on “normal” thinking with studies of thought disorders, such as schizophrenia (see Bachman & Cannon, Chapter 34).

Other early pioneers in the early and mid-century contributed to various fields of study that are now

embraced within thinking and reasoning. Cognitive development (see Gelman & Frazier, Chapter 26) continues to be influenced by the early theories developed by the Swiss psychologist Jean Piaget and the Russian psychologist Lev Vygotsky. In the United States, Charles Spearman was a leader in the systematic study of individual differences in intelligence (see Stanovich, Chapter 22). In the middle of the century, the Russian neurologist Alexander Luria made immense contributions to our understanding of how thinking depends on specific areas of the brain, anticipating the modern field of cognitive neuroscience (see Morrison & Knowlton, Chapter 6). Around the same time in the United States, Herbert Simon argued that the traditional rational model of economic theory should be replaced with a framework that accounted for a variety of human resource constraints, such as bounded attention and memory capacity and limited time (see LeBoeuf & Shafir, Chapter 16). This was one of the contributions that in 1978 earned Simon the Nobel Prize in Economics.

In 1943, the British psychologist Kenneth Craik sketched the fundamental notion that a mental representation provides a kind of model of the world that can be “run” to make predictions (much like an engineer might use a physical scale model of a bridge to anticipate the effects of stress on the actual bridge intended to span a river).⁴ In the 1960s and 1970s, modern work on the psychology of reasoning began in Britain with the contributions of Peter Wason and his collaborator Philip Johnson-Laird (see Evans, Chapter 8; Johnson-Laird, Chapter 9).

The modern conception of thinking as computation became prominent in the 1970s. In their classic treatment of human problem solving, Allen Newell and Herbert Simon (1972) showed that the computational analysis of thinking (anticipated by Alan Turing, the father of computer science) could yield important empirical and theoretical results. Like a program running on a digital computer, a person thinking through a problem can be viewed as taking an input that represents initial conditions and a goal, and applying a sequence of operations to reduce the difference between the initial conditions and the goal. The work of Newell and Simon established computer simulation as a standard method for analyzing human thinking (see Doumas & Hummel, Chapter 5). It also highlighted the potential of production systems, which were subsequently developed extensively as cognitive models by John Anderson and his colleagues (see Koedinger & Roll, Chapter 40).

The 1970s saw a wide range of major developments that continue to shape the field. Eleanor Rosch, building on earlier work by Jerome Bruner (Bruner, Goodnow, & Austin, 1956), addressed the fundamental question of why people have the categories they do, and not other logically possible groupings of objects (see Rips, Smith, & Medin, Chapter 11). Rosch argued that natural categories often have fuzzy boundaries (a whale is an odd mammal), but nonetheless have clear central tendencies, or prototypes (people by and large agree that a bear makes a fine mammal). The psychology of human judgment was reshaped by the insights of Amos Tversky and Daniel Kahneman, who identified simple cognitive strategies, or heuristics, that people use to make judgments of frequency and probability. Often quick and accurate, these strategies can in some circumstances lead to nonnormative judgments. After Tversky's death in 1996, this line of work was continued by Kahneman, who was awarded the Nobel Prize in Economics in 2002. The current view of judgment that has emerged from 30 years of research is summarized by Griffin et al. (Chapter 17; also see LeBoeuf & Shafir, Chapter 16). Goldstone and Son (Chapter 10) review Tversky's influential theory of similarity judgments.

In 1982 David Marr, a young vision scientist, laid out a vision of how the science of mind should proceed. Marr distinguished three levels of analysis, which he termed the levels of *computation*, *representation and algorithm*, and *implementation*. Each level, according to Marr, addresses different questions, which he illustrated with the example of a physical device, the cash register. At Marr's most abstract level, computation (not to be confused with computation of an algorithm on a computer), the basic questions are "What is the goal that the cognitive process is meant to accomplish?" and "What is the logic of the mapping from the input to the output that distinguishes this mapping from other input-output mappings?" A cash register, viewed at this level, is used to achieve the goal of calculating how much is owed for a purchase. This task maps precisely onto the axioms of addition (e.g., the amount owed shouldn't vary with the order in which items are presented to the sales clerk, a constraint that precisely matches the commutativity property of addition). It follows that without knowing anything else about the workings of a particular cash register, we can be sure that (if it is working properly) it will be doing addition (not division).

The level of representation and algorithm, as the name implies, deals with the questions, "What is the representation of the input and output?" and "What is the algorithm for transforming the former into the latter?" Within a cash register, addition might be performed using numbers in either decimal or binary code, starting with either the leftmost or rightmost digit. Finally, the level of implementation addresses the question, "How are the representation and algorithm realized physically?" The cash register could be implemented as an electronic calculator, or a mechanical adding machine, or even a mental abacus in the mind of the clerk.

In his book, Marr stressed the importance of the computational level of analysis, arguing that it could be seriously misleading to focus prematurely on the more concrete levels of analysis for a cognitive task without understanding the goal or nature of the mental computation.⁵ Sadly, Marr died of leukemia before his book was published, so we do not know how his thinking about levels of analysis might have evolved. In very different ways, Marr's conception of a computational level of analysis is reflected in several chapters in this book (see especially Chater & Oaksford, Chapter 2; Griffiths, Tenenbaum, & Kemp, Chapter 3; Cheng & Buehner, Chapter 12; and Hahn & Oaksford, Chapter 15).

In the most recent quarter century many other springs of research have fed into the river of thinking and reasoning, including relational reasoning (see Holyoak, Chapter 13), neural network models (see Doumas & Hummel, Chapter 5), cognitive neuroscience (see Morrison & Knowlton, Chapter 6), and cognitive neurogenetics (Green & Dunbar, Chapter 7). The chapters of this *Handbook* collectively paint a picture of the state of the field in the early years of the new millennium.

Overview of the Handbook

This volume brings together the contributions of many of the leading researchers in thinking and reasoning to create the most comprehensive overview of research on thinking and reasoning that has ever been available. Each chapter includes a bit of historical perspective on the topic and ends with some thoughts about where the field seems to be heading. The book is organized into seven sections.

Part I: General Approaches to Thinking and Reasoning

The seven chapters in Part I address foundational issues. Chapter 2 by Chater and Oaksford lays out

the major normative theories (logic, probability, and rational choice) that have been used as standards against which human thinking and reasoning are often compared. In Chapter 3, Griffiths, Tenenbaum, and Kemp provide an overview of the Bayesian framework for probabilistic inference, which has been reinvigorated in recent years. Chapter 4 by Markman provides an overview of different conceptions of mental representation, and Chapter 5 by Doumas and Hummel surveys approaches to building computational models of thinking and reasoning. Then in Chapter 6, Morrison and Knowlton provide an introduction to the methods and findings of cognitive neuroscience as they bear on higher cognition, and in Chapter 7 Green and Dunbar discuss the emerging links between thinking and cognitive neurogenetics.

Part II: Inductive, Deductive, and Abductive Reasoning

Chapters 8–15 deal with core topics of reasoning. In Chapter 8, Evans reviews dual-process theories of reasoning, with emphasis on the psychology of deductive reasoning, the form of thinking with the closest ties to logic. In Chapter 9, Johnson-Laird describes the work that he and others have done using the framework of mental models to deal with various reasoning tasks, both deductive and inductive. Chapter 10 by Goldstone and Son reviews work on the core concept of similarity—how people assess the degree to which objects or events are alike. Chapter 11 by Rips, Smith, and Medin considers research on categories, and how concepts are organized in semantic memory. In Chapter 12, Cheng and Buehner discuss causal learning, a basic type of induction concerning how humans and other creatures acquire knowledge about causal relations, which are critical for predicting the consequences of actions and events. Then, in Chapter 13, Holyoak reviews the literature on reasoning by analogy and similar forms of relational reasoning. In Chapter 14, Lombrozo explores the multifaceted topic of explanation, which is closely related to abductive reasoning (often called “inference to the best explanation”). Then, in Chapter 15, Hahn and Oaksford apply the Bayesian framework to understand how people interpret informal arguments, including types of arguments that have classically been viewed as logical fallacies.

Part III: Judgment and Decision Making

In Chapters 16–20 we turn to topics related to judgment and decision making. In Chapter 16,

LeBoeuf and Shafir set the stage with a general review of work on decision making. Then, in Chapter 17, Griffin, Gonzalez, Koehler and Gilovich review the fascinating literature on heuristics and biases that influence judgment. In Chapter 18, Camerer and Smith discuss behavioral game theory, an approach rooted in economics that has been applied in many other disciplines. They also touch upon recent work on neuroeconomics, the study of the neural substrate of decision making. In Chapter 19, Waldmann, Nagel, and Wiegmann review a growing literature on moral reasoning and decision making. Then, in Chapter 20, Molden and Higgins review research revealing the ways in which human motivation and emotion influence judgment.

Part IV: Problem Solving, Intelligence, and Creative Thinking

The five chapters that comprise this section deal with problem solving and the many forms of individual differences observed in human thinking. In Chapter 21, Bassok and Novick provide a general overview of the field of human problem solving. In Chapter 22, Stanovich analyzes different conceptions of rationality and discusses individual differences in both rational thought and intelligence. Problem solving has close connections to the topic of creativity, the focus of Chapter 23 by Smith and Ward. In Chapter 24, van Steenburgh, Fleck, Beeman, and Kounios review research that takes a cognitive neuroscience approach to understanding the basis for insight in problem solving. Finally, in Chapter 25 Simonton reviews what is known about the thinking processes of those who function at the extreme of individual differences commonly termed “genius.”

Part V: Ontogeny, Phylogeny, Language, and Culture

Our understanding of thinking and reasoning would be gravely limited if we restricted investigation to young adult English speakers. Chapters 26–29 deal with the multifaceted ways in which aspects of thinking vary across the human life span, across species, across speakers of different languages, and its connections to larger human groups. In Chapter 26, Gelman and Frazier provide an overview of the development of thinking and reasoning over the course of childhood. In Chapter 27, Penn and Povinelli consider the fundamental question of what makes human thinking special when compared to the mental functioning of nonhuman animals. One of the most controversial topics in the field is the relationship

between thinking and the language spoken by the thinker. In Chapter 28, Gleitman and Papafragou offer a fresh perspective on the hypotheses and evidence concerning the connections between language and thought. Finally, in Chapter 29, Rai discusses the ways in which human thinking can be viewed as distributed across social and cultural groups.

Part VI: Modes of Thinking

There are many modes of thinking, distinguished by broad variations in representations and processes. Chapters 30–34 consider a number of these. In Chapter 30, Opfer and Siegler discuss mathematical thinking, a special form of thinking found in rudimentary form in nonhuman animals and which undergoes complex developmental changes over the course of childhood. In Chapter 31, Hegarty and Stull review work on the role of visuospatial representations in thinking; and in Chapter 32, Goldin-Meadow and Cook discuss the ways in which spontaneous gestures reflect and guide thinking processes. In Chapter 33, McGillivray, Friedman, and Castel describe the changes in thinking and reasoning brought on by the aging process. In Chapter 34, Bachman and Cannon review research and theory concerning brain disorders, notably schizophrenia, that produce striking disruptions of normal thought processes.

Part VII: Thinking in Practice

In cultures ancient and modern, thinking is put to particular uses in special cultural practices. Chapters 35–40 focus on thinking in particular practices. In Chapter 35, Dunbar and Klahr discuss thinking and reasoning as manifested in the practice of science. In Chapter 36, Spellman and Schauer review different conceptions of legal reasoning. In Chapter 37, Patel, Arocha, and Zhang discuss reasoning in a field—medicine—in which accurate diagnosis and treatment is literally an everyday matter of life and death. Lowenstein discusses reasoning as it relates to business in Chapter 38. Thinking is also involved in many aspects of music, including composition; this topic is covered by Thompson and Ammirante in Chapter 39. Finally, Chapter 40 by Koedinger and Roll concludes the volume by considering one of the major challenges for education—finding ways to teach people to think more effectively.

Examples of Chapter Assignments for a Variety of Courses

The present volume offers a comprehensive treatment of higher cognition. As such, it serves as an

excellent source for courses on thinking and reasoning, both at the graduate level and for advanced undergraduates. While instructors for semester-length graduate courses in thinking and reasoning may opt to assign the entire volume as a textbook, there are a number of other possibilities (including using chapters from this volume as introductions for various topics and then supplementing with readings from the primary literature). Here are a few examples of possible chapter groupings, tailored to a variety of possible course offerings.

Introduction to Thinking and Reasoning

1. Thinking and Reasoning: A Reader's Guide
2. Normative Systems: Logic, Probability, and Rational Choice
3. Bayesian Inference
4. Knowledge Representation
8. Dual-Process Theories of Reasoning: Facts and Fallacies
9. Inference in Mental Models
10. Similarity
11. Concepts and Categories: Memory, Meaning, and Metaphysics
12. Causal Learning and Inference
13. Analogy and Relational Reasoning
14. Explanation and Abductive Inference
15. Rational Argument
16. Decision Making
17. Judgment Heuristics
21. Problem Solving
22. On the Distinction Between Rationality and Intelligence: Implications for Understanding Individual Differences in Reasoning
23. Cognition and the Creation of Ideas

Development of Thinking

1. Thinking and Reasoning: A Reader's Guide
4. Knowledge Representation
10. Similarity
11. Concepts and Categories: Memory, Meaning, and Metaphysics
13. Analogy and Relational Reasoning
14. Explanation and Abductive Inference
26. Development of Thinking in Children
27. The Human Enigma
28. Language and Thought
30. Mathematical Cognition
31. Visuospatial Thinking
32. Gesture in Thought

33. Impact of Aging on Thinking
40. Learning to Think: Cognitive Mechanisms of Knowledge Transfer

Modeling Human Thought

1. Thinking and Reasoning: A Reader's Guide
3. Bayesian Inference
4. Knowledge Representation
5. Computational Modeling of Higher Cognition
6. Neural Substrate of Thinking
9. Inference in Mental Models
10. Similarity
11. Concepts and Categories: Memory, Meaning, and Metaphysics
12. Causal Learning and Inference
13. Analogy and Relational Reasoning
15. Rational Argument
18. Cognitive Hierarchies and Emotions in Behavioral Game Theory
40. Learning to Think: Cognitive Methods of Knowledge Transfer

Applied Thought

1. Thinking and Reasoning: A Reader's Guide
35. Scientific Thinking and Reasoning
36. Legal Reasoning
37. Thinking and Reasoning in Medicine
38. Thinking in Business
39. Musical Thought
40. Learning to Think: Cognitive Methods of Knowledge Transfer

Differences in Thought

1. Thinking and Reasoning: A Reader's Guide
19. Moral Judgment
20. Motivated Thinking
23. Cognition and the Creation of Ideas
24. Insight
25. Genius
26. Development of Thinking in Children

27. The Human Enigma
28. Language and Thought
29. Thinking in Society and Culture
32. Gesture in Thought
33. Impact of Aging on Thinking
34. The Cognitive Neuroscience of Thought Disorder in Schizophrenia

Acknowledgments

Preparation of this chapter was supported by grants from the Office of Naval Research (N000140810186) and the Institute of Education Sciences (R305C080015) (KJH); and by the National Institute of Aging (T32AG020506), the Illinois Department of Public Health Alzheimer's Disease Research Fund, and the Loyola University Chicago Deans of Arts and Sciences and the Graduate School (RGM).

Notes

1. Notice the linguistic connection between "thinking" and "seeing," thought and perception, which was emphasized by the Gestalt psychologists of the early 20th century.
2. The distinction between deduction and induction blurs in the study of the psychology of thinking, as we will see in Part II of this volume.
3. There are echoes of the old meaning of *reckon* in such phrases as "reckon the cost." As a further aside, the term "dead reckoning," a procedure for calculating the position of a ship or aircraft, derives from "deductive reasoning." And in an old Western movie, a hero in a tough spot might venture, "I reckon we can hold out till sun-up," illustrating how calculation has crossed over to become a metaphor for mental judgment.
4. See Johnson-Laird, Chapter 9, for a current view of thinking and reasoning that owes much to Craik's seminal ideas.
5. Indeed, Marr criticized Newell and Simon's approach to problem solving for paying insufficient attention to the computational level in this sense.

Normative Systems: Logic, Probability, and Rational Choice

Nick Chater and Mike Oaksford

Abstract

Normative theories of how people *should* reason have been central to the development of the cognitive science of thinking and reasoning, both as standards against which how thought is assessed and as sources of hypotheses about how thought might operate. This chapter sketches three particularly important types of normative system: logic, probability, and rational choice theory, stressing that these can each be viewed as providing consistency conditions on thought. From the perspective of understanding thought, logic can be viewed as providing consistency conditions on *beliefs*; probability provides consistency conditions on *degrees of beliefs*; and rational choice provides consistency conditions on *choices*. Limitations of current normative approaches are discussed. Throughout this chapter, we provide pointers concerning how these ideas link with the empirical study of thinking and reasoning, as described in this book.

Key Words: logic, probability, rational choice, decision theory, consistency, normative explanation

Introduction

This volume addresses one of the central questions in psychology: how people think and reason. Like any scientific endeavor, the psychology of thinking and reasoning is concerned not with how things should be, but with how things actually are. So the psychological project is not directly concerned with determining how people *ought* to reason; all that matters is figuring out how they *do* reason.

This chapter is, nonetheless, concerned purely with *normative* questions, that is, questions of how reasoning *should* be conducted—it focuses on normative theories, including logic, probability theory, and rational choice theory. These normative questions are traditionally discussed in philosophy and mathematics, rather than science. But questions about how people *should* reason are important for creating a cognitive science of how people *do* reason, in at least three ways.

First of all, a normative theory can provide a standard against which actual behavior can be assessed. That is, it provides an analysis of what the system is “supposed” to do: It determines what counts as successful performance and what counts as error. Note, though, that it may not be straightforward to determine which normative theory is appropriate, in relation to a particular aspect of thought or behavior; or how that normative theory should be applied. Nonetheless, comparison with normative theories is crucial for framing many of the key questions concerning thinking and reasoning. For example, even to ask whether, or to what extent, people reason deductively (see Evans, Chapter 8) requires an analysis of what deduction is; and deduction is a *logical* notion. Similarly, the study of decision making (see LeBoeuf & Shafir, Chapter 16) is organized around comparisons with the theory of “correct” decision making, deriving from rational choice theory.

Second, normative theories of reasoning provide a possible starting point for descriptive theories of reasoning, rather than a mere standard of comparison. Thus, just as a natural starting point for a theory of the operation of a calculator is that it follows, perhaps to some approximation, the laws of arithmetic, it is natural to assume that a rational agent follows, to some approximation, normative principles of reasoning. This second use of normative theories is by far the most controversial. Many theories in the psychology of reasoning are built on foundations from normative theories. For example, mental logics and mental models view the reasoner as approximating logical inference (Johnson-Laird, 1983; Rips, 1994; see Evans, Chapter 8; Johnson-Laird, Chapter 9) and Bayesian approaches view cognition as approximating Bayesian inference (Griffiths, Kemp, & Tenenbaum, 2008; Oaksford & Chater, 2007; see Griffiths, Tenenbaum, & Kemp, Chapter 3). But other accounts, based, for example, on heuristics (e.g., Evans, 1984; Gigerenzer & Todd, 1999), take this to be a fundamental mistake.

Third, unless people's words and behavior obey some kind of rationality constraints, their words and behavior are rendered, quite literally, meaningless. Thus, a person randomly generating sentences, or moving arbitrarily, cannot usefully be attributed intentions, beliefs, or goals, at least according to many influential philosophical accounts (e.g., Davidson, 1984; Quine, 1960). To put the point starkly: to see a human body as a *person*, with a *mind*, rather than merely a collection of physiological responses, requires that he or she can be attributed some measure of rationality. And normative theories of rationality attempt to make some headway in explaining the nature of such rationality constraints. Similarly, returning to comparison with the calculator, without some degree of conformity with the laws of arithmetic, it will be impossible to interpret the key presses and displays of the calculator as being about numbers or arithmetic operations.

A natural initial question is: Is it meaningful to attempt to develop a general theory of rationality *at all*? We might tentatively suggest that it is a *prima facie* sign of irrationality to believe in alien abduction, or to will a sports team to win in order to increase their chance of victory. But these views or actions might be entirely rational, given suitably nonstandard background beliefs about other alien activity and the general efficacy of psychic powers. Irrationality may, though, be ascribed if there is a *clash* between a particular belief or behavior and such

background assumptions. Thus, a thorough-going physicalist may, perhaps, be accused of irrationality if she simultaneously believes in psychic powers. A theory of rationality cannot, therefore, be viewed as clarifying either what people should believe or how people should act—but it can determine whether beliefs and behaviors are compatible. Similarly, a theory of rational choice cannot determine whether it is rational to smoke or to exercise daily; but it might clarify whether a particularly choice is compatible with other beliefs and choices.

From this viewpoint, normative theories can be viewed as clarifying conditions of *consistency* (this is a broader notion than “logical consistency,” which we shall introduce later). In this chapter, we will discuss theories that aim to clarify notions of consistency in three domains. *Logic* can be viewed as studying the notion of consistency over *beliefs*. *Probability* (from the subjective viewpoint we describe shortly) studies consistency over *degrees of belief*. *Rational choice* theory studies the consistency of beliefs and values with *choices*. In each domain, we shall interpret the formalisms in a way most directly relevant to thought. Logic can be applied to formalizing mathematical proofs or analyzing computer algorithms; probability can capture limiting frequencies of repeatable events; rational choice theory can be applied to optimization problems in engineering. But we shall focus, instead, on the application of these formal theories to providing models of thought.

Logic

Our intuitions about the rationality of any single belief crucially may be influenced by background beliefs. This type of *global* relationship, between a single belief and the morass of general background knowledge, will inevitably be hard to analyze. But logic focuses on *local* consistency (and consequence) relationships between beliefs, which depend on those beliefs alone, so that background knowledge is irrelevant. Such local relationships can only depend on the *structure* of the beliefs (we'll see what this means shortly); it can't depend on what the beliefs are about, because understanding what a belief is *about* requires reference to background knowledge (and perhaps other things besides).

So, for example, there seems something wrong, if Fred believes the following:

All worms warble
Albert is a worm
Albert does not warble

Roughly, the first two beliefs appear to imply that Albert does warble; and yet the third belief is that he does not. And surely a minimal consistency condition for any reasoner is that it should not be possible to believe both P & not P —because this is a *contradiction*. This inconsistency holds completely independently of any facts or beliefs about worms, warbling, or Albert—this is what makes the inconsistency *local*.

How can these intuitions be made more precise? Logic plays this role, by translating sentences of natural language (expressing beliefs) into formulae of a precisely defined formal language; and specifying inferential rules over those formulae. Sometimes there are also axioms as well as rules; we will use rules exclusively here for simplicity, thus following the framework of natural deduction in logic (Barwise & Etchemendy, 2000). The idea that human reasoning works roughly in this way is embodied in mental logic approaches in the psychology of reasoning (e.g., Braine, 1978; Rips, 1994).

Beliefs can be represented in many different logical languages; and many different sets of inferences can be defined over these languages. So there is not one logic, but many. Let us represent the beliefs mentioned earlier in perhaps the best known logical language, the first-order predicate calculus:

All worms warble	$\forall x. (\text{worm}(x) \rightarrow \text{warble}(x))$
Albert is a worm	$\text{worm}(\text{Albert})$
Albert does not warble	$\neg\text{warble}(\text{Albert})$

where “ $\forall x$ ” can be glossed as “for all x ,” and “ \rightarrow ” can be glossed as “if...then...” (although with a very particular interpretation; different interpretations of the conditional are numerous and contested, e.g., Edgington, 1995; Evans & Over, 2004), and “ \neg ” can be glossed as “not” (i.e., as negating the following material within its scope). The variable x ranges over a set of objects; and Albert is one of these objects.

Now there is a logical rule (\forall -elimination) which holds in the predicate calculus; this captures the intuition that, if some formulae applies to any object (any x), then it must apply to any particular object, such as Albert. Applying this rule to $\forall x. (\text{worm}(x) \rightarrow \text{warble}(x))$, we obtain:

$$\text{worm}(\text{Albert}) \rightarrow \text{warble}(\text{Albert})$$

Then we can apply a second logical rule, \rightarrow -elimination, which says (simplifying slightly), that, for any beliefs P, Q , if it is true that $P \rightarrow Q$ and it

is true that P , then Q is also true. Since we already know $\text{worm}(\text{Albert})$, and that $\text{worm}(\text{Albert}) \rightarrow \text{warble}(\text{Albert})$, this rule tells us that we can derive $\text{warble}(\text{Albert})$.

So, with this reasoning, our first two premises have derived $\text{warble}(\text{Albert})$; and the third premise is $\neg\text{warble}(\text{Albert})$. To make the contradiction explicit, we need to apply a final logical rule, $\&$ -introduction, which states that, if we have established P , and Q , we can derive $P \& Q$. Thus, we can derive $\text{warble}(\text{Albert}) \& \neg\text{warble}(\text{Albert})$, which is, of course, of the form $P \& \neg P$, that is, a contradiction.

Thus, from the point of view of the cognitive science of reasoning, logic can be viewed as providing a formal mechanism for detecting such inconsistencies: by determining the sets of beliefs from which a contradiction can be derived. (The field of logic does not exhaust such methods. For example, the denial of Fermat’s Last Theorem may be in contradiction with the rules of arithmetic, but the detection of such an inconsistency, by proving Fermat’s Last Theorem, requires mathematics far outside the confines of logic.) The chains of reasoning that result from applying logical rules step by step is studied by one major branch of mathematical logic: proof theory.

But what makes the logical rules (\forall -elimination, $\&$ -introduction, and so on) appropriate? One answer is that, ideally, these rules should allow the derivation $P \& \neg P$ from a set of logical formulae just when that set of formulae is incompatible from the point of view of *meaning*. That is, whatever the properties of *warbling* or being a *worm* refer to, and whoever or whatever is denoted by *Albert*, our three statements cannot be true together. It turns out that, for the purposes of figuring out whether it is possible for a set of beliefs to be simultaneously true or not, under some interpretation, it is often sufficient to restrict our interpretations to sets of numbers (so we don’t have to worry about worms, warbling, or any other real or imagined features of the actual world), though more complex mathematical structures may be appropriate for other logics.

From this standpoint, our formulae

$$\begin{aligned} &\forall x. (\text{worm}(x) \rightarrow \text{warble}(x)) \\ &\text{worm}(\text{Albert}) \\ &\neg\text{warble}(\text{Albert}) \end{aligned}$$

can be true simultaneously just when there is some (potentially infinite) set of numbers S_{worm} denoted by *worm* and another S_{warble} by *warble*; and a number a denoted by *Albert*, such that each of these formulae

are true together. This can be done by defining a precise relationship between formulae and numbers and sets. Roughly, the first formula translates into $S_{\text{worm}} \subset S_{\text{warble}}$, that is, the first set of numbers is a subset of the second, following the possibility that the sets might be identical. The second translates as $a \in S_{\text{worm}}$, and the third as $a \notin S_{\text{warble}}$. There are clearly no numbers and sets of numbers that can make this true: $S_{\text{worm}} \subset S_{\text{warble}}$ requires that every number that is in S_{worm} is also in S_{warble} , and a provide a counterexample. We say that this set of formulae has no *model* in set-theory, that is, no set-theoretic interpretation that makes all of the formulae true. Conversely, if the first formula were, instead, the innocuous $\text{warble}(Albert)$, then the formulae would have a model (indeed, infinitely many such models). For example, Albert could be the number 5; S_{worm} could be the set {3, 5, 8}; and S_{warble} the set {3, 4, 5, 8}. If a set of formulae has a model (i.e., an interpretation under which all the statements are true), then it is *satisfiable*; otherwise it is *unsatisfiable*. The study of the relationship between formulae and possible interpretations in terms of sets (or in terms of more complex structures such as fields and rings) is the subject of a second major branch of mathematical logic: model theory.

So we now have introduced two notions of consistency, one proof-theoretic (using the logical rules, can we derive a contradiction of the form $P \& \neg P$?), and the other model-theoretic (are the formulae satisfiable, i.e., is there some model according to which they can all be interpreted as true?). Ideally, these notions of consistency should come to the same thing.

We say that a logical system is *sound* (with respect to some interpretation) just when its inference rules can derive a contradiction of the form $P \& \neg P$ from a set of formulae only when that set of formulae is unsatisfiable. Informally, soundness implies that proof theory respects model theory. Even more informally: If the logical rules allow you to derive a contradiction from some set of formulae, then they really can't all be true simultaneously.

Conversely, a logical system is *complete* (with respect to some interpretation) just when a set of formulae is unsatisfiable only when the inference rules can derive a contradiction of the form $P \& \neg P$ from that set of formulae. Informally, completeness implies that the interpretation in the model theory is captured by the proof theory. Even more informally: If a set of formulae can't all be true simultaneously, then the logical rules allow a contradiction to be derived from them.

We have introduced logic so far as a calculus of *consistency*, both to clarify the comparison with probability and rational choice theory and to illustrate some key points concerning the relationship between logic and reasoning, which we will discuss shortly. But the more conventional starting point, particularly appropriate given the roots of mathematical logic in clarifying the foundations of mathematics, is that logic provides an account of *consequence*. According to this standpoint, we consider a set of premises

$$\begin{aligned} &\forall x. (\text{worm}(x) \rightarrow \text{warble}(x)) \\ &\text{worm}(Albert) \end{aligned}$$

and wonder whether the conclusion $\text{warble}(Albert)$ follows. The link with consistency is direct: $\text{warble}(Albert)$ follows from these premises if and only if adding $\neg \text{warble}(Albert)$ to those premises leads to a contradiction. More generally, any argument from a set of premises Γ to the consequence P is *syntactically valid* (i.e., P can be derived from Γ , by applying the rules of inference) just when $\Gamma, \neg P$ allows a contradiction to be derived. And on the model-theoretic side, there is a corresponding notion of consequence: An argument from Γ to P is *semantically valid* just when any models satisfying Γ also satisfy Γ, P . And this will be true just when no model satisfies $\Gamma, \neg P$ —that is, $\Gamma, \neg P$ is unsatisfiable. So we can explain soundness and completeness in a different, although equivalent, way: A logic is sound when syntactically valid conclusions are always also semantically valid; and complete when the converse holds. But we shall continue primarily to think of terms of consistency in the following discussion.

Happily, standard predicate calculus (a fragment of which we used earlier) is both sound and complete (with respect to a standard set-theoretic interpretation), as Gödel showed (Boolos & Jeffrey, 1980). More powerful logics (e.g., those that allow the representation of sufficiently large fragments of arithmetic) can be shown not to be both sound and complete (Gödel's incompleteness theorem is a key result of this kind; Nagel & Newman, 1958). A logic that is not sound is not very useful—the proof theory will generate all kinds of “theorems” that need not actually hold. Sound but incomplete logics can, though, be very useful. For example, in mathematics, they can be used to prove interesting theorems, even if there are theorems that they cannot prove.

Let us stress again that (in)consistency is, crucially, a *local* notion. That is, a set of beliefs is

(in)consistent (when represented in some logical system) dependent only on those beliefs—and completely independent of background knowledge. This is entirely natural in mathematics—where we are concerned with what can be derived from our given axioms and crucially want to see what follows from these axioms alone. But where reasoning is not about mathematics, but about the external world, our inferences may be influenced by background knowledge—for example, in understanding a news story or a conversation, we will typically need to draw on large amounts of information not explicitly stated in the words we encounter. Our conclusions will not follow with certainty from the stated “premises,” but will, rather, be tentative conjectures based on an attempt to integrate new information with our background knowledge. Such reasoning does not seem to fit easily into a logical framework (Oaksford & Chater, 2007).

Moreover, consistency is also a *static* notion. Suppose we imagine that we believe the three previous statements—but that, on reflection, we realize that these are inconsistent. So at least one of these beliefs must be jettisoned. But which? Standard logic says nothing about this (Harman, 1986; see also, Macnamara, 1986). The *dynamic* question, of how we should modify our beliefs in order to restore consistency, is much studied—but it is a fundamentally different question from whether there is inconsistency in the first place.

As we have stressed, for this reason, logic cannot be viewed as a theory of reasoning: that is, as a theory of how beliefs should be changed, in the light of reflection. Suppose I believe that *worms warble* and that *Albert is a worm*. The conclusion that *Albert warbles* follows from these beliefs. But suppose I initially doubt that Albert warbles. Then, if I decide to hold to the first two beliefs, then I had better conclude that Albert does warble after all. But I might equally well maintain my doubt that Albert warbles and begin to suspect that not all worms warble after all; or perhaps Albert is not actually a worm. The key point is that logic tells us when inconsistency has struck, but it does not tell us how it can be restored. In mathematics, for which logic was developed, it is usual to take certain axioms (e.g., of geometry, set theory, or group theory) for granted—and then to accept whatever can be derived from them. But outside mathematics, no belief has protected status—and hence the question of how to restore consistency is a challenging one.

We have seen that logic has, on the face of it, an important, but limited, role in a theory of reasoning: focusing on local consistency relations. Nonetheless, various theorists have considered logic to play a central psychological role. Inhelder and Piaget (1955) viewed cognitive development as the gradual construction of richer logical representations; symbolic artificial intelligence modeled thought in terms of variants of logical systems, including frames, scripts, and schemas (Minsky, 1977; Schank & Abelson, 1977), and logical systems are still the basis for many theories of mental representation (see Chapter 4). Moreover, Fodor and Pylyshyn (1988) have argued that the central hypothesis of cognitive science is to view “cognition as proof theory,” a viewpoint embodied in the psychological proposals of “mental logic” (Braine, 1978; Rips, 1994).

An alternative proposal takes model-theoretic entailment as its starting point, proposing that people reason by formulating “mental models” of the situations being described (Johnson-Laird, 1983; Chapter 9, this volume; Johnson-Laird & Byrne, 1991). Possible conclusions are “read off” these mental models; and there is a search for alternative mental models that may provide counter-examples to these conclusions.

We have focused here on predicate logic, dealing with the analysis of terms such as *not*, *or*, *and*, *if...then...*, *all*, and *some*. But the variety of logics is very great: There are deontic logics, for reasoning about moral permissibility and obligation; modal logics for reasoning about possibility and necessity; temporal logics for modeling tense and aspect; second-order logics for reasoning about properties; and so on. Each such logic aims to capture a complementary aspect of the structure of beliefs; and one might hope that a fusion of these logics might capture these different features simultaneously. Typically, though, such fusion is very difficult—different aspects of logical structure are usually studied separately (Montague Grammar provides a partial exception; see Dowty, Wall, & Peters, 1981). Moreover, with regard to any natural language term, there are typically a variety of possible logical systems that may be applied, which do not yield the same results. The psychological exploration of the variety of logical systems is relatively underdeveloped, although the mental models approach has been applied particularly broadly (e.g., Johnson-Laird, Chapter 9). And, more generally, the degree to which people are sensitive at all to the kinds of local consistency relations described by logic, or indeed other normative theories, is a matter of controversy

(e.g., Gigerenzer & Todd, 1999; Oaksford & Chater, 2007; Rips, 1994).

Probability

Logic can be viewed as determining which sets of *beliefs* are (in)consistent. But belief may not be an all-or-none matter. Human thinking is typically faced with uncertainty. The senses provide information about the external world; but this information is not entirely dependable. Reports, even from a trustworthy informant, cannot be entirely relied upon. So, outside mathematics, we might expect belief to be a matter of degree.

Probability theory can be viewed as capturing consistency of *degrees of belief*. But what exactly is a degree of belief? It turns out that surprisingly few assumptions uniquely fix a calculus for degrees of belief—which are just the laws of probability. And different assumptions lead to the same laws of probability (e.g., Cox, 1946; Kolmogorov, 1956; Ramsey, 1926).

Viewing probability as modeling degrees of belief is, in philosophy, known as the *subjective* interpretation of probability. In statistics, machine learning, and, by extension, the cognitive sciences, this is typically known as the *Bayesian* approach (see Griffiths, Tenenbaum, & Kemp Chapter 3; Oaksford & Chater, 2007).

The Bayesian approach is named after Bayes theorem, because of the frequent appeal to the theorem in uncertain inference. While the Bayesian approach to probability and statistics is controversial (probabilities may, for example, be interpreted as limiting frequencies; see von Mises, 1939), and statistics may be viewed as involving the sequential rejection of hypotheses (see Fisher, 1925), Bayes theorem is not: It is an elementary theorem of probability.

In its very most basic form, Bayes theorem arises directly from the very definition of conditional probability: $\text{Pr}(A|B)$ is the probability that A is true, given that B is true. Then, it follows ineluctably that the joint probability $\text{Pr}(A, B)$, that both A and B are true, is simply the probability that B is true ($\text{Pr}(B)$) multiplied by the probability that A is true, given that B is true, $\text{Pr}(A|B)$: that is, $\text{Pr}(A, B) = \text{Pr}(A|B)\text{Pr}(B)$. By the symmetry roles of A and B , it also follows that $\text{Pr}(A, B) = \text{Pr}(B|A)\text{Pr}(A)$, and so that $\text{Pr}(B|A)\text{Pr}(A) = \text{Pr}(A|B)\text{Pr}(B)$. Dividing through by $\text{Pr}(A)$ gives a simple form of Bayes theorem:

$$\text{Pr}(B|A) = \frac{\text{Pr}(A|B)\text{Pr}(B)}{\text{Pr}(A)}$$

Bayes theorem plays a crucial role in probabilistic approaches to cognition. Often, $\text{Pr}(A|B)$ is known (e.g., the probability of some pattern data arising, if some hypothesis is true); but the “converse” $\text{Pr}(B|A)$ (e.g., the probability that the hypothesis is true, given that we are observed the pattern of data) is not known. Simplifying somewhat, Bayes theorem helps derive the unknown probability from known probabilities.

Given the axioms of probability (and the ability to derive corollaries of these axioms, such as Bayes theorem), the whole of probability theory is determined—and, at the same time, one might suppose, the implications of probability for cognitive science. But, as in other areas of mathematics, merely knowing the axioms is really only the starting point: the consequences of the axioms turn out to be enormously rich. Of particular interest to cognitive science is the fact that it turns out to be very useful to describe some cognitively relevant probability distributions in terms of graphical models (see Pearl, 1988), which are both representationally and computationally attractive. These models are beyond the scope of this chapter (but see Griffiths, Tenenbaum, & Kemp, Chapter 3). Note though that much current work on the representation of knowledge (see Markman, Chapter 4) in artificial intelligence, cognitive science, computer vision, and computational linguistics works within a probabilistic framework (Chater, Tenenbaum, & Yuille, 2006). The psychology of reasoning has widely adopted probabilistic ideas (e.g., Evans, Handley, & Over, 2003; McKenzie & Mikkelsen, 2007; Oaksford & Chater, 1994, 2007; see Buehner & Cheng, Chapter 12); and the same ideas have been extended to model argumentation (see Hahn & Oaksford, Chapter 15).

Rational Choice

From the point of view of the psychology of thought, logic can be viewed as providing consistency constraints on belief; and probability can be viewed as providing consistency constraints on degrees of belief. How far is it possible to specify consistency conditions over choices? This is the objective of the theory of rational choice (in this subsection, we draw some material from Allingham, 2002, who provides a beautifully concise introduction).

According to the theory, following Hume, no choice can be judged rational or irrational when considered in isolation. It may seem bizarre to choose a poke in the ribs, P , over a meal, M , in a top restaurant; but such a preference is not irrational.

But there surely is something decidedly odd about choosing P , when offered $\{P, M, D\}$; but choosing M , from the options $\{P, M\}$ where now a third “decoy” option has been removed. The first choice seems to indicate a preference for P over M ; but the second seems to indicate the contradictory preference of M over P . The *contraction* condition is that this pattern is disallowed.

Let us consider another possible rationality condition. Suppose that we choose P , when offered either $\{P, M\}$ or $\{P, D\}$, but we do not choose P when offered $\{P, M, D\}$ —perhaps we choose D . This again seems odd. The *expansion* condition is that this pattern is ruled out.

If we obey both the contraction and expansion conditions, there is a preference relation over our items, which we can interpret as meaning “at least as good as,” so that any choice from a set of options is at least as good as any of the other items (there may be more than one such choice). If this preference relation is *transitive* (i.e., X is at least as good as Y ; Y is at least as good as Z requires that X is at least as good as Z), then this preference relation is an ordering.

If these three consistency conditions are respected, it turns out that we can order each option (possibly with ties), with most favored options at one end, and least favored at the other. And, if we like, we can place the ordering on to the number line (in any way we like, as long as higher numbers represent items further to the favored end of the ordering)—it is conventional to call these numbers *utilities*. It is important to think of this notion as a purely formal notion, not necessarily connected with value or usefulness in any intuitive sense. So, we can now give a simple criterion for rational choice: When given a set of options, choose the item with the highest utility.

Here is a simple argument in favor of all three of these conditions: If a person violates them, it appears that the person’s money can systematically be taken from him or her. The person becomes a “money pump.” Suppose that agent, A , violates the contraction condition: that A chooses P , when offered $\{P, M, D\}$, but chooses M , from the options $\{P, M\}$. Money can be removed from this hapless agent by an evil counterparty, E , as follows. Suppose A , initially, has option P . E suggests that perhaps A might prefer the alternative M . Considering the set $\{P, M\}$, A prefers M , by hypothesis. This seems to imply that E can persuade A to “swap” to his or her preferred choice, by paying a sufficiently small sum of money, Δ_1 .

Now, having made the payment, A has M . Now the evil counterparty asks whether A might instead prefer either D or P . A now faces the choice set $\{P, M, D\}$. Now, by hypothesis, and in violation of the contraction condition, A prefers P . So E can persuade A to switch M for P , on payment of an arbitrarily tiny sum, Δ_2 . So the hapless A now has exactly the option he or she started with; but is $\Delta_1 + \Delta_2$ poorer. E repeats, removing A ’s money until there is none left. According to this argument, we violate the contraction condition at our peril.

So far we have focused on options with certain outcomes. But many choices are between options whose outcome is not certain. For example, we might wonder whether to buy a stock or make a gamble; or how much one would enjoy a particular choice on the menu. We now have some extra consistency conditions that seem natural. If I prefer P to M , then surely I should prefer a gamble with a probability q of P , and $1-q$ of X (for any option X), to a gamble with a probability q of M , and $1-q$ of X . This is the *substitution* condition.

And if I prefer P to R , and R to M , then it seems reasonable that there must be some s such that I am indifferent between R and a gamble mixing P and M , with probability s . After all, if $s = 1$, that is, P is certain, then the mixed gamble will be preferred to R ; when $s = 0$, and M is certain, the mixed gamble will be dispreferred. The *continuity* condition is simply that there must be some intermediate value of s where the mixed gamble is neither preferred nor dispreferred.

When and only when these two apparently mild conditions are respected, then the pattern of preferences over a gamble can be represented by a more precise “utility scale”—one which associates a real number with each outcome; the preferred option from some set is always that which has the highest expected utility (i.e., the average of the utilities of the possible outcomes, weighted by their probability). This is the normative principle of maximizing expected utility (EU).

EU has provided a fundamental starting point for many areas of economics; and EU has also been the standard against which the quality of human decision making is often judged. Crucially, from the point of view of this volume, EU has also been viewed as a starting point for *descriptive* theories of decision making, from which various departures can be made (see contributions in this volume by LeBoeuf and Shafir, Chapter 16; and Camerer & Smith, Chapter 18).

Exploring apparent departures from the predictions of rational choice theory and probability in human behavior has been a major field of research over the last 50 years—to a fair approximation, the entire field of judgment and decision making (e.g., Goldstein & Hogarth, 1997) is devoted to this topic. By contrast, rational choice theory provides a foundation for modern microeconomics (but see Camerer & Smith, Chapter 18); and the same “economic” style of explanation has been enormously productive in behavioral ecology (e.g., Stephens & Krebs, 1986).

Note, finally, that rational choice theory extends in a variety of directions that we have not touched on here. Perhaps the most important is *game theory*, the theory of rational strategic interaction between players, where the outcome of each agent’s actions depends on the action of the other. We will not treat this vast and enormously important topic here, as it arises infrequently throughout the rest of this volume. We have focused instead on thinking and reasoning within a single individual.

Conclusions

This volume is primarily concerned with the descriptive project of understanding how people think and reason. The present chapter, by contrast, has outlined normative theories that aim to say something about how people *should* think. More accurately, normative theories provide consistency conditions on thought. Logic can be viewed as helping to clarify which sets of beliefs are (in)consistent; probability theory can clarify which degrees of belief are consistent; and rational choice theory imposes consistency conditions on choices, values, and beliefs. Perhaps one reason why we think and reason at all is to attempt to reestablish such consistency, when it is disturbed—but the dynamic process of reestablishing equilibrium is relatively little understood.

But if we assume that the mind is at such an equilibrium, then the consistency conditions can be used to determine how people should believe or choose, given some given set of beliefs or choices. So, if a rational agent prefers *A* to *B*, and *B* to *C*, then the transitivity of preference requires that the agent prefers *A* to *C*. If a person believes *A* or *B*, and not *B*, then logical consistency (according to the standard translation into the propositional calculus) requires that the person believe *A*. This brings us back to the first of our three motivations for considering the relevance of normative theories to descriptive theories

of thought: that it describes the “right answers” in reasoning problems, just as arithmetic provides the right answers against which mental calculation can be judged. Note, though, that mere consistency conditions do not appear to provide the basis for an exhaustive analysis of the functions of thought. A variety of topics in the present volume, including the study of similarity (Goldstone & Son, Chapter 10), analogy (Holyoak, Chapter 13), creative thinking (Smith & Ward, Chapter 23), and insight (van Steenburgh et al., Chapter 24), seem not readily to be understood as merely avoiding inconsistency—and have largely been resistant to the encroachment of normative theory. Despite appearances, however, it remains possible that some of these aspects of thought may be governed by normative principles (e.g., Chater & Vitányi, 2003; Holyoak, Lee, & Lu, 2010; Tenenbaum & Griffiths, 2001; see also Holyoak, Chapter 13).

Second, note that consistency conditions provide the starting point for descriptive theories. One way in which human thinking and reasoning can adhere to the standards of a normative theory is by actually carrying out the calculations defined by the normative theory, at least to some approximation. Thus, mental logics and mental models are inspired by different approaches to logical proof; Bayesian cognitive science has been inspired by developments in probability theory; and most descriptive theories of decision making are departures, to varying degrees, from rational choice models.

Finally, picking up on our final role for normative accounts of rationality, we stress that without some normative constraints on thinking and reasoning, it becomes impossible to interpret thought, and resulting utterances or behavior, at all. We do not have direct access to people’s beliefs or degrees of belief; we have to infer them from what they say and how they behave (protestations that the food is safe to eat may be undermined by a stubborn refusal to eat any). And utilities (in the technical sense, recall) are defined by choices; but we can only observe a fraction of possible choices, and, as theorists, we have to infer the rest. Consistency conditions can, on this account, be critical in making such inferences possible, by binding together beliefs or choices that we have observed with beliefs and choices that we have not observed.

Future Directions

In this brief tour of normative theories of thinking and reasoning, we have, inevitably, focused on what

normative theories handle successfully. In closing, we highlight three areas that appear to provide challenges for current normative approaches.

The first area concerns understanding how thinking, reasoning, and decision making are influenced by world knowledge. One of the most important observations in early artificial intelligence and cognitive science research was the extraordinary richness of the knowledge required to understand even the simplest story or scenario (Clark, 1975; Minsky, 1977). Our thoughts effortlessly draw on rich knowledge of the physical and social worlds, not merely the logical forms of the sentences that we are hearing or reading; and such knowledge itself appears to have a “fractal” character (Chater & Oaksford, 2001). That is, explaining any given fact about the physical and social worlds appears to require drawing on yet further such knowledge, and so on indefinitely. While mathematical concepts, such as sets, groups, and the real line, can neatly be captured by a few axioms (although there is sometimes controversy about which axioms are most appropriate), real-world categories, such as “chair,” “country,” “person,” or “belief,” stubbornly resist such formalization (see Rips et al., Chapter 11). Rather, they appear to be part of an interdependent “web of belief” (Quine & Ullian, 1978), which is difficult, or perhaps even impossible, to characterize piecemeal. One consequence of this observation is that the specification of the world knowledge that underlies particular aspects of everyday reasoning will be difficult, if not impossible (c.f. Fodor’s, 1983, discussion of “central” cognitive processes; and AI skeptics such as Dreyfus, 1972). One particularly notorious problem that arises in this context is the “frame problem” (McCarthy & Hayes, 1969; Pylyshyn, 1987). Suppose that an agent decides to perform some action: The frame problem is to determine which aspects of the agent’s knowledge can be left unchanged, and which must be updated (by analogy with the question of which aspects of the background frame an animator can leave unchanged, or must modify from frame to frame, as a cartoon character moves). Despite appearing, at first sight, fairly innocuous, the frame problem was the rock upon which many proposals in early artificial intelligence foundered, in large part because it requires relating a local piece of new information (concerning the action) with the endless and ill-understood network of background world knowledge. A central task for future research is to establish how far it is possible to extend the use of current

methods based on normative principles to ever richer aspects of knowledge (e.g., Griffiths, Kemp, & Tenenbaum, 2008; Pearl, 2000) or to develop new tools to allow this.

A second challenging area for current normative models concerns dealing with inconsistency. We have stressed that normative models are typically inherently static: They determine what beliefs, degrees of belief, or beliefs, utilities, and actions are consistent with each other. But, on the face of it at least, human thought is riddled with inconsistency. We may believe that the probability of an air crash is infinitesimally low, but simultaneously be terrified of flying; we may be desperate to save for the future, yet spend compulsively; and, more prosaically, we may accept the axioms of arithmetic but believe that Fermat’s last theorem is false. Indeed, as this last case makes clear, the problem of determining whether your beliefs are consistent is enormously difficult. But if we accept that human thought is inconsistent, then we face two challenges. The first is finding general principles that determine how consistency should best be restored; and the second is avoiding the inferential chaos that may appear to result from the mere existence of inconsistency. This latter problem is particularly immediate in classical logic, in which a set of propositions S_1, S_2, \dots, S_n has, as a consequence proposition T unless it is possible that S_1, S_2, \dots, S_n are true, but T is false. If S_1, S_2, \dots, S_n are inconsistent, then these premises can never simultaneously be true, and hence this type of counterexample can be never generated. But this means that, from an inconsistency, anything at all follows. Inconsistencies propagate in similarly pathological ways in probability and rational choice theory. But if inconsistency is ubiquitous in human thought, then how can normative theories gain any explanatory purchase? One approach within logic is the development of so-called paraconsistent logics (Priest & Tanaka, 2009), which do not allow inferential “explosion” when a contradiction is reached. Nonetheless, the problem of dealing with the inconsistency of beliefs and choices remains extremely challenging for the application of normative theories to cognition.

Finally, following the dictates of a normative theory of reasoning precisely would require carrying out calculations of enormous complexity—for reasonably complex problems, such calculations appear to far exceed the capacity of human thought. For example, figuring out whether a particular set of beliefs is consistent, even in elementary logics such

as the propositional or first-order predicate calculus, is not, in general, computationally feasible (in the case of propositional calculus, the problem is NP-complete; see Cooke, 1971; for first-order logic it is undecidable; seeBoolos & Jeffrey, 1980). Such intractability is at least as troublesome, in general, for calculations concerning probability or rational choice (e.g., Binmore, 2008; van Rooij, 2008).

The problem of computational tractability is especially problematic for our second potential role for normative theories: providing the starting point for descriptive theories of thinking and reasoning. On the face of it, the mind cannot perfectly implement the precepts of logic, probability, or rational choice theory—because the mind is presumably limited to computable processes. One reaction to this problem is to entirely reject normative theory as a starting point for descriptive accounts. Gigerenzer and Goldstein (1996), for example, argue that rational choice theory requires that the mind is a Laplacian demon, with infinite computational resources; and argue instead that human judgment and decision making involves “fast and frugal” heuristics, unrelated to rational norms. Alternatively, perhaps human thought is a cheap *approximation* to normative calculations (Vul, Goodman, Griffiths, & Tenenbaum, 2009). More broadly, the relationship between normative and descriptive theories of thinking and reasoning is likely to remain an important area of controversy and future research.

Bayesian Inference

Thomas L. Griffiths, Joshua B. Tenenbaum, and Charles Kemp

Abstract

Inductive inferences that take us from observed data to underdetermined hypotheses are required to solve many cognitive problems, including learning categories, causal relationships, and languages. Bayesian inference provides a unifying framework for understanding how people make these inductive inferences, indicating how prior expectations should be combined with data. We introduce the Bayesian approach and discuss how it relates to other approaches such as the “heuristics and biases” research program. We then highlight some of the contributions that have been made by analyzing human cognition from the perspective of Bayesian inference, including connecting symbolic representations with statistical learning, identifying the inductive biases that guide human judgments, and forming connections to other disciplines.

Key Words: Bayesian inference, rational models, inductive inference, learning

Introduction

People solve a remarkable variety of problems in the course of everyday life, such as learning the categories that organize our world, identifying causal relationships, and acquiring language. Cognitive science has tended to take a “divide and conquer” approach to understanding the mind, analyzing each of these aspects of human learning separately. However, viewed abstractly, these problems all have something in common: They are inductive problems, requiring us to evaluate underdetermined hypotheses using limited data. The shared structure of these problems suggests that it might be possible to develop a single theory that would provide a unifying account of all of these different aspects of cognition.

Recently, a number of researchers have begun to explore the possibility that a unifying account of inductive inference might be provided by probability theory, as used in Bayesian statistics (Anderson, 1990; Chater & Oaksford, 1999; Oaksford & Chater, 1998; Tenenbaum, Griffiths, & Kemp, 2006). This is an idea that has been growing in

popularity in cognitive science, and it is bolstered by the widespread adoption of Bayesian methods in computer science (e.g., Bishop, 2006; Russell & Norvig, 2010) and statistics (e.g., Robert, 1994). Developing automated systems that can match human abilities in solving inductive problems such as learning categories, causal relationships, and languages has been a goal of artificial intelligence research for the last 50 years. Recently, significant steps toward this goal have been made by recognizing that ideas from Bayesian statistics can be useful in handling the uncertainty that is inherent in inductive inferences. Research in artificial intelligence and machine learning has led to powerful statistical models and efficient computer algorithms for working with those models.

Applying these computational and statistical ideas to human inductive inference has the potential to shed light on some of the deepest questions in cognitive science, such as the nature and origins of the constraints on human learning, and whether cognition is best thought about in terms of symbolic

representations or statistics. In this chapter, we review the basic ideas behind Bayesian inference, consider how this approach relates to other theoretical perspectives, and highlight some of the contributions that this approach has made to the investigation of human thinking and reasoning.

Basics of Bayesian Inference

If you were assessing the prospects of a 60-year-old man, how much longer would you expect him to live? If you heard that a movie had made \$40 million so far at the box office, how much would you expect it to make in total? Answering these questions requires an inductive inference that combines prior knowledge with the observed data. Bayesian inference provides a way to solve problems of this kind, and it relies upon one simple assumption: that our degrees of belief about a set of hypotheses can be expressed in terms of a probability distribution over those hypotheses. A variety of arguments have been given for this assumption, from proofs that it follows from a particular axiomatic description of common sense to proofs that a gambler who does not behave in this way will lose money (see Jaynes, 2003). However, in the context of cognitive science, we can adopt this as a methodological assumption—one that should be evaluated in terms of the amount of insight it ultimately gives us into human cognition.

If we are willing to express our degrees of belief in terms of probabilities, the problem of updating these beliefs in light of evidence is solved for us by the rules of probability theory. In particular, we should update our beliefs following a principle known as Bayes' rule. Assume that a learner has a prior probability distribution, $P(h)$, specifying the probability assigned to the truth of each hypothesis h in a set of hypotheses H (known as the hypothesis space) before seeing d . Bayes' rule states that the probability that should be given to each hypothesis after seeing d —known as the posterior probability, $P(h | d)$ —is

$$P(h | d) = \frac{P(d | h)P(h)}{\sum_{h \in H} P(d | h)P(h)} \quad (1)$$

where $P(d | h)$ —the likelihood—indicates how probable d is under hypothesis h .

We can apply Bayes' rule to any inductive problem. For example, when predicting human life spans, the hypotheses are total life spans and the

datum is the age of the man in question. The prior is the distribution over total life spans, as specified, for instance, by census data. The likelihood reflects the probability of encountering a man of a certain age given his total life span (e.g., an age greater than the total life span is impossible, so the probability of such an event would be zero). Combining prior and likelihood yields the posterior probability a learner should assign to each life span given the observed age, which can be used to make predictions. Griffiths and Tenenbaum (2006) used this analysis to study people's inductive predictions for a number of everyday events, including life spans and movie grosses, as well as the lengths of poems, political terms, or cake baking times. They showed a striking consistency between optimal Bayesian predictions and median human judgments, suggesting both that people have accurate knowledge of the distributions for these everyday events and that people can use this knowledge as Bayes' rule prescribes to predict new observed events (see Fig. 3.1).

Relationship to Other Theoretical Approaches

Bayesian models of cognition differ in some of their goals from other theoretical approaches to human cognition. In this section, we discuss the different levels at which thinking and reasoning can be analyzed, and how different theoretical approaches fit into this framework. We then consider how Bayesian models, which assume people express degrees of belief using probabilities and update these degrees of belief via mechanisms for probabilistic inference, can be reconciled with research in the “heuristics and biases” tradition that has famously argued against both of these assumptions.

Levels of Analysis

Marr (1982) argued that analyses of information processing systems can be conducted at three levels: the computational level, focusing on formalizing the problem being solved and identifying its ideal solution; the algorithmic level, focusing on the representations and processes that are used in executing that solution; and the implementation level, focusing on how these representations and processes are implemented in hardware. Several alternative frameworks for how to understand cognition at different levels of analysis have since been proposed (for a review, see Anderson, 1990), but all agree on the distinction between the functional characterization of a cognitive problem and its ideal solution, and

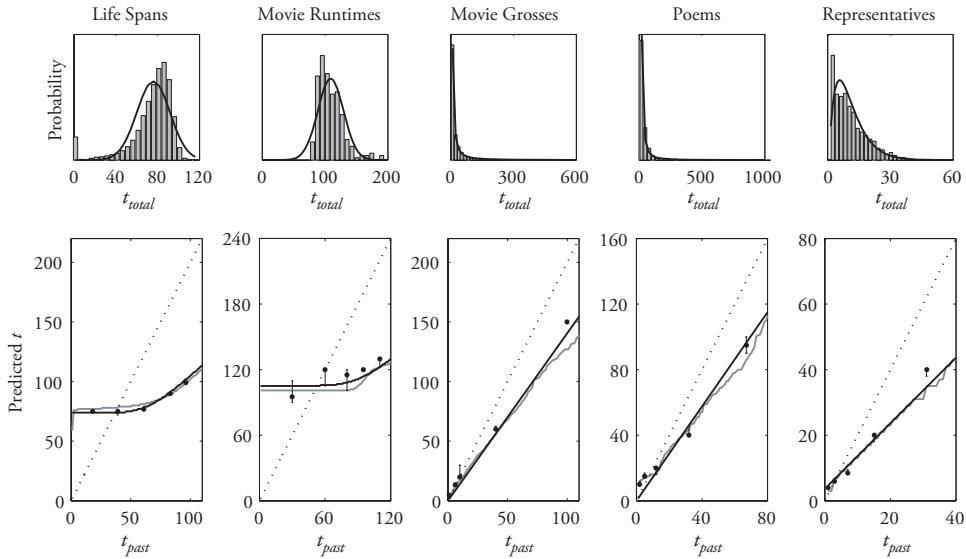

Fig. 3.1 People optimally integrate the evidence from a single observation with the appropriate prior distributions. The upper panels show the empirical distribution of the total duration or extent, t_{total} for five different everyday phenomena. The values of t_{total} are the hypotheses h to be evaluated, and these distributions are the appropriate priors. The first two distributions are approximately power-law, the next two are approximately Gaussian, and the last is approximately Erlang. Best-fitting parametric distributions are plotted in red. In the lower panels, black dots show subjects' median predictions for t_{total} when given a single observed sample t of a duration or extent in each of five domains (the data d used when applying Bayes' rule). Judgments are consistent with Bayesian predictions using the empirical prior distribution shown in the upper panel (black lines) and the best-fitting parametric prior (red lines). Predictions based on a single uninformative prior (dotted lines) are not consistent with these judgments. (Adapted from Griffiths and Tenenbaum, 2006.)

the mechanistic process that takes place inside people's heads.

The distinction between function and mechanism is important for understanding the goals of Bayesian models of cognition and how those goals differ from other theoretical perspectives. Bayesian inference could be taken as an account of human thinking and reasoning at either of these levels: as a proposed characterization of the ideal solution to the inductive problems that people face or as an account of the processes that people go through when they are solving those problems. However, most Bayesian models of cognition begin with and focus on the former, corresponding to Marr's (1982) computational level or Anderson's (1990) rational analysis. Many of the objections to Bayesian models of cognition result from assuming that these models are intended to apply straightforwardly or literally as mechanistic accounts, describing the actual processes that people follow when solving inductive problems.

In contrast to the "function first" approach to characterizing human inductive inference taken in many Bayesian models, most other approaches to computational modeling in psychology have emphasized the mechanistic level (see Doumas &

Hummel, Chapter 5). Symbolic cognitive architectures (e.g., Anderson, 1993) and connectionist models (e.g., McClelland & Rumelhart, 1986) are two primary examples. The components of these models, such as production rules or nodes in a neural network, are intended to correspond to isolable cognitive processes that support behavior and could in principle be reduced to some mechanism in the brain. If one looks at the basic ingredients of Bayesian models in the same way, as mechanistic proposals, even simple models could seem implausible. They would appear to require that human minds and brains explicitly represent very large, even infinite, hypothesis spaces, along with complex probability distributions over those spaces, and some kind of explicit implementation of Bayesian conditionalization. But this is not how most Bayesian models of cognition are intended to be interpreted, when framed at the computational level. They aim instead to identify the ideal solutions to inductive problems, given assumptions about the knowledge of the learner expressed through the choice of hypothesis space, prior, and likelihood. These models can be used to show that people act in a way that is at least approximately consistent with Bayesian

inference given hypothesis spaces, priors, and likelihoods of some form, providing insight into the kind of knowledge that guides people's inferences and constraints on the kind of algorithms that people could use to carry out those inferences.

Bayesian modelers are not uninterested in the mechanistic level, and they increasingly are turning their attention to integrating functional and mechanistic accounts—but still working within and extending the Bayesian paradigm. “Rational process models” attempt to characterize psychological mechanisms in terms of principled algorithms for approximate probabilistic inference, algorithms developed in Bayesian statistics and machine learning for approximate solution of large-scale problems that would be intractable for exact Bayesian calculations. Monte Carlo algorithms for sampling-based approximate inference have been particularly influential in recent work (Brown & Steyvers, 2009; Levy, Reali, & Griffiths, 2009; Sanborn, Griffiths, & Navarro, 2006; Vul, Goodman, Griffiths, & Tenenbaum, 2009) and computational neuroscientists have proposed that spiking in neural networks can implement forms of approximate probabilistic inference in biologically plausible ways (Fiser, Berkés, Orbán, & Lengyel, 2010). The Bayesian approach to cognitive modeling is thus best understood as a toolkit for reverse engineering the workings of human thought at all of Marr’s levels, following a top-down strategy that begins with ideal analyses at the computational level and then studies how these computations are implemented mechanistically at the algorithmic and hardware levels.

On Normativity, Reverse Engineering, and Heuristics

While Bayesian models emphasize ideal solutions to inductive problems, the way that they are used in cognitive modeling is different from traditional normative models. Logic, probability, and decision theory are often presented as defining a standard against which human thinking and reasoning can be compared (see Chater & Oaksford, Chapter 2). In such comparisons, the key question is whether people are rational, by the standards of those models, and in what ways they deviate from rational standards. In contrast, Bayesian models typically turn these questions around. These models ask what can we learn about human cognition by assuming people are rational, and what kind of rationality human thinking embodies (McKenzie, 2003). Rationality is thus not an empirical question, but

a methodological assumption that may or may not prove to be useful in understanding cognition.

Taking rationality as a guiding assumption derives directly from a focus on reverse engineering the mind, starting by viewing different aspects of cognition from a functional perspective. From an engineering standpoint, the central question is, “How does human cognition work so well, far better than any artificial intelligence system ever built?” Like any engineering solution, reverse-engineering accounts of human cognition should be framed in terms of rational solutions to the core problems, where “rational” does not mean ideal or globally optimal but simply “doing something for a reason,” which we can explore through a range of approaches to bounded or approximate or local optimization. The reverse-engineering questions then become, more precisely, “What is being optimized—what is the appropriate framing of the inductive problem to be solved?” and “How is it being optimized—what kind of approximations are used?”

The distinction between these two ways of using ideal models, the traditional normative approach and the reverse-engineering approach, arises starkly in what is often taken to be the greatest challenge to the view of cognition as Bayesian inference: the extensive literature on heuristics and biases that grew out of the work of Kahneman and Tversky (see Gilovich, Griffin, & Kahneman, 2002; Kahneman, Slovic, & Tversky, 1982; also see Frederick & Kahneman, Chapter 17). Their classic research program on judgment and decision under uncertainty set out to explore the cognitive processes by which people approach these problems that are normatively cast as probabilistic inference tasks, with an eye toward the heuristic rules people use to approximate rational probabilistic norms and the deviations from normative solutions (“biases”) that result from following these heuristics. Contemporary research in judgment and decision making (JDM) has focused on these deviations, leading to a view of human cognition as error prone and irrational (e.g., Ariely, 2008; Gilovich, 1993).

This JDM view has been the source of some natural and understandable skepticism about Bayesian approaches to cognitive modeling. Yet the Bayesian approach and the heuristics and biases program are more compatible than they might seem at first. Partly this is due to their complementary focus. Kahneman and Tversky, and much of the JDM work that followed, studied explicit reasoning about basic probability or statistics questions, often with

clear relevance to economic or policy questions, as well as more intuitive judgments about economic or policy questions where people's sense for the value of money is critical. People are typically asked to reason consciously and deliberately with information in more or less the same form that statisticians, policy makers, or economic decision makers typically work with: statistics, monetary values, and so on. It turns out that people often deviate from rational norms in these cases, and this has very important implications for many areas of applied decision making in our society.

This does not mean, however, that human minds always deviate from rational norms to such an extent or in these same ways. Much Bayesian modeling can be seen as an attempt to fill in this other side of the picture, to reverse engineer those aspects of human common sense that do work surprisingly well—better than any engineered machine reasoning systems. These are very different behavioral settings than typically studied in the JDM literature. The probabilistic judgments are often implicit, rather than explicit. The tasks are drawn less from the modern socioeconomic policy world and more from the real world of natural everyday experience—tasks which our brains have solved mostly unconsciously, automatically, and rapidly, in some form dating back to birth or early childhood. The data presented to people take the form of natural observations rather than explicitly stated statistics or monetary values. It turns out that in many of these settings, the principles of rational probabilistic inference are a valuable tool for explaining how our minds work—even the minds of young children (Perfors, Tenenbaum, Griffiths, & Xu, 2011).

Having said this, there are also significant areas of overlap in the JDM and Bayesian modeling literatures—both behavioral tasks and aspects of cognitive processing which both paradigms have studied and where it might seem that they have reached largely opposite conclusions (for example, the results of Griffiths and Tenenbaum, 2006, presented earlier seem inconsistent with previous work emphasizing errors in human predictions). We believe that many of these differences are superficial or can be resolved upon closer inspection. At heart we see real common purpose between the two approaches, although this can be hard for researchers in either camp to see with their different vocabularies and explanatory styles. We will try to draw out some of these connections in the following discussion.

When considering their implications for Bayesian models of cognition, the findings of nonnormative

behavior in the heuristics and biases research program can be divided into two broad classes. In the first class are results that can be viewed as rational, but under a different construal of the problem than the one the experimenter originally had in mind. Typically, the question of whether people are rational is framed by the experimenter defining a particular problem, and then examining whether people's behavior corresponds to a stipulated normative solution to that problem. However, there is no guarantee that people interpret the problem in the way intended by the experimenter or that the experimenter's interpretation is in any objective sense the "correct" one for the purposes of cognition in natural environments. If we instead assume that people are doing something reasonable, and consider what problem they might be solving, it often appears that people might be producing behavior that is a rational solution to a different problem—often a more complex, more interesting, but more natural problem. For example, Oaksford and Chater (1994) argued that apparently irrational behavior on Wason's (1966) card selection task could be understood as a rational attempt to maximize the information obtained by performing an action. Sher and McKenzie (2006) have conducted a number of experiments suggesting that framing effects and other instructional manipulations that are intended to change behavior without altering the form of a decision problem could result from a rational inference based on linguistic pragmatics. Griffiths and Tenenbaum (2001) argued that apparently irrational judgments about random processes—such as believing that HHTHT is more likely than HHHHH to be generated when a fair coin is flipped—could result from making a diagnostic inference about which outcome provides greater evidence in favor of a random process, rather than a predictive judgment about their probability under a random process. Likewise, our sense of coincidence seems to reflect the mirror image of subjective randomness as a rational inference: a measure of the strength of evidence for some structured hidden cause as the explanation for our observations, as opposed to a uniform random process (Griffiths & Tenenbaum, 2007a).

From a reverse-engineering perspective, these cases could be seen as signs that the computational-level analysis of the original experiments was miscast or inappropriate somehow. By showing how people's apparently irrational behavior can be interpreted as rational under an alternative framing, we come to a better understanding of the computational problem

the mind is actually solving. Of course, there are very real dangers of constructing “just so stories” here, so it is vital that these sorts of rational reanalyses be backed up by extensive and quantitative experimental support designed to test distinctive predictions of the proposed analysis versus compelling alternative or heuristic accounts. From a JDM viewpoint, these cases could be understood as people heuristically substituting an alternative problem or task that is easier for them to think about than the one originally posed (Kahneman & Frederick, 2002). This could lead to biases, and it could have serious policy or economic implications that no one could argue are rational. But this does not mean that the substituted problem, the heuristic shortcut, cannot itself be given a sensible rational analysis.

A second class of behavioral results are those that seem to admit no satisfying interpretation as Bayesian inference under a plausible problem formulation. These cases genuinely point to deviations from the ideal solutions to the problems people face and provide an opportunity to identify the cognitive mechanisms by which people might approximate ideal Bayesian computations. This style of explanation was arguably the intent of Kahneman and Tversky’s original work on heuristics and biases, although they did not have the theoretical vocabulary of approximate probabilistic inference that we do as a source of hypotheses for how cognitive mechanisms might work. Contemporary research in JDM focuses more on the errors that result from applying heuristics than on the value of those heuristics as approximations to computationally intractable inference problems. In some ways, this seems to reflect an expectation that human cognition should be error prone. For example, a very different view of the utility of ideal solutions can be found in research on human perception, where it is assumed that people do a good job of solving the inductive problems posed by the environment (Carpenter & Williams, 1995; Freeman, 1994; Huber, Shiffrin, Lyle, & Ruys, 2001; Kording & Wolpert, 2004; Platt & Glimcher, 1999; Weiss, Simoncelli, & Adelson, 2002). Consideration of inductive problems that go beyond the range typically considered in research on judgment and decision making, including problems such as categorization, causal learning, and language acquisition, reveals that people are generally very good at solving these problems. In fact, in many cases they are the only systems we know that can solve these problems, outperforming state-of-the-art machine learning systems. Viewed in this light, we

should be trying to understand how people succeed so often in solving these problems, rather than focusing on the cases where they make errors.

We should also comment briefly on how Bayesian models relate to another contemporary approach to JDM issues. In contrast to the emphasis on errors in much of the literature on judgment and decision making, Gigerenzer and colleagues (Gigerenzer et al., 1999) have argued that simple heuristics can in fact be adaptive. As part of this argument, they have shown that such heuristics can outperform more complex “rational” models, such as approaches to combining cue weights based on maximum-likelihood logistic regression. We do not view these results as being inconsistent with the claims typically made by Bayesian models—such heuristics might provide a way to approximate more computationally challenging probabilistic inference. However, the claim that the heuristics outperform rational models relies on comparing the heuristics against models that make weaker assumptions about the structure of the environment, in environments that match the assumptions made by the heuristics. The resulting advantage for the heuristics is simply an instance of what statisticians have termed the “bias-variance tradeoff,” with the more flexible model generalizing poorly (Geman, Bienenstock, & Doursat, 1992). When the rational models make assumptions about the environment more analogous to those made by the heuristics, they achieve similar or better performance (e.g., Martignon & Laskey, 1999).

Contributions to Understanding Thinking and Reasoning

Many of the central problems studied in cognitive science are inductive problems, including learning categories, identifying causal relationships, and acquiring language. Each of these problems can be analyzed using Bayesian inference. When learning categories, our hypotheses are ways of categorizing objects and our data are labeled category members (Anderson, 1990; Ashby & Alfonso-Reese, 1995; Sanborn, Griffiths, & Navarro, 2010). When learning causal relationships, our hypotheses are causal structures relating variables and our data are observations of those variables (Anderson, 1990; Griffiths & Tenenbaum, 2005). When acquiring language, our hypotheses are grammars or other schemes for expressing the probability of different utterances and our data are the utterances themselves (Chater & Manning, 2006; Goldwater, Griffiths, & Johnson, 2009; Perfors, Regier, & Tenenbaum, 2006). Viewing

all of these problems as different species of Bayesian inference has proven fertile in developing new cognitive models with a high degree of mathematical rigor, precision, and quantitative support in behavioral experiments. Rather than emphasizing the quantitative aspects of this work, here we describe the contributions in more conceptual terms—how Bayesian models enable cognitive scientists to think in new and productive ways about several questions of long-term interest.

Integrating Symbols and Statistics

Symbolic representation and statistical learning were long viewed as alternative or even opposing approaches to modeling the mind (Pinker, 1997). Models that rely on structured symbolic representations (e.g., Chomsky, 1957) have typically relied on weak learning mechanisms, and models that highlight the role of statistical learning (e.g., Rumelhart & McClelland, 1986) have typically relied on unstructured “subsymbolic” representations. Probabilistic models provide a new perspective on the debate between these approaches by showing how symbolic structures can be combined with statistical learning. Earlier statistical models of learning were typically defined over large arrays of numbers. For example, learning has been formulated as estimating strengths in an associative memory, weights in a neural network, or parameters of a high-dimensional nonlinear function (McClelland & Rumelhart, 1986; Rogers & McClelland, 2004). In contrast, Bayesian cognitive models often define probabilities over structured symbolic representations, including graphs, grammars, predicate logic, relational schemas, and functional programs.

In learning words and concepts from examples, the knowledge that guides both children’s and adults’ generalizations can be described using probabilistic models defined over tree-structured representations (Xu & Tenenbaum, 2007a, 2007b). Reasoning about other biological concepts for natural kinds—for example, given that cows and rhinos have protein X in their muscles, how likely is it that horses or squirrels do?—is also captured by Bayesian models that assume nearby objects in the tree are likely to share properties (Kemp & Tenenbaum, 2009). However, trees are by no means a “universal” representation. Inferences about other kinds of categories or properties are best captured using probabilistic models with different forms: two-dimensional spaces or grids for reasoning about geographic properties of cities, one-dimensional orders for

reasoning about values or abilities, or directed networks for causally transmitted properties of species (e.g., diseases) (Kemp & Tenenbaum, 2009).

Knowledge about causes and effects more generally can be expressed in a directed graphical model (Pearl, 1988): a graph structure where nodes represent variables and directed edges between nodes represent probabilistic causal links. In a medical setting, for instance, nodes might represent whether a patient has a cold, a cough, a fever, or other conditions, and the presence or absence of edges shows that colds tend to cause coughing and fever but not chest pain; lung disease tends to cause coughing and chest pain but not fever; and so on.

Such a “causal map” represents a simple kind of intuitive theory (Gopnik et al., 2004), but learning causal networks from limited data depends on the constraints of more abstract knowledge. For example, learning causal dependencies between medical conditions is enabled by a higher level framework theory (Wellman & Gelman, 1992) specifying two classes of variables (or nodes)—diseases (D) and symptoms (S)—and the tendency for causal relations (or graph edges) to run from D to S, rather than within these classes, or from S to D. This abstract framework can be represented using probabilistic models defined over relational data structures such as graph schemas (Kemp, Tenenbaum, Niyogi, & Griffiths, 2010), templates for graphs based on types of nodes, or probabilistic graph grammars (Griffiths & Tenenbaum, 2007b), similar in spirit to the probabilistic grammars for strings that have become standard for representing linguistic knowledge (Chater & Manning, 2006).

Models that rely on representations such as tree structures, causal maps, graph schemas, or graph grammars help to explain how inductive inferences are guided by different kinds of knowledge but also help to explain how these knowledge structures are acquired. If we take symbolic structures as our hypotheses, Bayes’ rule provides a way to learn which of these symbolic structures best describes our data. Combining structured representations and probabilistic inference therefore helps to explain how knowledge guides learning and how this knowledge is itself acquired.

Shedding Light on the Nature and Origins of Human Inductive Biases

Arguments from philosophy (Goodman, 1955) and formal analyses of learning (Geman et al., 1992; Kearns & Vazirani, 1994; Vapnik, 1995) indicate that the key to solving inductive problems is

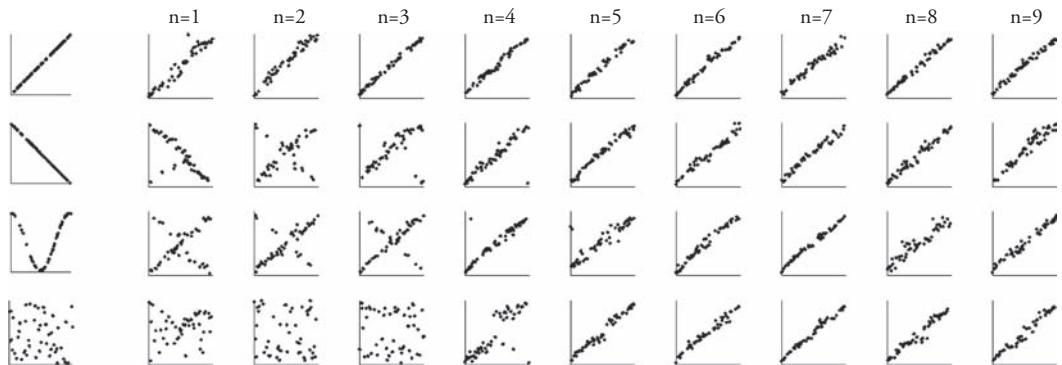

Fig. 3.2 Iterated learning reveals inductive biases. The leftmost panel in each row shows the set of samples from a function seen by the first learner in a sequence. The (x, y) pairs were presented as the lengths of two bars on a computer screen. During training, participants predicted the length of the y bar from the x bar, receiving feedback. The second panel shows the predictions produced by the first learner in a test phase, predicting y for a range of x values without feedback. These predictions were used as the training data for the second learner, who produced the predictions shown in the third column. The other panels show the data produced by each generation of learners, trained from the predictions produced by the previous learner. Regardless of the function used to generate the data shown to the first participant, iterated learning quickly converges to a linear function with positive slope, consistent with findings indicating that human learners are biased toward this kind of function. (Adapted from Kalish, Griffiths, & Lewandowsky, 2007.)

constraining the set of hypotheses under consideration. Bayesian methods provide a way to formalize the question of what kind of constraints guide human inductive inference and a language for expressing these constraints, through the prior distribution over hypotheses. They also allow the intermediate position that inferences can be strongly guided by knowledge acquired during a learner's lifetime, with priors being affected by the environment.

Bayesian models provide three ways to identify the constraints informing inductive inferences. The first, most obvious way is to conduct experiments and attempt to explain the results in terms of models using different prior distributions. This was the approach taken in the experiment by Griffiths and Tenenbaum (2006) presented earlier in the chapter, where the results suggested that people seemed to be using priors that corresponded well with the actual distributions of everyday quantities. The second way to identify constraints is to ask an abstract learnability question: What priors would be needed for people to learn the things that they do from the data that they observe? This kind of approach has typically been taken in studying language acquisition, where linguistic corpora provide a source of the utterances that children hear and can be used to obtain a good estimate of the data from which languages are learned (Goldwater et al., 2009; Perfors et al., 2006).

The third way to identify constraints on inductive inference is to specifically design experimental methods for estimating priors. One such method resulted from analyzing models of language evolution based

on “iterated learning”—the idea that every speaker of a language learns that language from another speaker, who had to learn it from somebody else in turn (Kirby, 2001). Formally, we can imagine a sequence of learners, each of whom receives data from the previous learner, forms a hypothesis from those data, and then uses that hypothesis to generate new data that are passed to the next learner. Griffiths and Kalish (2007) showed that if the learners use Bayes' rule, the probability that a learner selects a particular hypothesis converges to the prior probability assigned to that hypothesis as the length of the sequence increases. This result suggests a procedure for exploring human inductive biases: implement iterated learning in the laboratory with human learners and examine which hypotheses survive. Several experiments have shown that this method reveals constraints on learning consistent with the results of previous studies (Griffiths, Christian, & Kalish, 2006; Kalish, Griffiths, & Lewandowsky, 2007; Reali & Griffiths, 2009; see Fig. 3.2).

In addition to characterizing inductive constraints, psychologists attempt to understand the origin of these constraints. The acquisition of new inductive constraints is primarily the province of cognitive development (Carey, 2009; Gopnik & Meltzoff, 1997) but continues throughout life. In probabilistic terms, the challenge is to explain how hypothesis spaces and priors over these hypothesis spaces arise. Hierarchical Bayesian models (HBMs) (Gelman, Carlin, Stern, & Rubin, 1995) address the origins of hypothesis spaces and priors by positing

not just a single level of hypotheses to explain the data, but multiple levels: hypothesis spaces of hypothesis spaces, with priors on priors. Bayesian inference across all levels allows hypotheses and priors needed for a specific learning task to themselves be learned at larger or longer time scales, at the same time as they constrain lower level learning.

We illustrate the hierarchical Bayesian approach by building on the theme of the previous section and discussing how different kinds of symbolic representations can be learned. Symbolic representations provide a powerful source of constraints. For instance, in learning concepts over a domain of n objects, there are 2^n subsets and hence 2^n logically possible hypotheses for the extension of a novel concept. Assuming concepts correspond to the branches of a specific binary tree over the objects restricts this space to only $n - 1$ hypotheses. The constraints captured by a tree might be useful, but how might a learner find out which tree is best, and how might she discover in the first place that she should construct a tree rather than some other kind of representation? Discoveries like these have been pivotal in scientific progress: Mendeleev launched modern chemistry with his proposal of a periodic structure for the elements. Linnaeus famously proposed that relationships between biological species are best explained by a tree structure, rather than a simpler linear order (premodern Europe's "great chain of being") or some other form. Such structural insights have long been viewed by psychologists and philosophers of science as deeply mysterious in their mechanisms—more magical than computational. Conventional algorithms for unsupervised structure discovery in statistics and machine learning—hierarchical clustering, principal components analysis, multidimensional scaling, clique detection—assume a single fixed form of structure (Shepard, 1980). Unlike human children or scientists, they cannot learn multiple forms of structure or discover new forms in novel data.

Recently cognitive modelers have begun to explore how hierarchical Bayesian models can address these challenges. Kemp and Tenenbaum (2008, 2009) showed how HBMs defined over graph- and grammar-based representations can discover the form of structure governing similarity in a domain. Structures of different forms—trees, clusters, spaces, rings, orders, and so on—can all be represented as graphs, while the abstract principles underlying each form are expressed as simple grammatical rules for growing graphs of that form. Embedded in a hierarchical Bayesian framework, this approach can discover

the correct forms of structure (the grammars) for many real-world domains, along with the best structure (the graph) of the appropriate form, as shown in Figure 3.3.

Hierarchical Bayesian models can also be used to learn abstract causal knowledge, such as the framework theory of diseases and symptoms, and other simple forms of intuitive theories (Kemp et al., 2010). Mansinghka et al. (2006) showed how a graph schema representing two classes of variables, diseases (D) and symptoms (S), and a preference for causal links running from D to S nodes, can be learned from the same data that support learning causal links between specific diseases and symptoms—and learned just as fast or faster (see Fig. 3.4). The learned schema, in turn, dramatically accelerates learning of specific causal relations at the level below. Getting the big picture first—discovering that diseases cause symptoms before pinning down any specific disease-symptom link—and then using that framework to fill in the gaps of specific knowledge is a distinctively human mode of learning. It figures prominently in children's development and scientific progress but has not previously fit into the landscape of rational or statistical learning models.

Across several case studies of learning abstract knowledge—discovering structural forms, causal framework theories, and other inductive constraints acquired through transfer learning—it has been found that abstractions in HBMs can be learned remarkably fast, from relatively little data compared to what is needed for learning at lower levels. This is because each degree of freedom at a higher level of the HBM influences—and pools evidence from—many variables at levels below. This property of HBMs has been called the "the blessing of abstraction" (Goodman, Ullman, & Tenenbaum, 2011). It offers a top-down route to the origins of knowledge that contrasts sharply with the two classic theories of development: nativism (Chomsky, 1986; Spelke, Breinlinger, Macomber, & Jacobson, 1992), in which abstract concepts must be present from birth, and empiricism or associationism (Rogers & McClelland, 2004), in which abstractions are constructed but only slowly, in a bottom-up fashion, by layering many experiences on top of each other and filtering out their common elements. Only HBMs thus seem suited to explaining the two most striking features of abstract knowledge in humans: that it can be learned from experience, and that it can be present remarkably early in life, serving to constrain more specific learning tasks.

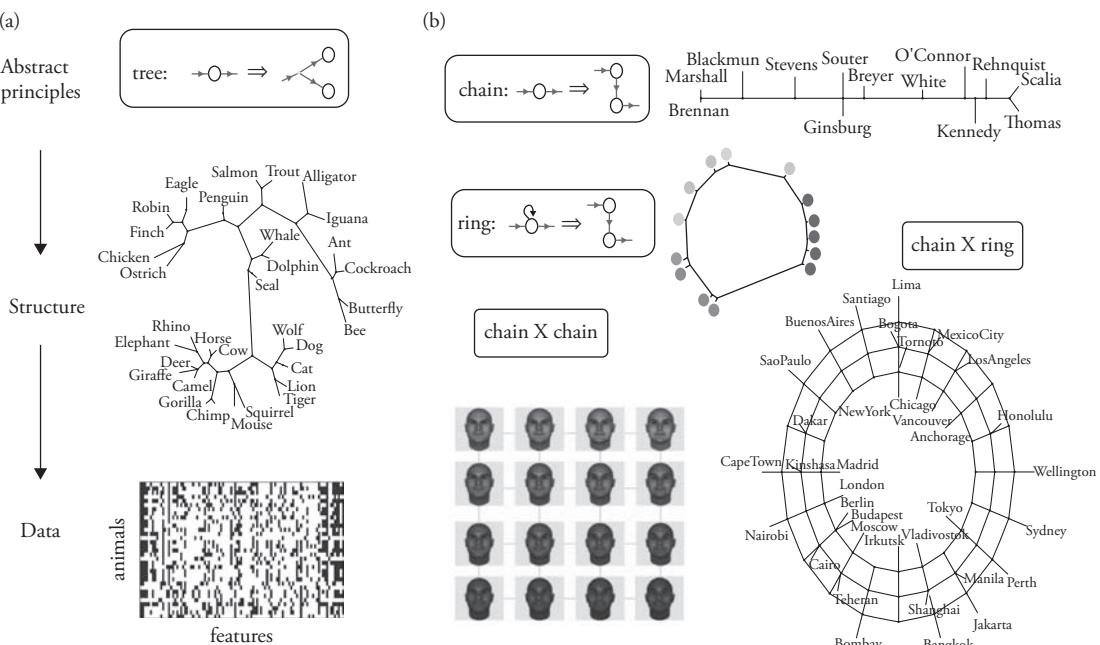

Fig. 3.3 Kemp and Tenenbaum (2008) showed how the form of structure in a domain can be discovered using a hierarchical Bayesian model defined over graph grammars. At the bottom level of the model is a data matrix D of objects and their properties, or similarities between pairs of objects. One level up is a graph describing how properties are distributed over objects. Intuitively, objects nearby in the graph are expected to share properties. At the highest level grammatical rules specify the form of structure in the domain—rules for growing graphs of a constrained form out of an initial seed node. A search algorithm attempts to find the combination of a form grammar F and graph G generated by that grammar which jointly receive highest posterior probability $P(F,G|D)$. (a) Given observations about the features of animals, the algorithm infers that a tree structure best explains the data. The best tree found captures intuitively sensible categories at multiple scales. (b) The same algorithm discovers that the voting patterns of U.S. Supreme Court judges are best explained by a linear “left-right” spectrum, and that subjective similarities among colors are best explained by a circular ring. Given images of faces varying in two dimensions, race and masculinity, the algorithm successfully recovers the underlying two-dimensional grid structure. Given proximities between cities on the globe, the algorithm discovers a cylindrical representation analogous to latitude and longitude. See color figure.

Developing Connections to Other Disciplines

Considering the ideal solutions to inductive problems has often resulted in surprising connections to ideas in other disciplines. In particular, statistics, artificial intelligence, and machine learning are disciplines that all involve inductive problems, and all are interested in rational solutions to those problems. Probabilistic approaches have recently become the standard approach to induction in all of these disciplines. If people are solving inductive problems well, we might expect that this lingua franca extends to psychology. To the extent that the inductive problems being addressed in psychology and the engineering disciplines take the same form, with the same inputs and outputs and the constraints of operating in the same world, we might even expect to find precise correspondences between the solutions adopted by the human mind and

those that have been identified in these other fields. For example, Ashby and Alfonso-Reese (1995) observed that a number of psychological models of categorization, such as exemplar and prototype models, can be viewed as corresponding to different methods of estimating a probability distribution, a problem known as “density estimation” in statistics. Likewise, Anderson’s (1990, 1991) rational model of categorization corresponds to a class of models used in nonparametric Bayesian statistics (Neal, 1998). This connection provides a link to a rich literature building on this class of models, which can be a source of new psychological hypotheses (Sanborn et al., 2010).

Recognizing connections to other disciplines is also useful because mathematical tools from those disciplines can sometimes be used to clarify psychological questions. Recent work on causal induction provides a prime example. Griffiths and Tenenbaum

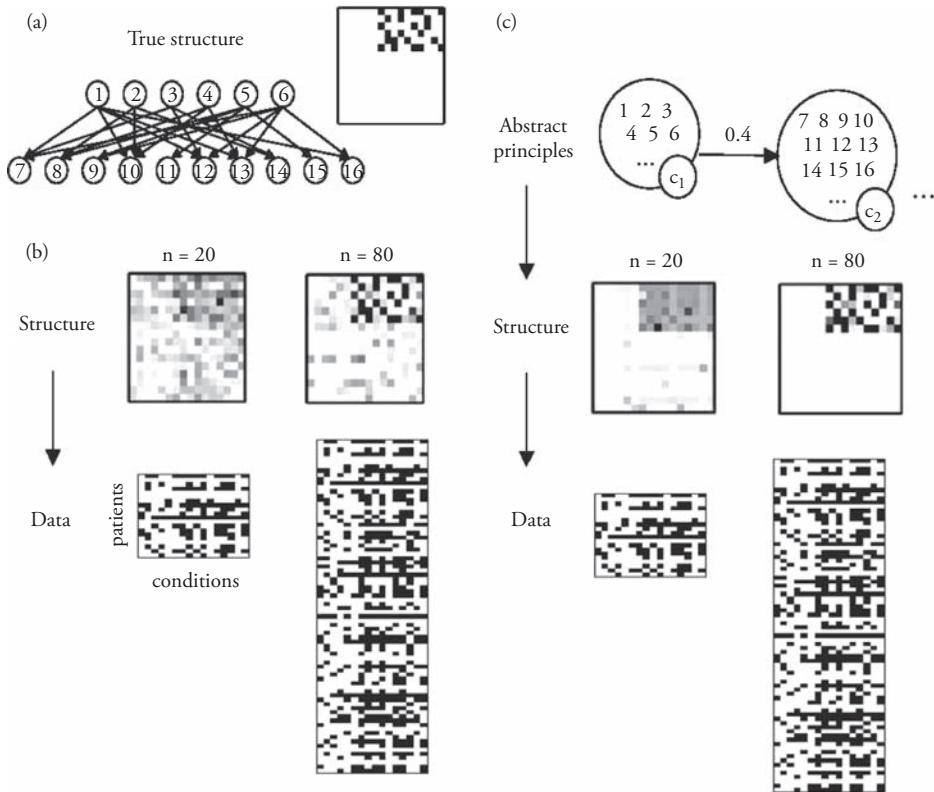

Fig.3.4 Hierarchical Bayesian models defined over graph schemas can acquire intuitive theories and use those theories to learn about specific causal relations from limited data (Kemp, Tenenbaum, Niyogi, & Griffiths, 2010). (a) For example, a simple medical reasoning domain might be described by relations among 16 variables: the first six are “diseases,” with causal links to the next ten “symptoms.” This causal network can be visualized as a binary matrix (upper right). (b) A two-level hierarchical Bayesian model (HBM) formalizes bottom-up causal learning, or learning with an uninformative prior on networks. At bottom we observe data D on patients and the conditions afflicting them. The second level encodes causal relations among these conditions; a grayscale matrix visualizes the posterior probability that any given pairwise causal link exists, conditioned on observing n patients. The true causal network can be recovered perfectly only from observing very many patients ($n = 1,000$; not shown). With $n = 80$, spurious links are inferred, and with $n = 20$ almost nothing can be learned. (c) Mansinghka et al. (2006) introduced a three-level HBM, where the highest level is a graph schema. The schema can represent the disease-symptom theory by assigning nodes to classes C1 and C2, and placing a prior on the level below favoring C1 → C2 links. The effective number of node classes is discovered automatically via the Bayesian Occam’s razor. Although this three-level model has many more degrees of freedom than the model in (b), causal learning is faster and more accurate. With $n = 80$ data points, the causal network is identified near-perfectly. Only $n = 20$ data points are sufficient to learn the high-level C1 → C2 schema and thereby to limit uncertainty at the network level to just the question of which diseases cause which symptoms.

(2005) used causal graphical models, a formal language for representing and reasoning about causal relationships that was developed in computer science and statistics (Pearl, 2000; Spirtes, Glymour, & Scheines, 1993), to make the distinction between learning whether a causal relationship exists and estimating the strength of this relationship. This distinction was valuable because existing rational models could be shown to correspond to methods for estimating the strength of a relationship, while some of the judgments that people made in causal induction tasks seemed better characterized in terms of inferences about whether a relationship existed.

Subsequent work has built on this observation, producing a more complete Bayesian account of how people might estimate the strength of causal relationships (Lu, Yuille, Liljeholm, Cheng, & Holyoak, 2008). Developmental psychologists have shown how Bayesian inference over appropriate hypothesis spaces of graphical models can illuminate children’s causal learning (Gopnik et al., 2004; Griffiths & Tenenbaum, 2007b; Sobel, Tenenbaum, & Gopnik, 2004). Other areas of perception and cognition that were not always seen as species of causal inference, such as classical conditioning, multisensory integration, or perceptual organization, have been

influenced by this work and usefully informed by a new generation of causal graphical models (Courville, Daw, & Touretzky, 2006; Kording et al., 2007; Orbán, Fiser, Aslin, & Lengyel, 2008).

The work on rational process models described earlier, taking Bayesian approaches down to the algorithmic and hardware levels, represents a particularly fertile flow of ideas between the engineering disciplines and psychology. To date, the idea flow has been mostly from the engineering side into psychology, with various principled Monte Carlo methods for approximate inference suggesting new rational interpretations of classic cognitive processing mechanisms, as well as new processing accounts. But cognitive scientists thinking about the challenges of developing more flexible and robust approximate inference schemes have also made contributions back to the engineering side. For example, Vul et al. (2009) show when and why decision making based on just a single sample from the Bayesian posterior may represent an optimal tradeoff between the expected gain of a correct decision and the expected reward timescale. These analyses could be useful in understanding how very efficient sampling-based approximate inference might work in the brain, or how it could most efficiently be instantiated in robots. Goodman, Mansinghka, Roy, Bonawitz, and Tenenbaum (2008) have proposed and implemented a general-purpose approach to Monte Carlo inference on arbitrary computable probability distributions, or probabilistic programs, which was originally developed for modeling process-level effects in rule-based categorization (Goodman, Tenenbaum, Feldman, & Griffiths, 2008). Much of the work described earlier in building rich hierarchical or nonparametric models for learning categories and causal networks can also be seen as importing ideas from machine learning and computer science into psychology. But again, cognitive scientists have built on these first generations of probabilistic models and developed new artificial intelligence and machine learning techniques motivated by trying to capture distinctively human learning abilities, such as the infinite relational model for learning simple relational theories (Kemp et al., 2010), the hierarchical Bayesian approach to structural form discovery (Kemp & Tenenbaum, 2008), or nonparametric Bayesian models for feature discovery (Griffiths & Ghahramani, 2006).

Conclusions and Future Directions

The Bayesian toolkit offers several contributions to understanding human thinking and reasoning. It

provides a unifying mathematical language for framing cognition as the solution to inductive problems and for building principled quantitative models of thought with a minimum of free parameters and ad hoc assumptions. Deeper, it offers a framework for understanding why the mind works the way it does, in terms of rational inference adapted to the structure of real-world environments, and what the mind knows about the world—abstract schemas and intuitive theories revealed only indirectly through how they constrain generalizations. The new tools we obtain by adopting this perspective allow us to integrate symbolic representations with statistical learning, identify human inductive biases and understand their origins, and connect cognitive psychology with other scientific disciplines.

Most important, the Bayesian approach lets us move beyond classic “either-or” dichotomies that have long shaped and limited debates in cognitive science: “empiricism versus nativism,” “domain-general versus domain-specific,” “logic (rules, symbols) versus probability (statistics, numbers).” Instead we can ask harder questions of reverse engineering, with answers potentially rich enough to help us build more human-like artificial intelligence. The future directions for Bayesian models involve grappling with some of the central questions of cognitive science. How can domain-general mechanisms of learning and representation build domain-specific systems of knowledge? How can structured symbolic knowledge be acquired by statistical learning? The answers that are emerging from current research suggest new ways to think about the development of a cognitive system. Powerful abstractions can be learned surprisingly quickly, together with or prior to learning the more concrete knowledge they constrain. Structured symbolic representations need not be rigid, static, hardwired, or brittle. Embedded in a probabilistic framework, they can grow dynamically and robustly in response to the sparse, noisy data of experience.

Knowledge Representation

Arthur B. Markman

Abstract

Theories in psychology make implicit or explicit assumptions about the way people store and use information. The choice of a format for knowledge representation is crucial, because it influences what processes are easy or hard for a system to accomplish. In this chapter, I define the concept of a representation. Then, I review three broad types of representations that have been incorporated into many theories. Finally, I examine proposals for the role of body states in representation as well as proposals that the concept of knowledge representation has outlived its usefulness.

Key Words: knowledge representation, features, structured representation, analogy, embodied cognition, dynamical systems, multidimensional scaling

Introduction

Theories of psychological functioning routinely make assumptions about the type of information that people use to carry out a process. They also make proposals for the form in which that information is stored and the procedures by which it is used. The type, form, and use of information by psychological mechanisms are incorporated into psychological proposals about *knowledge representation*. This chapter aims to provide a broad introduction to knowledge representation (see Markman, 1999, for a more detailed discussion of these issues).

In this chapter, I start by defining what I mean by a representation. Then, I discuss some of the kinds of information that people have proposed to be central to people's mental representations. Next, I describe three proposals for the way that people's knowledge is structured. Finally, I explore some broader controversies within the field. For instance, I describe an antirepresentationalist argument that suggests that we can safely dispense with the notion

of knowledge representation. I end with a call for a pluralist approach to representation.

Mental Representations

The modern notion of a mental representation emerged during the *cognitive revolution* of the 1950s, when the computational view of the mind ascended. The behaviorist approach to psychology that played a significant role in American psychology explicitly denied that the form and content of people's knowledge were legitimate objects of scientific study. Advances in the development of digital computers, however, provided a theoretical basis for thinking about how information could be stored and manipulated in a device.

On this computational view, *minds* are descriptions of the nature of the program that is implemented (in humans) by *brains*. Just as computers with very different hardware architectures could implement the same word-processing program (and thus make use of the same data structures and algorithms), different brains might compute the same sorts of functions and thus

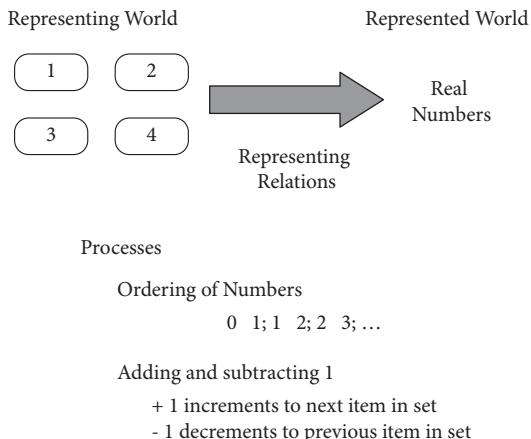

Fig. 4.1 Example of the four key aspects of a definition of a representation. A representing world corresponds to a represented world through some set of representing relations. Processes must be specified that make use of the information in the representation.

create representations (mental data structures) and processes (mental algorithms). Thus, proposals for knowledge representation are often stated at a level of description that abstracts across the details of what the brain is doing to implement that process yet nonetheless specifies in some detail how some functions are computed. Marr (1982) called this the *algorithmic level* of description. He called the abstract function being computed by an algorithm the *computational level* (see Griffiths, Tenenbaum, & Kemp, Chapter 3). What the brain is doing, which Marr (1982) called the *implementational level* of description, may provide some constraints on our understanding of these mental representations (see Morrison & Knowlton, Chapter 6; Green & Dunbar, Chapter 7), but not all of the details of an implementation are necessary to understand the way the mind works.

Defining Mental Representation

To define the concept of representation, I draw from work by Palmer (1978) and Pylyshyn (1980). In order for something to qualify as a representation, four conditions have to hold. First, there has to be some *representing world*. The representing world is the domain serving as the representation. In theories of psychological processing, this representing world may be a collection of symbols or a multidimensional space. In Figure 4.1, mental symbols for the numbers 0–9 are used to represent numerical quantities.

There is also a *represented world*. The represented world is the domain or information that is to be represented. There is almost always more information

in the world than can be captured by some representing world. Thus, the act of representing some world almost always leads to some loss of fidelity (Holland, Holyoak, Nisbett, & Thagard, 1986). In the example in Figure 4.1, representing the world of numbers with mental symbols will lose information, because the space of numbers is continuous, while this symbolic representation has discrete elements in it.

The third component of a representation is a set of *representing relations* that determines how the represented world stands in for the represented world. In Figure 4.1, these representing relations are shown as an arrow connecting the representing world to the represented world. There has to be some kind of relationship between the items that are used as the representation and the information being represented. These relations are what give the representation its meaning. I'll discuss this issue in more detail in the next section.

Finally, in order for something to function as a representation, there has to be some set of processes that use the information in the representation for some function. Without some processes that act on the representing world, the potential information in the representation is inert. In the case of the number representation in Figure 4.1, there need to be procedures that generate an ordering of the numbers and procedures that specify operations such as how to add or multiply or create other functions defined over numbers.

One reason why it is important to specify both the represented world and the processes is that it is tempting for readers to look at a representing world and have intuitions about the information that is captured in it. For example, you probably know a lot about numbers, and so you may bring that knowledge to bear when you see that the symbols in Figure 4.1 are associated with numbers. However, unless the system that is going to use this representation has procedures for manipulating these symbols, then the system that has this representing world does not have the same degree of knowledge that you do.

The definition that I just gave does not distinguish between mental representations and other things that serve as representations. For example, I may take a digital photograph as a representation of a visual scene. The photograph represents color by having a variety of pixels bunched close together that take on the wavelength of light that struck a detector when the picture was taken. This lawful

relationship is what allows this photo to serve as a representation of some scene. Furthermore, when you look at that photo, your visual and conceptual systems are able to interpret what is in the image, thereby serving as a process for extracting and using information from the representation.

In order for something to count as a mental representation, of course, the representing world needs to be inside the head. Humans use a variety of external representations, including photos, writing, and a variety of tools. The relationship between humans and the representations they put in their environment is interesting, and I discuss it a bit more at the end of this chapter.

Giving Meaning to Representations

In a computer program, data structures function to store the data that a program is going to manipulate in order to carry out some function. As I discussed earlier, a mental representation plays a role within cognitive systems that is analogous to the role of the data structure in a program. In order for this representation to serve effectively, though, there has to be some way to ensure that the representation captures the right information. We can think of the information that is captured by a particular representation as its *meaning*.

What are the sources of meaning in mental representations? Obviously, one source of meaning is the set of representing relations that relate the representing world to the represented world. These relations help to *ground* the representation. As a very simple example, consider a thermostat. One way to build a thermostat is to use a bimetal strip. The two metals that make up the strip expand and contract at different rates when exposed to heat. Thus, the curvature of the strip changes continuously with changes in temperature. In a typical thermostat, the bimetal strip is connected to a vial of conducting liquid (like mercury) that will close an electrical switch between two contacts when the right level of curvature is reached. Within this system, the lawful relationship between air temperature and the curvature of the strip provides a grounding for the representation of temperature.

Many mental representations that get (part of) their meaning through grounding are actually grounded in other representations. For example, research on vision focuses on how people detect the edges of objects in an image. Even these basic processes, however, are making use of other internal states. After all, light hits the retina at the back of the eye, and then the retina turns that light into

electrical signals that are sent to the brain. From that point forward, all other computations are performed on information that is already internal to the cognitive system. In some cases, we can trace a chain of representations all the way back out to states in the world through the set of representing relations that link one relation to the next.

The ability to ground representations in actual perceptual states of the world, though, is complicated by the fact that people are able to represent things that are not present at the moment in the environment. That is, not only can I clearly see my dog in front of me when she is in the room, I can also imagine what my dog looks like when I am at work and she is at home. In this case, I may have some representations in my head that are grounded in others, but at some point, there are states of my cognitive system that are not lawfully related to any existing state of the world at that moment. For that matter, I can believe in all sorts of things like ghosts, unicorns, or the Tooth Fairy that do not exist and never have. Thus, there must be other sources of meaning in mental representations.

A proposal for dealing with the fact that not every concept can be defined solely in terms of a lawful representing relationship to another representation comes from philosophical work on conceptual role semantics (Fodor, 1981; Stich & Warfield, 1994). On this view, a mental representation gets its meaning as a result of the role that it plays within some broader representational system. This proposal acknowledges that the connections among representations may be crucial for their meaning. When I discuss semantic networks in the section on structured representations, we will see how the connections among representational elements influence meaning.

Obviously, not every mental representation in a cognitive system can derive its meaning from its connection to other representational elements (Searle, 1980). As an analogy, imagine that you had an English dictionary, but you didn't actually speak English. You could look up a word in the dictionary, and it would provide you the definition using other words. You could look up those words as well, but that would just give you additional definitions that use other words. Without having the sense of how some of the words relate to things that are not part of language (like knowing that *dog* refers to a certain class of four-legged creatures, or that *above* is a certain kind of relationship in the world), you would not really understand English. Likewise, at least some mental representations need to be grounded.

Types of Representations

There have been many different proposals for mental representations. In this section, I will catalog three key types of representations: mental spaces, featural representations, and structured representations. I discuss each of these representations in a separate section, but before that I want to discuss some general ways that proposals for representations differ from each other (see also Markman & Dietrich, 2000).

First, proposals for representations differ in the presence of discrete symbols. Some representations use continuous spaces. For example, an analog clock represents time using a circle. Every point on that circle has some meaning, though that meaning depends on whether the second hand, minute hand, or hour hand is pointing to that location. In contrast, a digital clock uses symbols to represent time. I will have more to say about symbols when discussing feature representations.

Second, representations differ in whether they include specific connections among the representational elements. Some representations (like the spatial and feature representations I discuss) involve collections of independent representational elements. In contrast, the semantic networks and structured representations discussed later specify relationships among the representational elements.

These two dimensions of difference are generally correlated with the type of representation. In addition, there are dimensions of difference that cross-cut the general proposals for types of representations. For example, representations differ in how enduring the states of the representation are intended to be. Some representations—particularly those that are involved in capturing basic visual information and states of the motor system—are meant to capture moment-by-moment changes in the environment. In contrast, others capture more enduring states.

A final dimension of difference is whether the representation is analog or symbolic. An analog representation is one in which the representing world has the same structure as the represented world. For example, I mentioned that watches represent time using a circle. These watches are analog representations, because both space and time are continuous. Increasing rotational distance in space is used to represent increasing differences in time up to the limit of the time span of the circle.

One advantage of an analog representation is that there are many aspects of the structure of the representing world that can be used to represent

relationships in the represented world without having to define them explicitly. Let us return to the example of using angular distance to represent time, when distances are measured on an absolute scale. If one interval is represented by a 90-degree movement and a second is represented by a 180-degree movement, the first interval moves half the distance of the second. Without having to create any additional relations, we can also assume that the first time interval is half the length of the second.

It is rare to find a representing world that has structure that is similar enough to one in a represented world to warrant creating an analog representation. Thus, most representations are *symbols*: They have an arbitrary relationship between the representing world and the represented world. With symbolic representations, the representing world does not have any structure, and so all of the relationships within the representing world have to be defined explicitly. For example, if we used numbers to represent time, then the representing world of symbols has to define all of the relationships among the symbols for the different numbers to capture relevant relations among numbers in the represented world. For example, the ability to determine that one interval is half the length of another has to be defined into the system, rather than being a part of the structure of the representing world itself.

Finally, it is important to note that an important reason why there are so many different proposals for kinds of knowledge representations is that any choice of a representation makes some processes easy to perform and makes other things difficult to do (see Doumas & Hummel, Chapter 5). There is good reason to believe that the cognitive system uses many different kinds of representations in order to provide systems that are optimized for particular tasks that must be carried out (Dale, Dietrich, & Chemero, 2009; Dove, 2009). Thus, when evaluating proposals about representations, it is probably best to think about what kinds of representations are best suited to a particular process rather than trying to find a way to account for all of cognition with a particular narrow set of representational assumptions. I return to this point at the end of the chapter.

Spatial Representations

DEFINING SPACES

The first type of representation on our tour uses space as the representing world (Gärdenfors, 2000). It might seem strange to think about a mental

representation involving space. We clearly use physical spaces to help us represent things all the time. For example, a map creates a two-dimensional layout that we then look at to get information about the spatial relationships in the world. And I have already discussed analog clocks in which angular distance in space is used to represent time.

Space in the outside world has three dimensions. That means that you can put at most three independent (or *orthogonal*) lines into space. Once you have those three lines set up in your space, you can create an address for every object in the space using the distance along each of those three dimensions. Mathematically, though, a space can have any number of dimensions. In these high-dimensional spaces, points in space have a coordinate for each dimension that determines its location, just as in the familiar three-dimensional space. Objects can then be represented by points or perhaps regions in space.

Once you have located points in space, it is straightforward to measure the distance between them using the formula

$$d(x, y) = \left[\sum_{i=1}^N (x_i - y_i)^r \right]^{1/r} \quad (1)$$

where $d(x,y)$ is the distance between points x and y (each with coordinates for each dimension i , x_i and y_i), N is the number of dimensions, and r is the distance metric, sometimes called the Minkowski metric. When measuring distance in a space, the familiar Euclidean straight-line distance sets $r = 2$. When $r = 1$, then distance is measured using a “city

block” metric in which the distance corresponds to the summed distances along the axes of the space.

It is easy to calculate distance within a space, and so the distance between points becomes an important element in spatial representations. For example, Rips, Shoben, and Smith (1973) tried to map people’s conceptual spaces for simple concepts like birds and animals (see Rips et al., Chapter 11). An example of these spaces is shown in Figure 4.2. The idea here is that pairs of similar birds (like robin and sparrow) are near in space, while pairs of dissimilar birds (like robin and goose) are far away in space. A cognitive process that uses a spatial representation can calculate the distance between concepts when it needs information about the similarity of the items. For example, Rips et al. found that the amount of time that it took to verify sentences like “A robin is a bird” was inversely related to the distance between the points representing the concepts in the space. Consistent with this model, people are faster to verify that the sentence “A robin is a bird” is true than to verify that the sentence “A duck is a bird” is true.

One reason why mental space models of mental representation are appealing is that there are mathematical methods for generating spaces from data about the closeness of items in that space. One technique, called *multidimensional scaling* (MDS), is the one that Rips et al. used in their study (Shepard, 1962; Torgerson, 1965). Multidimensional scaling places points in a space based on information about the distances among those points. For example, if you were to give an MDS algorithm the distances among

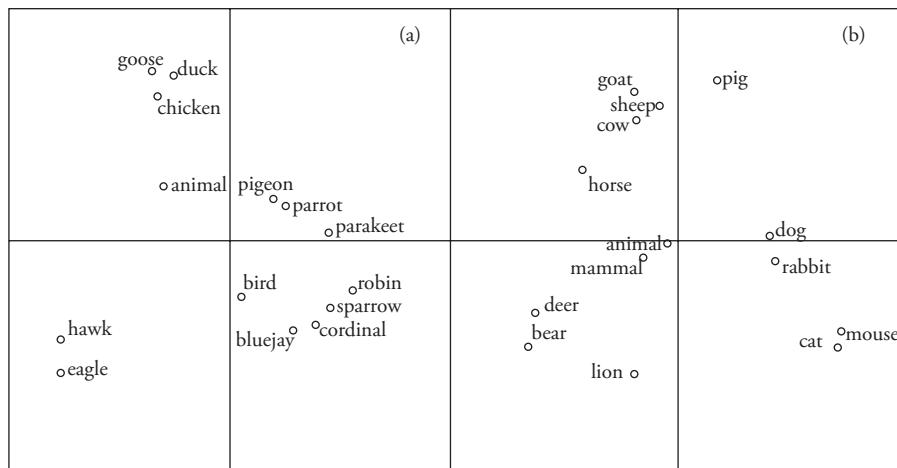

Fig. 4.2 A sample semantic space of a set of concepts representing various birds (taken from Rips, Shoben, & Smith, 1973).

15 European cities, you would get back a map of the locations of those cities in two dimensions.

This same technique can be used for mental distances. For example, Rips et al. had people rate the similarities among the pairs of concepts in Figure 4.2. Similarity ratings can be interpreted as a measure of mental closeness (see Goldstone & Son, Chapter 10). These similarity ratings can be fed into an MDS algorithm. The space that results from this algorithm is the one that best approximates the mental distances it was given. One difficulty with creating spaces like this is that they require a lot of effort from research participants. If there are X items in the space, then there are

$$X(X - 1)/2 \quad (2)$$

distances among those points. That requires a lot of ratings from people, and so in practice it becomes difficult to generate spaces with more than 15 or 20 items in them.

Other techniques have been developed that create very high-dimensional spaces among larger sets of items. A powerful set of techniques uses the co-occurrence relationships among words to develop high-dimensional semantic spaces from corpora of text (Burgess & Lund, 2000; Landauer & Dumais, 1997). These techniques take advantage of the fact that words with similar meanings often appear along with the same kinds of words in sentences. For example, in the sentence “The X jumped up the stairs” the words that can play the role of X are all generally animate beings.

These techniques can process millions of words from on-line databases of sentences from newspapers, magazines, blog entries, and Web sites. As a result, these techniques can create spaces with hundreds or thousands of dimensions that represent the relationships among thousands of words. The interested reader is invited to explore the papers cited in the previous paragraph for details about how these systems operate. For the present purposes, what is important is that after the space is generated, the high-dimensional distances among these concepts in the space are used to represent differences in meanings among the concepts.

STRENGTHS AND WEAKNESSES OF SPATIAL MODELS

There are two key strengths of spatial models of representation. On the practical side, the availability of techniques like MDS and methods for generating

high-dimensional semantic spaces from text provide modelers with a way of creating representations from the data obtained from subjects in studies. For the other types of representations described in this chapter, it is often more difficult to determine the information that ought to end up in the representations generated as parts of explanations of particular cognitive processes.

A second strength of spatial representations is that the mental operations that can be performed on a space are typically quite efficient. For example, there are very simple algorithms for calculating distance among points in a space, and so the processes that operate on spatial representations are quite easy to carry out. Thus, spatial representations are often used when comparisons have to be made among a large number of items.

Despite these strengths, there are also limitations of spatial representations. The core limitation is that the calculation of distance among points provides a measure of the degree of proximity among points. It is also possible to generate vectors that measure a distance and direction between points. However, the underlying dimensions of a semantic space have no obvious meaning. A modeler looking at the representation may ascribe some meaning to that distance and direction, but the system itself has access only to the vector or distance.

People are also able to focus on specific commonalities and differences among pairs of items, and these properties influence people's assessments of similarity. For example, Tversky and his colleagues (Tversky, 1977; Tversky & Gati, 1982) explored the commonalities and differences that affect judgments of similarity. As an example of the kinds of items he used, I'll paraphrase a discussion by William James (1892/1985). When people compare the moon and a ball, they find a moderate degree of similarity, because both are round. When people compare the moon and a lamp, they find a moderate degree of similarity, because both are bright. However, when people compare a ball and a lamp, they find no similarity at all, because they don't share any properties. As Tversky (1977) pointed out, this pattern of similarities is incompatible with a space, because if two pairs of items in a real space are fairly close to each other, then the third pair of points must also be reasonably close. In the mathematical definition of a space, this aspect is called the *triangle inequality*. The observed pattern of similarity judgments by people reflects that they give a lot of weight to specific commonalities among pairs, though different

pairs may focus on different commonalities. Thus, human similarity judgments frequently violate the triangle inequality.

One response to patterns of data that seem inconsistent with spatial representations is to add mechanisms that allow spaces or distances to be modified in response to context (Krumhansl, 1978; Nosofsky, 1986). However, these mechanisms tend to complicate the determination of distance. Because the simplicity of the computations in a space was one of the key strengths of spatial representations, many other theories have opted to use representations with explicit symbols in them to capture cognitive processes that involve a specific focus on particular representation elements. We turn to representations that consist of specific features in the next section.

Feature Representations

The reason why it is difficult to focus on particular commonalities and differences or particular properties in a spatial representation is that spaces are continuous. The core aspect of a feature representation is that it has discrete elements that make up the representation. These discrete elements allow processes to fix reference to particular items within the representation (Dietrich & Markman, 2003).

Typically, feature representations assume that some mental concept is represented by a collection or set of features, each of which corresponds to some property of the items. For example, early models of speech perception assumed that a set of features could be used to distinguish among the various phonemes that make up the sounds of a language (Jakobsen, Fant, & Halle, 1963). On this view, the sound /b/ as in *bog* and the sound /d/ as in *dog* differ by the presence of a feature that marks where in the mouth the speech sound is produced. Linguists identified the particular features that distinguished phonemes by finding pairs of speech sounds that were as similar as possible except for particular features that led them to be distinguished. To return to the example of /b/ and /d/, these phonemes are similar in other properties like engaging the vocal cords (which would distinguish /b/ from /p/).

When this proposal for phoneme representation was being evaluated, a key aspect of the research program for understanding speech perception involved finding some mapping between the features of speech sounds and the speech signal itself (Blumstein & Stevens, 1981). On this view, the speech perception system would identify the features in a particular phoneme from aspects of the

audio signal. A particular phoneme would be recognized when the collection of features associated with it was understood. While this process is straightforward, a weakness of this particular approach to speech perception was that it has proven difficult to isolate particular aspects of the speech signal that reliably indicate particular phonetic features.

Featural models have also been used prominently to study similarity (see Goldstone & Son, Chapter 10). In particular, Tversky's (1977) contrast model assumed that objects could be represented as sets of features. Comparing a pair of representations then required elementary set operations. The intersection of the feature sets of a pair were the commonalities of that pair, while the set differences were the differences of the pair. Tversky proposed that people's judgments of similarity should increase with the size of the set of common features and decrease with the size of the sets of distinctive features. He provided support for this model by having people describe various objects by listing their features. He found that people's judgments of the similarity of various pairs was positively related to the number of features that the lists had in common and negatively related to the number of features that were unique to one of the lists.

Some proposals for feature representations augment the features with other information. For example, it is common to include information about the importance of particular features to a category in a representation. In a classic paper, Smith, Shoben, and Rips (1974) argued that people distinguish between core feature of items and characteristic properties. For example, having feathers is a core characteristic of birds, while singing is typical of birds but is not central for something to be a bird.

They argued that when people classify an object, they look first at all of the properties of the object. If they are uncertain of the category that something belongs to based on its overall similarity, then they focus just on the characteristic properties. That is why people have difficulty classifying objects like dolphins. Dolphins have many features that are characteristic of fish, but they also have features of mammals. Only when people focus on the core characteristics of fish and mammals is it possible to classify a dolphin correctly as a mammal.

Some featural models also include information about the degree of belief in the feature. That is, there are some properties that someone may be certain are true of an object but others for which it is less clear. Some models have proposed that there are

certainty factors that allow a system to keep track of the degree of belief in a particular property (see, e.g., Lenat & Guha, 1990; Shafer, 1996).

While people clearly need information about the degree of belief in a property or the likelihood that the information is true, it is not clear that some kind of marking on features is the best way to handle this kind of information. Often, we want to know more than just how strongly we believe something or how central it is to a category. We want to know *why* a particular fact is central or what it is that causes us to believe it. To support this kind of reasoning, it is useful to have representations that contain explicit connections among the representational elements. The following section discusses types of representations that capture relationships among representational elements.

Structured Representations

Feature representations do a good job of representing the properties of items but a poor job at representing relationships. Consider a variety of relationships that may exist in the world. Poodles are *a kind of* dog. John is *taller than* Mary. Sally *outperformed* Jack. These kinds of relationships are more than just properties of some item. The way that items are connected (or *bound*) to the relationship also matters. Saying that poodles are a kind of dog is true, but saying that dogs are a type of poodle is not.

To capture these relational bindings, structured representations contain mechanisms for creating representations that take arguments that specify the scope of the representation. For example, we can use the notation *kind-of*(?x,?y) to denote that some item?x is a kind of?y. I precede the letter x with a question mark here to denote that it is a variable that can be filled in with some value. Thus, to specify a particular relation, we fill in values for the variables.

Representations of this type are often called *predicates*. Once the values are specified, the representation states a *proposition*, and in a logical system all propositions can be evaluated as true or false, though most proposals for using predicate representations in psychological models do not evaluate the logical form of these predicate structures.

The example *kind-of* (?x,?y) is a *binary* predicate, because it takes two arguments. A predicate that takes one argument, like *red* (?x), is often called an *attribute*, because it is typically used to describe the properties or attributes of objects. This type of

predicate is particularly useful in situations in which there are multiple items in a scene, and it is necessary to bound the scope of the representation.

For example, consider the simple scenes at the top of Figure 4.3. One depicts a circle on top of a square and the other shows a square on top of a circle. In the left-hand scene, one figure is shaded and another is striped. If we just had a collection of features (as shown in the middle of this figure), then it wouldn't be clear which object was striped and which one was shaded. Indeed, the same collection of features could be used to describe both the left- and right-hand scenes, even though they are clearly different.

Because attributes take arguments, though, it is possible to determine the scope of each representational element. The bottom section of Figure 4.3 shows a structured representation of the same pair of scenes drawn as a graph. The relation above (?x,?y) is presented as an oval with lines connecting the relation to its arguments. Likewise, the rounded rectangles are attributes that are connected to the objects they describe. Using this type of representation, it is possible to specify that it is the circle that is striped in the left-hand scene.

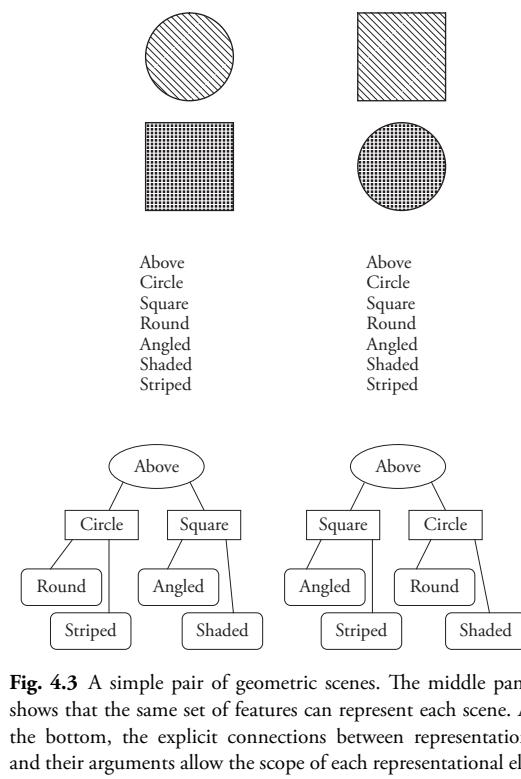

Fig. 4.3 A simple pair of geometric scenes. The middle panel shows that the same set of features can represent each scene. At the bottom, the explicit connections between representations and their arguments allow the scope of each representational element to be defined.

The increase in expressive power that structured representations provide requires that there be processes that are sensitive to this structure. These structure-sensitive processes often require more computational effort than the processes that were specified for spatial and featural representations. In the next two sections, I discuss two different approaches to structured representations that use different processing assumptions to access the connections among representational elements.

SEMANTIC NETWORKS

An early use of structured representations in psychology was semantic networks (Collins & Loftus, 1975; Collins & Quillian, 1972; Quillian, 1968). In a semantic network, objects are represented by nodes in the network. These nodes are connected by links that represent the relations among concepts. The links are directed so that the first argument of a relation points to the second. For example, Figure 4.4 shows a part of a simple semantic network with nodes relating to the concepts vampire and hematologist. This network has a variety of relations in it such as *drinks* (*vampire*, *Blood*) and *studies* (*hematologist*, *Fluid*).

One use of semantic networks was to make simple inferences (Collins & Quillian, 1972). One way to make inferences in a semantic network is to use *marker passing*. In this process, you seek a relationship between a pair of concepts by placing a marker at each of the concepts. The markers are labeled with the concept where they originated. At each step of the process, markers are placed on each node that can be reached from a link that points outward from a node that has a marker on it. When markers

from each concept are placed at the same node, then the path back to the original nodes is traced back, and that specifies the relationship between the concepts.

For example, in the network shown in Figure 4.4, if I wanted to know the relationship between a vampire and a hematologist, I would start by placing markers at the vampire and hematologist nodes. At the first time step, a marker from *vampire* would be placed on the *monster*, *cape*, and *Blood* nodes. A marker from *hematologist* would be placed at the *doctor*, *lab coat*, *water*, and *Blood* nodes. The presence of markers from each of the starting concepts at the *Blood* node would lead to the conclusion that vampires drink blood, while hematologists study blood. The amount of time that it takes to make the inference depends on the number of time steps it takes to find an intersection between paths emerging from each concept.

A second process often used in semantic networks is *spreading activation* (e.g., Anderson, 1983; Collins & Loftus, 1975). Spreading activation theories assume that there are semantic networks consisting of nodes and links, though they do not require the links to be directed. Unlike the marker passing process, activation can spread in both directions along a link.

Each node has some level of activation that determines how accessible that concept is in memory. When a concept appears in the world or in a discourse or in a sentence, then the node for that concept temporarily gets a boost in its activation. That activation then spreads across the links and activates neighboring concepts. Models of this sort have been used to explain priming effects in which processing

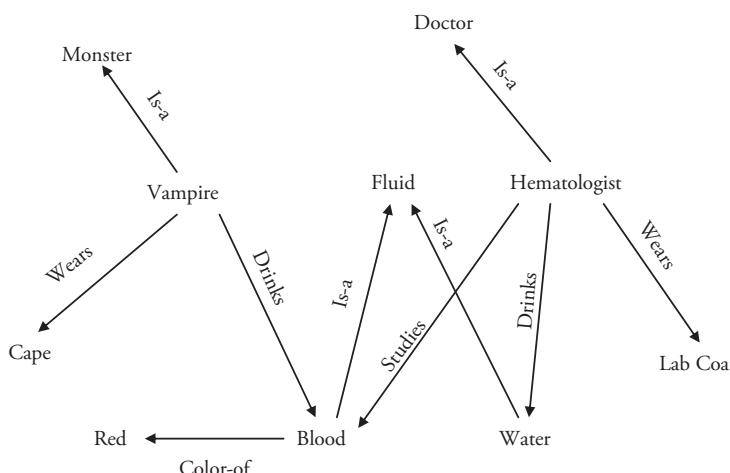

Fig. 4.4 A simple semantic network showing concepts relating to vampires and hematologists (drawn after Markman, 1999).

of one concept speeds processing of related concepts. For example, a classic finding in the priming literature is that seeing a word (e.g., *doctor*) speeds the identification of semantically related words like *nurse* (Meyer & Schvaneveldt, 1971).

Spreading activation theories have been augmented with a number of mechanisms to help them account for more subtle experimental results. For example, links in a network may vary in their strength, which is consistent with the idea that concepts differ in their strength of association. One interesting addition to spreading activation models is the concept of *fan* (Anderson, 1983). The fan of a node in a network is the number of links that leave it, which differs for each node. In some models, the total amount of activation that is spread from one node to others is divided by the number of links, so that nodes with a low fan provide more activation to neighboring nodes than do nodes with high fan. This mechanism captures the regularity that when a node has low fan, then the presence of one concept strongly predicts the presence of the small number of other concepts to which it is connected. In contrast, when a node has a high fan, the presence of one concept doesn't predict the presence of another concept all that strongly.

Semantic network models have been used primarily as models of the relationships among concepts in memory. These processing mechanisms are also shared with interactive activation models that have been used to account for a variety of psychological phenomena (see, e.g., McClelland & Rumelhart, 1981; Read & Marcus-Newhall, 1993; Thagard, 1989, 2000). There is much more that can be done with the relational structure in representations than just passing markers or activation among nodes. I discuss some additional aspects of structured representations in the next section.

STRUCTURED RELATIONAL REPRESENTATIONS

A variety of aspects of psychological functioning seem to rely on people's ability to represent and reason with relations. For example, language use seems to depend crucially on the ability to use relations. Verbs bind together the actors and objects that specify actions (e.g., Gentner, 1975, 1978; Talmy, 1975). Prepositions allow people to talk about spatial relationships (e.g., Landau & Jackendoff, 1993; Regier, 1996; Talmy, 1983). For both verbs and prepositions, the objects that they relate can be specified in sentences that essentially fill in the arguments to these relations.

Related to our ability to talk about complex relations is the ability to reason about the causal structure of the world. Obviously, many verbs focus on how events in the world are caused and prevented (Wolff, 2007; Wolff & Song, 2003). These verbs reflect that people are adept at understanding why events occur. For example, Schank and colleagues (Schank, 1982; Schank & Abelson, 1977) proposed that people form scripts and schemas to represent complex events like going to a restaurant or going to a doctor's office. These knowledge structures contain relationships among the components of an event that suggest the order that things typically happen. They also have causal relations among the events that explain why they are performed (see Buehner & Cheng, Chapter 12).

These causal relations are particularly important for helping people to reason about situations that do not go as expected. For example, when visiting a restaurant, the waiter typically brings you a menu. Thus, you expect to get a menu when you are seated. You also know that you get a menu, because it is necessary to know what the restaurant serves so that you can order food. If you do not get a menu, then you might start to look around for other sources of information about what the restaurant serves like a board posted on a wall.

This range of relations creates an additional burden, because processes have to be developed to make use of this structure. To provide an example of both the great power of these processes as well as their computational burden, I describe work on analogical reasoning. The study of analogical reasoning is a great cognitive science success story, because there is widespread agreement on the general principles underlying analogy, even if there is disagreement about some of the fine details of how analogy is accomplished (Falkenhainer, Forbus, & Gentner, 1989; Gentner, 1983; Holyoak & Thagard, 1989; Hummel & Holyoak, 2003; Keane, 1990; see Holyoak, Chapter 13).

Analogies involve people's ability to find similarities between domains that are not similar on the surface. To find these nonliteral similarities, people seek commonalities in the relations in two domains. For example, a classic example of an analogy is the comparison that the atom is like the solar system. This analogy came out of the Rutherford Model of the atom, which was prominent in the early 20th century. The domain that people know most about is typically called the *base of source* (in this case, the solar system¹), while the domain that is lessunderstood is

called the *target* (in this case, the atom). Atoms are not like solar systems because of the way they look. Atoms are small, and solar systems are large. The nucleus of an atom is not hot like the sun. There are no electrons that support life like planets do. What is similar between these domains is that the electrons of the atom revolve around the nucleus in the same way that the planets revolve around the sun.

Theories of analogy assume that people represent information with structured relational representations. So we could think of the solar system as being represented with some simple relations like

revolve-around (electron, nucleus)
and
greater (mass (nucleus), mass (electron))

which reflect that the electron revolves around the nucleus and that the mass of the nucleus is greater than the mass of the electron. Then, the solar system could be represented by a more elaborate relational system like

cause (greater (mass (sun), mass (planet)),
revolve-around (planet, sun))

These representations might also have a lot more descriptive information about the attributes of the nucleus, electrons, sun, and planets.

The process of analogical mapping seeks parallel relational structures. It does so by first matching up relations that are similar. So the revolve-around ($?x,?y$) relation in the representation of the solar system would be matched to the revolve-around ($?x,?y$) relation in the representation of the atom. Once relations are matched, the arguments of those relations are also placed in correspondence. This constraint on analogy is called *parallel connectivity* (Gentner, 1983), and it is incorporated into many models of analogical reasoning (Falkenhainer et al., 1989; Holyoak & Thagard, 1989; Hummel & Holyoak, 1997; Keane, 1990). So the electron in the atom and the planet in the solar system are matched, because both revolve around something (i.e., they are the first argument in the matched revolve-around ($?x,?y$) relation). Similarly, the nucleus of the atom and the sun in the solar system are matched because both are being revolved around. As many matching relations between domains are found as possible, provided that each object in one domain is matched to at most one object in the other domain (Gentner's, 1983, *one-to-one mapping* constraint).

Analogical mapping processes also allow one domain to be extended based on the comparison

to another. In this process of analogical inference, relations from the base that are consistent with the correspondence between the base and target can be carried over to the target. For example, in the simple representations of the atom and the solar system shown earlier, the match between the domains licenses the inference that the electron revolves around the nucleus because the nucleus is more massive than the electron. This example also demonstrates that inferences drawn from analogies may be plausible, but they need not be true.

One final point to make about analogy is that the structure in representations helps to define which information in a comparison is salient. In particular, some correspondences between domains may match up a series of independent relations that happen to be similar across domains. However, some relations take other relations as arguments. For example, the cause ($?x,?y$) relation in the solar system representation takes two other relations as arguments. Analogies can be based on similarities among entire systems of relations, some of which have embedded relations as arguments. Gentner's (1983) *systematicity* principle suggests that mappings that capture similarities in relational systems are considered to be particularly good analogies (Clement & Gentner, 1991).

This discussion of analogy raises two important general points about structured representations. First, the structure mapping process is complex. Compared to the comparison processes for spatial and featural representations, there are more constraints that have to be specified to describe the structure mapping process. The representation provides few constraints on the nature of the process, and so significant effort has to be put into setting up appropriate processes that act on the representation.

Second, structural alignment is much more computationally intensive than either distance calculations or feature comparison (see Falkenhainer et al., 1989 for an analysis of the computational complexity of structure mapping). Generally speaking, structure-sensitive processes are more computationally intensive than those that can operate on spatial and featural representations. Thus, they are most appropriate for models of processes for which significant time and processing resources are available.

This concludes our brief tour of types of representations. It is not possible to do justice to all of these types of representations in a chapter of this length. I have discussed all of these representations in more detail elsewhere (Markman, 1999, 2002).

Broader Issues About Representation

In the rest of this chapter, I focus on some broader issues and open questions in the area of knowledge representation in the field. I start with an exploration of the way that knowledge is treated in cognitive psychology and how that differs from the treatment of knowledge in other areas of psychology. Then, I discuss some approaches to representation that have focused on the importance of the physical body and of the context when thinking about mental representation. Finally, I discuss a stream of research in the field that has argued that the concept of representation has outlived its usefulness.

Content and Structure

One thing you may have noticed about this entire discussion about knowledge representation is that it has focused on the structure of the knowledge people have without regard to the content of what they know. Spatial representations, featural representations, and structured representations differ in their assumptions about how knowledge is organized. Models of this type have been used in theories that range from vision to memory to reasoning.

It is not logically necessary that the discussion of knowledge representation be organized around the structure of knowledge. Developmental psychology, for example, focuses extensively on the content of children's knowledge (e.g., Carey, 2010). It is quite common to see discussions within developmental psychology that focus on what information children possess and the ages at which they can use that knowledge to solve particular kinds of problems.

Cognitive psychology, however, emerged out of the cognitive revolution. This view of mind is dominated by computation. A computer does not care what it is reasoning about. Right now, my computer is executing the commands to power my word processor so that I can write this sentence. But the computer does not really care what this chapter is about. As long as the data structures within the program function seamlessly with the program, the word processor will do its job. Similarly, cognitive theories have focused on the format of mental data structures with little regard for the content of those structures.

In many areas, though, research in cognitive psychology will need to pay careful attention to content. Because most studies in the field have focused on college undergraduates, research has typically explored people with no particular expertise in the domain in which they are being studied. There is good reason to believe, though, that experts reason

differently from novices in a variety of domains, because of what they know (see e.g., Klein, 2000; Bassok & Novick, Chapter 21). Thus, future progress on core aspects of thinking will require attention both to the content of people's knowledge as well as its structure. There are some exceptions to this generalization, such as the work on pragmatic reasoning schemas (Cheng & Holyoak, 1985) and research that has been done on expertise, but studies incorporating the content of what people know are much more the exception than the rule in the field.

Embodied and Situated Cognition

The computational view of mind that dominated cognitive psychology had another key consequence. There has been a pervasive (if implicit) assumption that the sensory systems provide information to the mind and the mind in turn suggests actions that can be carried out by the motor system. More recently, this assumption has been challenged.

One approach challenges the assumption that cognition is somehow separate from perception and motor control (Barsalou, 1999; Glenberg, 1997; Wilson, 2002). This view, which is often called *embodied cognition*, suggests that understanding cognitive processing requires reorienting the view of mind from the assumption that the mind exists to process information to the assumption that cognition functions to guide action.

An early version of this view came from Gibson's (1986) work on vision. A dominant view of vision in the 1970s was that the goal of vision was to furnish the cognitive system with a veridical representation of the three-dimensional world (Marr, 1982). Gibson argued that the primary goal of vision was to support the goals of an organism. Consequently, vision should be biased toward information that suggests to an animal how it should act. He argued that people tend to see objects not in terms of their raw visual properties, but rather in terms of their *affordances*, that is, with respect to the actions that can be performed on an object. On his view, when seeing a chair, we immediately calculate whether we think we could sit on it, stand on it, or pick it up.

More recent approaches to embodied cognition have provided an important correction to the field, by emphasizing the role of perception and action on cognition. This work demonstrates influences of perception on higher level thinking and also the influence of thinking on perception. For example, Wu and Barsalou (2009) gave people different perceptual contexts and showed how the context

influenced their beliefs about the properties of objects. For example, when people list properties of a lawn, they typically talk about the grass and the greenness of the lawn. When they talk about a “rolled-up lawn,” though, they then talk about the roots, even though the grass in a lawn must also have roots. Findings such as this one suggest that people are able to generate simulations of what something would look like and then to use that information in conceptual tasks.

Conceptual processing may also influence perception. A number of studies, for example, have demonstrated that people’s perception of the slope of a hill is influenced by the perception of how hard it would be to climb up the hill. For example, people wearing a heavy backpack see a hill as steeper than those who are not wearing a heavy backpack (Proffitt, Creem, & Zosh, 2001). However, having a friend with you when wearing a heavy backpack makes the hill look less steep than it would look if you were alone. So your beliefs about the amount of social support you have can affect general perception.

The implication of this work on embodied cognition is that there is no clean separation between the mental representations involved in perception, cognition, and action. Instead, the cognitive system makes use of a variety of types of information. Even tasks that would seem on the surface to involve abstract reasoning often use perceptual and motor representations as well (see Goldin-Meadow & Cook, Chapter 32, for a review of the role of gesture in thought).

A related area of work is called *situated cognition* (Hutchins, 1995; Suchman, 1987). Situated cognition takes as its starting point the recognition that human thinking occurs in particular contexts. The external world in that context also plays a role in people’s thought processes. Humans use a variety of tools to help structure difficult cognitive tasks. For example, because human memory is fallible, we make lists to remind us of information we might forget otherwise. Hutchins (1995) examined the way that navigators aboard large navy ships navigate through tight harbors. He found that—while it is possible to think about the abstract process of navigation—the specific way that navigation teams work is structured by the variety of tools that they have to perform the task.

The embodied and situated cognition approaches have broadened the study of cognition by making clear that a variety of representations both inside

and outside the head influence thinking. The initial work in this area focused on demonstrations of the role of perception, action, and tools on cognitive processes. Ongoing research now focuses on how these types of representations coordinate with the kinds of representations more traditionally studied within cognitive psychology.

Antirepresentationalism and a Call for Pluralism

Despite the centrality of the concept of representation within cognitive psychology, some theorists have argued that the computational approach to mind has outlived its usefulness and thus that cognitive psychology should dispense with the concept of representation (Port & Van Gelder, 1995; Spivey, 2007; Thelen & Smith, 1994). There is an important insight underlying this claim. Much of the research, particularly in the period from the 1960s through the mid-1990s assumed that people did quite a bit of thinking before they performed any actions. For example, a classic model of how intelligent systems could plan actions assumed that people were able to generate complex plans that were then passed to a second system that carried out the plan (Fikes & Nilsson, 1971).

It is clear, however, that people coordinate their actions with the world. While it is often useful to have a general plan for how to carry out a task, that plan needs to be adapted to suit the constraints of the particular environment in which it is carried out. For example, it is fine to set a route to drive from your house to a friend’s house, but if a road is closed for construction, then the route will have to be changed along the way to take into account the actual state of the world.

Research on robotics showed that quite a bit of sophisticated behavior could be generated by having robots that were sensitive primarily to what is going on in the environment at that moment (Beer, 1995; Brooks, 1991; Pfeifer & Scheier, 1999). These systems had representations that would satisfy the minimal criteria for a representation that I described earlier, but they did not keep track of any enduring states of the world that would support complex planning. Nonetheless, these robots could achieve simple goals like traversing a hallway while still avoiding obstacles and adapting to changing circumstances. The initial success of these systems suggested that complex representations might play a minimal role in actual cognitive systems.

As with the work on embodied cognition and situated cognition, these antirepresentationalist

approaches have added valuable new insights to the study of thought. It is clear that paying attention to the way that behavior is carried out on-line is important for helping to constrain what a cognitive system is trying to accomplish. A model that assumes a complete plan can be generated and then passed off to modules that will execute that plan is simply not reasonable as a model of cognition.

At the same time, it is also clear that the hard work of generating theories in cognitive psychology will come from understanding how the variety of approaches to representation are coordinated in systems that carry out a number of complex behaviors. Important work remains to be done on the interfaces among representational systems.

For example, Kuipers (2000) has focused on the question of how to get intelligent agents to navigate through complex spatial environments. His system has a level of representation that responds dynamically to changing environmental conditions. It also has representations that generate general plans for how to get from one location in a large-scale environment to another. In between these levels of representation, the system has representations that generate specific programs for an agent's motor system to suggest how it should go about travelling from one location to the next. This system has been implemented successfully in robots that navigate through environments.

The success of systems such as the one I just described suggests that ultimately cognitive theories need to embrace representational pluralism (Dale et al., 2009; Dove, 2009; Markman & Dietrich, 2000). Each of the systems of representation discussed in this chapter has strengths and weaknesses. Some representations—like spatial representations—are good for carrying information about moment-by-moment states of the world. These representations support simple processes that can act quickly in a changing environment. Other representations excel at storing information for the long term and for creating abstractions across many instances. For example, structured representations support the generation of relational systems that can store the essence of the similarities of domains that seem distant on the surface.

Each form of representation seems particularly well suited to specific kinds of cognitive tasks. There is a tendency when generating theories in science to want to focus on a single approach to explanation. Parsimony is often a desirable characteristic of theories, and so a theory that posits only one form of representation would seem better than a theory

that posits multiple forms of representation. But the mind is likely to make use of a variety of forms of representation. We have a large number of cognitive mechanisms that have evolved over millions of years to accommodate a number of disparate cognitive abilities. There is no reason to think that the representations and processes that are best for understanding low-level vision or basic motor control are also going to be appropriate for handling the kinds of deeply embedded syntactic structures that people encounter when reading academic prose. Thus, rather than trying to create theories that focus on only a single kind of representation, cognitive scientists need to become conversant with many different approaches to representation. The key to developing a successful cognitive model will generally involve finding a set of representations and processes that support robust intelligent behavior.

Future Directions

How can we incorporate more research on the content of people's representations into the study of knowledge representation?

How do representations generated from states of the physical body and aspects of the environment interact with representations of more abstract states?

How can we incorporate and coordinate multiple representations within a single model?

Note

1. Some models of analogy refer to the base as the source (e.g., Holyoak & Koh, 1987).

Computational Models of Higher Cognition

Leonidas A. A. Doumas and John E. Hummel

Abstract

Process models of higher cognition come in three basic varieties: traditional symbolic models, traditional connectionist models, and symbolic-connectionist models. This chapter reviews the basic representational and processing assumptions embodied in each of these approaches and considers the strengths and limitations of each.

Key Words: computational models, process models, symbolic models, connectionist models

Models in cognitive science span all three of Marr's (1982) levels (see Holyoak & Morrison, Chapter 1). Normative systems (see Chater & Oaksford, Chapter 2), including the Bayesian framework (see Griffiths et al., Chapter 3), address the level of computational theory; neural models (see Morrison & Knowlton, Chapter 6) are specified at the implementation level; and information-processing models, or process models (perhaps the most common type of model in cognitive science), are specified at the level of representation and algorithm.

Process models of higher cognition come in three basic varieties: traditional symbolic models, traditional connectionist models, and symbolic-connectionist models. This chapter reviews the basic representational and processing assumptions embodied in each of these approaches and considers the strengths and limitations of each.

Symbolic Models

The earliest process models of human cognition were *symbolic* in the traditional sense of the term (e.g., Anderson, 1982; Newell & Simon, 1972), and traditional symbolic modeling continues to be important today (see Gentner & Forbus, 2011;

Taatgen & Anderson, 2008, for reviews). Although the details of specific symbolic models differ, at their core they share the underlying assumption that the mind is a symbol system that is best modeled using symbolic operations on symbolic data structures (see also Fodor & Pylyshyn, 1988).

Symbolic Representations

Any representational system consists minimally of a vocabulary of representational elements (e.g., symbols in a symbolic model or nodes in a neural or Bayesian network) and a set of rules for inferring new statements from existing statements (see Markman, Chapter 4). In order for a representational system to count as symbolic, it must also make it possible to combine its basic representational elements into complex structures capable of expressing an open-ended set of relations (Pierce, 1879, 1903; see also Deacon, 1997).

Traditional symbolic models use various representational formalisms, the most common being propositional notation (or labeled graphs). Propositional notation takes the general form *predicate* (*argument₁*, *argument₂*, ..., *argument_n*), where *predicate* specifies some property or relation, arguments 1...n are the arguments of that predicate,

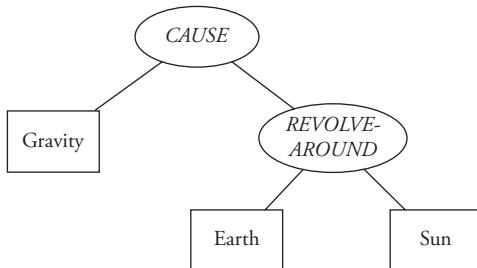

Fig. 5.1 A labeled-graph representation of the higher order relation, *cause*(gravity, *revolve-around*(earth, sun)). Ovals represent relations; rectangles, objects; lines, arcs.

and n is typically three or less. For example, *gave* (John, Mary, book) specifies that John gave Mary a book, and *heavy* (book) specifies that the book is heavy. Labeled graphs specify the same information as propositional notation (i.e., the two systems are isomorphic). In graphical form, nodes represent predicates and their arguments and arcs represent the bindings of arguments to roles of the predicate (see Fig. 5.1). Both formalisms are symbolic in the sense described earlier because they make it possible to form an open-ended (indeed, infinite, as both formalisms permit recursion) set of relational statements with a finite vocabulary of predicates and objects.

Processes

Symbolic representations such as propositions and labeled graphs provide a powerful representational platform that makes many kinds of processes convenient to perform. For example, Forbus, Gentner, and their colleagues (Falkenhainer, Forbus, & Gentner, 1989; Forbus, Gentner, & Law, 1995) have demonstrated that *graph matching*—a process of finding isomorphic substructures in pairs of (potentially very large) systems of labeled graphs—provides an excellent basis for simulating analogical reasoning (i.e., the process of reasoning about a novel *target* domain based on a more familiar *source* domain; see Holyoak, Chapter 13).

Similarly, John Anderson and his colleagues have used propositional notation in their various ACT models (e.g., Anderson, 2007; Anderson & Lebiere, 1998) to very successfully simulate aspects of memory, learning, and inference. The principles embodied in ACT have even been used to develop intelligent tutoring systems that model the learner during the learning process itself, in order to optimize instruction and learning (Anderson, Betts, Ferris, & Fincham, 2010).

In contrast to the graph matching algorithms that Gentner, Forbus, and colleagues have used to model analogical reasoning, the ACT models are based on *production systems*: systems of symbolic rules that operate on propositional knowledge representations to guide action and generate inferences (see Fig. 5.2). Like the graph-matching algorithms of Forbus, Gentner, and colleagues, production systems derive much of their computational power from the fact that they operate on symbolic knowledge structures. For example (see Fig. 5.2), one rule that might be part of a production system is *if* (*larger* (x, y) and *larger* (y, z)) *then* *larger* (x, z). Because this rule is symbolic, it can automatically be applied to any x , y , or z , regardless of their semantic content (e.g., it could infer that a battleship is larger than a submarine from the fact that a battleship is larger than a cruiser and a cruiser is larger than a submarine, and with equal facility make the same inference in the context of a Rottweiler, a housecat, and a mouse). As trivial as this ability might appear, it is a powerful one that cannot not be taken for granted (as we shall see in the context of connectionist models in the next section).

In our previous example, the production rule was completely abstract, defined over empty variables, x , y , and z . But production rules can also be defined over specific arguments (as in, *if* (*see* (me, neighbor's dog), *then run*(me)). Moreover, the rules need not be accurate. For example, a production system used to model the behavior of a young child might include a rule like *if* (*moves*(x), *then* (*has-legs*(x)), reflecting

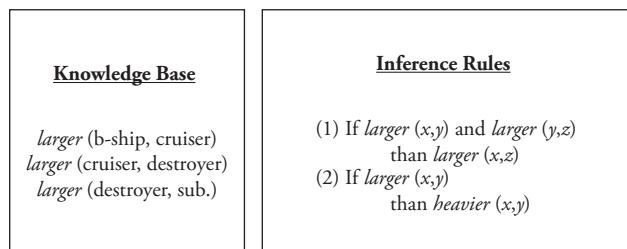

Fig. 5.2 An example of a simple production system.

the child's inaccurate belief that all moving things have legs (e.g., Sheya & Smith, 2006).

Strengths

Symbol systems have been used to successfully model a wide range of cognitive phenomena. The successes of the symbolic approach derive from the flexibility of symbolic representations, in particular the fact that predicates are free to vary in their arguments. As a result, anything that is learned about a predicate (e.g., in the form of a production rule) can, in the limit, be automatically applied to any new argument(s) taken by that predicate.¹ This kind of open-ended generalization—which permits extrapolation beyond the examples from which the rule is learned—is a very powerful inductive mechanism (Holland, Holyoak, Nisbett, & Thagard, 1986; Hummel & Holyoak, 2003). Without it, we would be limited to only those inferences and generalizations that can be found by interpolating over the training examples (Marcus, 2001). That is, without the ability to learn variabilized rules (i.e., rules defined over predicates that are free to vary in their arguments), having learned that relative size is a transitive relation (i.e., the “*if larger...*” rule) in the context of the naval vessels from the example above, we would be at a complete loss to infer *larger* (Rottweiler, mouse) given *larger* (Rottweiler, housecat) and *larger* (housecat, mouse) (see, e.g., Doumas, Hummel, & Sandhofer, 2008; Holyoak & Hummel, 2000; Hummel & Holyoak, 1997, 2003). Penn, Holyoak, and Povinelli (2008; see Penn & Povinelli, Chapter 27) have argued convincingly that this kind of relational generalization is the most important ability distinguishing human cognition from the cognitive abilities of our closest primate cousins.

It is this same capacity for variabilized, relational thinking that allows us to make analogies and to learn and reason from abstract schemas (Holland et al., 1986; Holyoak & Hummel, 2001; Hummel & Holyoak, 2003). Gick and Holyoak (1983) demonstrated that when people draw analogies between similar stories (i.e., specifying which elements of one correspond to which of the other), they may induce generalized schemas describing the shared aspects of those stories. For example, given one story in which Mary is the enemy of Bill and Bill is the enemy of Ted, so Mary regards Ted as her friend, and another story in which Dirk is the enemy of Roger and Roger is the enemy of Jake, so Dirk regards Jake as his friend, one might infer a schema of the general form, if *enemy-of*(person-1, person-2) and *enemy-of*

(person-2, person-3), then *friend-of*(person-3, person-1). If one were then to come across a situation in which Joe was the enemy of Tim, and Tim the enemy of Bill, one could map Joe onto person-1, Tim onto person-2, and Bill onto person-3, and subsequently infer that Bill is a friend of Joe. Notice that this sort of schema-driven inference is formally equivalent to inference based on a production rule in which the antecedent condition (the *if* portion of the rule) is fulfilled and the consequent (the *then* portion of the rule) fires (Anderson & Lebierre, 1998; Newell, 1990).

In the limit, the capacity to represent relational rules (or schemas) makes it possible to represent and reason about universally quantified functions (see Marcus, 2001). For example, consider the rule “ $\forall x,y,z \text{ if } (\text{pass}(x, y), \text{collect}(x, z))$ ” (or, for all x , if x passes y , then x collects z). The rule can apply to any set of x , y , and z , such as a player (x) passing the “GO” square (y) in Monopoly and collecting \$200 (z), or a person (x) passing the border of a country (y) and collecting a passport stamp (z). Without the power of symbolic representations—specifically, without the ability to represent predicates that are free to vary in their arguments—this kind of flexibility would be impossible.

Weaknesses

Despite their successes, a number of criticisms have been leveled against traditional symbolic models of cognition. A very basic one concerns the question of how (and even whether) it is possible to learn symbolic representations. How, for instance, would we learn a relational predicate like *larger*(x, y)? This question is made difficult, in part, by the very property that makes these representations powerful, namely, the fact that they are free to vary in their arguments: Although *larger* (battleship, cruiser) and *larger* (Rottweiler, housecat) express different ideas, they nonetheless express, if not identical, then at least very similar relations. It is our appreciation of this similarity that allows us to grasp that the battleship corresponds to the Rottweiler rather than the housecat.² In turn, the predicate’s ability to remain (at least largely) invariant over changes in its arguments renders it challenging to learn: We are never exposed to disembodied “*larger-ness*”; rather, all those cases where we have had the opportunity to observe an instance of the *larger* relation have presented it in the context of one specific thing being larger than some other specific thing. Given this type of input, how do we ever learn to represent *larger* in a way that is (even

partially) independent of its arguments (Doumas et al., 2008; Kellman, Burke, & Hummel, 1999)? The difficulty of this question—along with the fact that rather than answering it, traditional symbolic modelers have often simply hand-coded their symbolic representations—has led some to wonder whether it is even possible to learn symbolic representations, such as predicates, from nonsymbolic inputs (e.g., early perceptual representations), a concern that has been cited as one of the most significant shortcomings of the symbolic approach (see, e.g., Leech, Mareschal, & Cooper, 2008; Munakata & O'Reilly, 2003; O'Reilly & Busby, 2002; O'Reilly, Busby, & Soto, 2003). Certainly, with tools of traditional symbolic models it is unclear how these representations can be learned in the first place. However, as elaborated later this shortcoming does not mean that symbolic representations cannot be learned at all (e.g., Doumas et al., 2008).

A second limitation of the traditional symbolic approach, as an account of the human cognitive architecture, is that human mental representations have semantic content: They are *about* things, and they somehow naturally capture how those things are similar to and different from one another. By contrast, traditional symbolic approaches to cognition do not (and, worse, *cannot*; Doumas & Hummel, 2004) capture similarity relations among the entities to which symbols refer. For example, the symbols *Rottweiler* and *battleship* fail to specify what these concepts have in common (precious little besides being objects found on Earth) and how they differ (e.g., in animacy, size, and function). Based on the symbols alone, one's best guess about what battleships and Rottweilers have in common is that both require 10 letters to spell (11 in the plural). Moreover, the meanings of various relations seem to apply specifically to individual relational *roles*, rather than to the relation as a whole. As a result, it is easy to appreciate that the agent (i.e., killer) role of *murder* (x, y) is similar to the agent role of *attempted-murder* (x, y), even though the patient roles differ (i.e., the patient is dead in the former case but not the latter); and the patient role of *murder* (x, y) is similar to the patient role of *manslaughter* (x, y), even though the agent roles differ (i.e., the act is intentional in the former case but not the latter).

The semantic properties of human mental representations manifest themselves in countless ways in human cognition, influencing memory retrieval (e.g., Gentner, Ratterman, & Forbus, 1993; Ross, 1987; Wharton, Holyoak, & Lange,

1996), categorization, and reasoning (Bassok, Wu, & Olseth, 1995; Krawczyk, Holyoak, & Hummel, 2005; Kubose, Holyoak, & Hummel, 2002; Ross, 1987). The meanings of relations and their arguments also influence which inferences seem plausible from a given collection of stated facts. For instance, upon learning about a culture in which nephews traditionally give their aunts a gift on a particular day of the year, it is a reasonable conjecture that there may also be a day on which nieces in this culture give their uncles gifts. This inference is based on the *semantic* similarity of aunts to uncles and nieces to nephews, and on the semantics of gift giving, not the syntactic properties of the *give-gift* relation. Given the important role of semantics in the mental representation of relational roles and the objects that fill those roles, an important criterion for a general account for the human cognitive architecture is that the representations on which it is based be able to capture (or at least approximate) that semantic content.

On this point, traditional symbolic models based on varieties of propositional notation and labeled graphs fare poorly. It has been known for a long time that such representational schemes have difficulty capturing shades of meaning and other subtleties associated with semantic content. This limitation was a central focus of the influential critiques of symbolic modeling presented by the connectionists in the mid-1980s (e.g., Rumelhart, McClelland, & The PDP Research Group, 1986). A review of how traditional symbolic models have handled this problem (typically with look-up tables of one sort or another) also reveals that the question of semantics is, in the very least, a thorny inconvenience (see Doumas & Hummel, 2004, for an argument that the problem is more than simply an inconvenience).

Yet a third limitation of traditional symbolic approaches, also cited by the connectionists in the mid-1980s, is that they make no obvious contact with Marr's (1982) third level of analysis, *physical implementation*: It is not at all clear how something like a graph-matcher or a production system would or could be implemented in the brain (but see Anderson, Qin, Jung, & Carter, 2007, for some progress in this direction).

Connectionist Models

Connectionist neural-network models (also referred to as *parallel distributed processing*, or PDP) were motivated in large part by the perceived limitations of the traditional symbolic approach. Neurally inspired

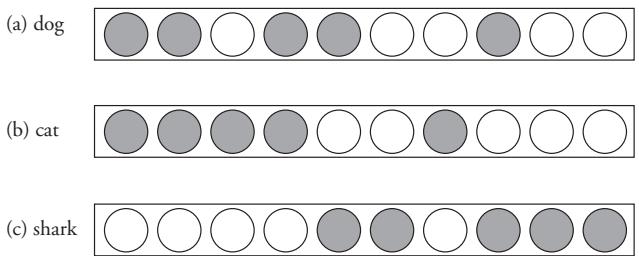

Fig. 5.3 Examples of distributed representations of the concepts, (a) dog, (b) cat, and (c) shark. Note that the same set of units is depicted in each row.

models date back to at least the 1940s (McCulloch & Pitts, 1943; Rosenblatt, 1958). However, their more recent appeal as a general account of the human cognitive architecture—and as a serious alternative to traditional symbolic models—was launched by the work of Rumelhart and colleagues in the mid-1980s (see McClelland et al., 1986; Rumelhart et al., 1986).

Like symbolic models, a variety of connectionist models have been proposed to simulate a wide range of cognitive phenomena; also like symbolic models, the diverse models in the traditional connectionist approach share some basic assumptions about how information is represented and processed.

Representations

Connectionist models consist of collections of simple processors, represented by nodes or *units*, that are connected to form large networks. Units in connectionist networks take activations, typically in the range 0–1. Representations are patterns of activation across *units* in the system. These patterns might correspond to a perception, a thought, a memory, a concept, or any other cognitive state. For example, in the very simple network depicted in Figure 5.3, the pattern of activation on the units depicted in Figure 5.3a might correspond to the concept “dog,” the pattern of activation depicted in Figure 5.3b might correspond to “cat,” and the pattern of activation depicted in Figure 5.3c to “shark.” Other concepts like “animal,” “large,” or “food” would be represented as other patterns.

An important distinction in connectionist models is the distinction between *localist* and *distributed* representations. A localist representation is one in which individual units have meaning (e.g., a unit for “dog”); a distributed representation is one in which the meaning of a concept is carried by a pattern of activation across many separate units (e.g., the concept dog being represented by units for “animal,” “mammal,” “canine,” “domesticated,” etc.). As illustrated by this example, whether a representation is localist or distributed is most often a function of the

relationship between the concept and the representation: With respect to the concept “dog,” units representing “animal,” “mammal,” and so on constitute a distributed representation; but with respect to each of the more general concepts “animal,” “mammal,” and so on, those same units constitute a localist representation. Thus, although the terms “localist” and “distributed” are most commonly used to describe representations (without regard for the entities they represent), they are better thought of as two-place predicates of the form: representation R is localist (or distributed) with respect to concept C (i.e., *distributed* (R, C)). The one exception to this generalization of which we are aware is some vector-symbolic architectures (such as those based on holographic reduced representations; e.g., Plate, 1991), in which the meaning of a unit in any pattern of activation depends entirely on the activity of the other units in that pattern. Such representational schemes are entirely distributed in the sense that no unit in the pattern can be interpreted without reference to the others.

One very appealing aspect of distributed representations (although not those that are entirely distributed) is that they very naturally capture the similarities of different concepts. In our simple network, the concepts of “dog” and “cat” are similar to the extent that their representations overlap. Thus, the network naturally captures the fact that dogs are more similar to cats than to sharks as a natural consequence of its representational scheme. Although there is debate about the utility of distributed and localist codes in connectionist systems (see, e.g., Page, 2000), most connectionist models use some combination of the two (e.g., O’Reilly & Busby, 2002; Rogers & McClelland, 2004).

Processes

Units in a connectionist system are densely interconnected via weighted *connections*. Positive weights act as excitatory connections, so that activity on one unit tends to activate the other, and negative weights act as inhibitory connections, so that activity in one unit tends to reduce activity in the other.

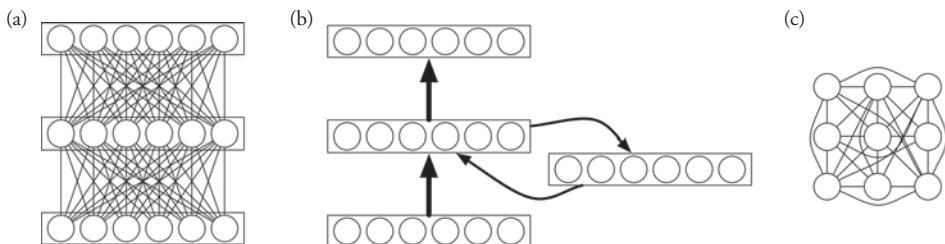

Fig. 5.4 Examples of (a) feed-forward, (b) recurrent, and (c) auto-associative connectionist systems. See text for details.

The architecture of a connectionist network is defined by the manner in which units are connected to one another. The most common architectures are feed-forward (e.g., McClelland & Rumelhart, 1985), recurrent (Elman, 1990), auto-associative (Hopfield, 1982), and hybrids thereof (e.g., O'Reilly, 2006). In a feed-forward architecture, units are arranged in layers such that the units in one layer pass activation (both excitation and inhibition) to the units in the next layer, but units do not typically pass activation to other units in the same layer or in earlier layers (see Fig. 5.4a). Recurrent networks (Fig. 5.4b) are much like feed-forward networks, except that the activation pattern on a “hidden” layer at time t serves as part of the input at time $t + 1$, thereby providing a kind of memory for past states of the network (see, e.g., Elman, 1990). In an auto-associative architecture (Fig. 5.4c) every unit typically has connections to every other unit.

Despite their differences, connectionist networks (at least traditional, nonsymbolic ones as opposed to symbolic ones, as described later) all share the property that the entire currency of computation is activation: Units excite or inhibit one another and over time the state of the network settles into some stable pattern of activation, either on the output units (in the case of feed-forward and recurrent networks) or over the network as a whole (in the case of auto-associative networks). The final or output pattern of activation is interpreted as the network's response to its input.

Strengths

The strengths of the traditional connectionist approach are numerous. Perhaps most obviously, connectionist networks offer a link between cognitive phenomena and their potential neural underpinnings: It is easy to see how the computational principles embodied in a connectionist network could be realized in neurophysiology. In addition, connectionist networks, with their representations based on distributed patterns of activation, provide for a natural kind of automatic generalization. If the representation of,

say, *dog*, consists of one pattern of activation (e.g., on the input units of some network) and the representation of *cat* consists of a similar pattern of activation, then many things learned about dogs will generalize automatically to cats (see McClelland et al., 1986). This kind of automatic generalization accounts for the semantic richness of human mental representations in a way that traditional symbolic representations simply cannot (Doumas & Hummel, 2005).

A third strength of the traditional connectionist approach is that, in contrast to the traditional symbolic approach, it provides a way to seamlessly integrate questions of representation with questions of learning: Connectionist networks are capable of learning their own representations for things, both in the “hidden” layers of feed-forward and recurrent networks, and in classes of unsupervised learning models (which represent a hybrid of feed-forward and auto-associative architectures; see, e.g., Marshall, 1995).

Still a fourth strength of the connectionist approach is that, like biological neural networks, connectionist networks degrade gracefully with damage. As such, they provide a natural platform for simulating the effects of brain damage, normal aging, and even cognitive development (e.g., Colunga & Smith, 2005; Joanisse & Seidenberg, 1999; Li, Lindenberger, & Sikstrom, 2001).

A fifth, less often cited, strength of connectionist models is their mathematical simplicity. In contrast to symbolic models, which are typically complex enough to defy proofs of their computing abilities, connectionist networks are comparatively simple, typically being constrained to using a fixed activation function in a fixed architecture. This makes it possible to prove, for example, that a three-layer (that is, three layers of connections, or a layer of input units, two hidden layers of units, and a layer of output units) feed-forward nonlinear network (where “nonlinear” refers to the activation function of the units in the network) is capable of computing any computable mapping.

Weaknesses

Despite their strengths, traditional connectionist models have some important limitations as models of higher cognition in humans. Most notably, they lack symbolic competence. Many authors have written extensively on this limitation (e.g., Doumas et al., 2008; Hummel, 2000; Hummel & Biederman, 1992; Hummel & Holyoak, 1997, 2003; Marcus, 1998, 2001; von der Malsburg, 1981, 1999), but its importance remains underappreciated.

Although a connectionist network can compute any computable mapping, it effectively must be trained on each individually. Although a properly trained NN can interpolate between learned input-output mapping, it cannot extrapolate to mappings that lie outside of its training set (e.g., Marcus, 1998; St. John, 1992; St. John & McClelland, 1990). Symbolic systems by contrast including humans extrapolate easily (e.g., as in the case of human relational reasoning; Hummel & Holyoak, 2003).

The fundamental reason why connectionist models fail to achieve symbolic competence is that traditional connectionist representations simply do not have enough degrees of freedom—they is, they are formally too weak (Hummel et al., 2004). A symbolic representation, such as propositional notation, has two degrees of freedom with which to express information. The first is the choice of which symbols to use: If a modeler wishes to represent that John loves Mary, she would use the symbols *loves*, John and Mary; to represent that John hates Mary, she would use *hates*, John and Mary. The corresponding degree of freedom in a connectionist representation is activation: To represent that John loves Mary, a connectionist network might activate units (or, in the distributed case, collections of units) representing *loves*, John and Mary.

The second degree of freedom in a symbolic representation specifies the bindings of arguments to the roles of the relation: To represent that John loves Mary, it is traditional to place John in the first slot inside the parentheses following the relation and Mary in the second slot, forming *loves* (John, Mary); to specify that Mary loves John, the modeler would place the *very same symbols* in the opposite slots to form *loves* (Mary, John). (An explanation for the italics appears two paragraphs later.) There is no analogous second degree of freedom in a traditional connectionist representation. Activating units or patterns for *loves*, John and Mary, could equally represent “John loves Mary” or “Mary loves John” (or, in the case of a distributed representation, a statement

about a narcissistic hermaphrodite; Hummel & Holyoak, 1997; von der Malsburg, 1981), so it is impossible to tell which is the intended meaning of the representation. The reason is that this representation fails to specify the bindings of the arguments to the roles of the relation. Unlike the symbolic representation, the traditional connectionist representation lacks a degree of freedom with which to specify this information.

The most common response to this problem is to use varieties of *conjunctive coding* to carry binding information. Under conjunctive coding, units represent, not objects or relational roles, but *conjunctions* of objects in relational roles. For example, rather than representing *loves*, John and Mary, the units in a conjunctive code might represent conjunctions such as *John+lover*, *Mary+beloved*, *Mary+lover*, and *John+beloved*. Now, to represent that John loves Mary, the network activates *John+lover* and *Mary+beloved*; to represent that Mary loves John, it activates *Mary+beloved* and *John+lover*. Specific varieties of conjunctive coding include tensor products (Halford, Wilson, & Phillips, 1998; Smolensky, 1990), holographic reduced representations (Plate, 1991), and spatter codes (Kanerva, 1998). These approaches vary in their particulars, but they all share the property that units represent specific conjunctions of roles and arguments rather than representing the roles or arguments individually.

Models based on conjunctive coding have been applied with varying degrees of success in various domains. And indeed, some kind of conjunctive coding is certainly necessary for encoding bindings in long-term memory (Doumas et al., 2008; Hummel & Biederman, 1992; Hummel & Holyoak, 1997, 2003; Shastri, 2002). But as a general, or the only, solution to the binding problem in connectionist or neural networks, conjunctive coding is sharply limited. Recall the italicized *very same symbols* wording from two paragraphs earlier. It is the fact that the symbols in *loves* (John, Mary) are the same as those in *loves* (Mary, John) that allows you to know what these statements have in common: Both are about loving, John and Mary. The same is true for the statements *jonks* (grummond, steplock) and *jonks* (steplock, grummond): Although these statements are largely meaningless, because they use and reuse the same symbols, in the very least we know that, whatever “jonking” is, the grummond is doing it (or else stands in that relation) to the steplock in one case and the steplock is doing it (or stands in that relation) to the grummond in the other.

This ability to preserve the identity of symbols across different relational structures is a characteristic of symbolic representations, made possible by the fact that they have two degrees of freedom, that is absolutely essential for symbolic thought—such as reasoning based on analogies, schemas, or rules (Holyoak & Hummel, 2002; Hummel & Holyoak, 1997, 2003; Penn et al., 2008). It is for this reason that there are no successful traditional connectionist models of analogy (see Leech, Mareschal, & Cooper, 2008, for an attempt, the shortcomings of which illustrate the need for that second degree of freedom).

A number of connectionist models have been developed that appear to solve the problem of relational processing. We argue that these models in fact fail to simulate human relational reasoning and instead simulate a proxy to relational reasoning.

A connectionist model developed by O'Reilly and Busby (2002) illustrates what can (and cannot) be achieved without the second degree of representational freedom enjoyed by symbolic systems. O'Reilly and Busby's model is designed to answer questions about the spatial relations among objects. The model consists of "input/output" units representing (a) object features at each of 4x4 locations in the visual field, (b) the locations of those objects,

(c) the objects' identities (independent of location), and (d) relations among the objects (e.g., above/below). There are also "query units" associated with the input/output units (used for querying the model after training). These units are connected to (and communicate via) a set of "hidden" units, forming a large auto-associative network. The model is trained by pairing patterns of activation across the input/output units and learning connections between those units and the hidden units using the Leabra learning algorithm (O'Reilly, 1996). After training, the model can be presented with objects in various locations and be asked questions about them. For example, in order to ask, "What is at location 3,2?" the location query unit would be activated, along with the unit for location 3,2. No units in the "object" or "relation" arrays would be activated. The model's task would be to activate the object units corresponding to the distributed representation of whatever object resides at location 3,2. Or if asked, "What is above?" the "above" query unit would be activated, and the model's task would be to activate the representation of the object that is above the other, i.e., that in location 2,2 (see Fig. 5.5).

O'Reilly and Busby (2002) trained the model on various subsets (from 1.3% to 25%) of the input/

Location (1,1)	Location (1,2)	Location (1,3)	Location (1,4)
Location (2,1)	Location (2,2) 	Location (2,3)	Location (2,4)
Location (3,1)	Location (3,2) 	Location (3,3)	Location (3,4)
Location (4,1)	Location (4,2)	Location (4,3)	Location (4,4)

Fig. 5.5 Example of the task simulated by the O'Reilly and Busby (2002) model. A circle is presented in location 2,2, and a square in location 3,2. The model might be asked, "What is above location, 3,2?" (which should activate location 2,3).

query conjunctions it is capable of representing, and tested it for its ability to generalize to the untrained input/query conjunctions. After training on 25% of its input space, the model successfully generalized to roughly 95% of the untrained inputs. Based on this performance, O'Reilly and Busby concluded that "... rich distributed representations containing coarse-coded conjunctive encodings can effectively perform binding" (p. 6).

However, this claim, and the simulations on which it is based, deeply underestimate the power of relational perception, thought, and generalization. Being able to answer "What is above?" is not the same as being able to represent " x is above y ," for all x and all y , and being able to draw inferences based on the latter—for example, if x is above (and on) y , then x could potentially fall off of y . Far from this, the O'Reilly and Busby (2002) model can simply say "what is above": it can answer " x is above" (provided the features of x were part of its training regime), but it cannot say *what x is above*: It lacks even the basic capacity to specify the second argument of the *above* relation.

What makes human relational perception and thought powerful (and difficult to model) is not our ability to answer simple questions of the form "What is above?" (a question the O'Reilly & Busby, 2002, model answers based strictly on associative learning), but our ability to represent relations such as *above* (x, y), explicitly, to bind arguments to the roles of those relations, and to use that knowledge to make inferences about x and y for all x and y (not just those whose features have appeared in our training space). The O'Reilly and Busby model, by contrast, can only answer questions whose answers it has already been taught. Like other traditional connectionist models, the O'Reilly and Busby model can only generalize to new patterns by interpolating among patterns on which the model has been explicitly trained (e.g., patterns that are linear combinations of the examples on which the model has already been trained). And it cannot even represent, much less answer, questions of the form, "If x is in top of y , can x fall off of y or can y fall off of x ?", a question even a 3-year-old child would look at you askance for asking her in the first place.

This limitation is not restricted to the O'Reilly and Busby (2002) model, but is true of all models that have tried to tackle symbolic processing using strictly associationist tools (e.g., Rogers & McClelland, 2004, 2008; St. John & McClelland, 1990). As noble as these efforts are, their tools simply are not up to the task.

Symbolic-Connectionist Models

In response to the complementary strengths and weaknesses of the traditional symbolic and connectionist approaches, some researchers have attempted to implement symbolic structures within connectionist architectures with distributed representations. In principle, achieving symbolic competence in a connectionist system should not be difficult: All that is needed is some basis for representing role-filler bindings in a way that allows the representation of the roles and fillers to remain invariant (i.e., to be "reused" as they are in symbolic systems) across different bindings. Proposed solutions to this problem come in two general forms.

Models Based on Vector Multiplication

One approach to implementing symbolic structure in connectionist systems is to use tensor products (Smolensky, 1990; see also Halford et al., 1994; Halford et al., 1998)—or their variants, such as holographic reduced representations (HRRs; Plate, 1991), spatter codes (Kanerva, 1998), or circular convolutions (Metcalfe, 1990)—to represent role-filler bindings. A tensor product is an outer product of two or more vectors (i.e., a matrix) that is treated as an activation vector rather than a matrix (Smolensky, 1990). For example, to bind a one-place predicate, \mathbf{r} (such as *eats* (x) or *runs* (x)), to its argument, \mathbf{f} , the tensor \mathbf{rf} is formed by multiplying the i th element of vector \mathbf{r} , representing the role, by the j th element of \mathbf{f} , representing the filler (for all combinations of i and j):

$$\mathbf{rf}_{ij} = \mathbf{r}_i \mathbf{f}_j. \quad (1)$$

There are two ways to bind multiplace relations to their arguments using tensor products. One is to define tensors of progressively higher rank (where the rank of a tensor is the number of vectors that come together to define it; see, e.g., Halford et al., 1994). For example, a two-place relation (such as *loves* (x, y) or *larger-than* (x, y)) could be represented by the rank three tensor \mathbf{rfg} :

$$\mathbf{rfg}_{ijk} = \mathbf{r}_i \mathbf{f}_j \mathbf{g}_k \quad (2)$$

where \mathbf{r} represents the relation (e.g., *loves* in *loves* (x, y)), \mathbf{f} represents the argument bound to the first role of the relation (x), and \mathbf{g} represents the argument bound to the second (y). An alternative approach

is to designate separate tensors for each role-filler binding and represent the complete proposition as their sum (e.g., Tesar & Smolensky, 1994). For example:

$$\mathbf{rf} = \mathbf{rf}^1 + \mathbf{rf}^2, \quad (3)$$

where \mathbf{rf}^1 is a tensor representing the binding of the first role to its argument and \mathbf{rf}^2 represents the binding of the second role to the second argument.

The deep problem with all these approaches is that, because tensors are a variety of conjunctive coding, they violate role-filler independence. A tensor is a *product* of two or more vectors (see Eqs. 1–3), so the similarity of two tensors—and hence the ability to generalize something learned about one of them to the other—scales with the *product* of the similarities of the simple vectors from which the tensors were created. For example, if vector similarity is defined in terms of the inner (“dot”) product, then:

$$\mathbf{rf}_1 \cdot \mathbf{rf}_2 = (\mathbf{r}_1 \cdot \mathbf{r}_2)(\mathbf{f}_1 \cdot \mathbf{f}_2), \quad (4)$$

where \mathbf{rf}_1 and \mathbf{rf}_2 are tensors made from \mathbf{r}_1 and \mathbf{f}_1 and from \mathbf{r}_2 and \mathbf{f}_2 , respectively, and \cdot indicates the dot product. Similarly, if vector similarity is defined in terms of the cosine of the angle between two vectors, then:

$$\cos(\mathbf{rf}_1, \mathbf{rf}_2) = \cos(\mathbf{r}_1, \mathbf{r}_2)\cos(\mathbf{f}_1, \mathbf{f}_2). \quad (5)$$

Under both these definitions of vector similarity, two tensors will be similar to one another only to the extent that both their roles *and* fillers are similar: Identical roles, bound to completely different fillers, result in completely different tensor products, precluding any generalization from one to the other. This property is true, not only of tensor products, but of any binding scheme based on tensors (such as HRRs; Plate, 1991).

This property of tensors reflects the fact that they are the result of vector multiplication: Since role and filler vectors are multiplied by one another to form role-filler bindings, the similarities of those vectors are multiplied to determine the similarity of the resulting tensors. This observation suggests that one way to avoid role-filler interaction in role-filler binding similarity is to perform role-filler binding by role-filler addition rather than multiplication.

Models Based on Vector Addition

A second approach to implementing symbolic structure in connectionist networks is to bind roles to fillers by vector addition, which can be implemented as synchrony of neural firing (see Hummel & Holyoak, 1997, 2003). The basic idea is that units representing a relational role are added to (i.e., fire in synchrony with) the units representing the argument filling that role; units representing separate role-filler bindings fire out of synchrony with one another. A related proposal is to represent role-filler bindings by systematic *asynchrony* of firing, such that units representing a relational role fire, for example, just before the units representing its filler, and separate bindings fire in more distant temporal relations (see Doumas & Hummel, 2005; Doumas et al., 2008; Love, 1999). In either case, the binding is represented as a kind of vector addition because a given vector always represents a given role or object, regardless of the object or role to which it happens to be bound, and the bindings of roles to their fillers are represented by operations (synchrony or systematic asynchrony of firing) that put roles together with their fillers in an additive rather than multiplicative fashion.

However, synchrony of firing cannot be the whole story concerning the neural basis for binding, because temporal patterns of neural activity are necessarily transient. At a minimum, conjunctive codes are necessary for the purposes of storing bindings in LTM, and for forming localist tokens of roles, objects, role-filler bindings, and complete propositions (Hummel & Holyoak, 1997, 2003). A complete account of the human cognitive architecture must incorporate both dynamic binding (for independent representation of roles bound to fillers in WM) and conjunctive coding (for LTM storage and token formation), and specify how these coding systems are related.

One example of a system that binds via vector addition is a model of analogical reasoning called Learning and Inference by Schemas and Analogies, or LISA (see also the SHRUTI model; Shastri & Ajjanagadde, 1993). In LISA, relational structures are represented by a hierarchy of distributed and localist codes (see Fig. 5.6). At the bottom, “semantic” units represent the features of objects and roles in a distributed fashion. At the next level, these distributed representations are connected to localist predicate-and-object units (POs) representing individual predicates (or relational roles) and objects. Localist role-binding units (RBs) link object and

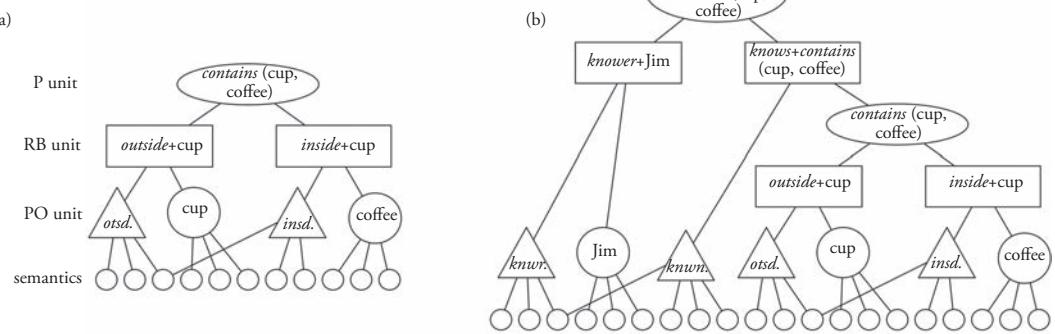

Fig. 5.6 Representation of propositions in LISA (Learning and Inference by Schemas and Analogies). Objects and relational roles are represented both as patterns of activation distributed over units representing semantic features (*semantic units*; small circles) and as localist (PO) units representing tokens of objects (large circles) and relational roles (triangles). Roles are conjunctively bound to fillers by localist role-binding (RB) units (rectangles), and role-filler bindings are conjunctively bound into complete propositions by localist P units (ovals). (a) Representation of *contains* (cup, coffee). (b) Representation of *knows* (Jim, *contains* (cup, coffee)). When one proposition takes another as an argument, the lower (argument) proposition serves in the place of an object unit under the appropriate RB of the higher level P unit (in this case, connecting *contains* (cup, coffee) to the RB representing what is known). In the figure we represent these localist units (i.e., POs, RBs, and Ps) with different shapes for the purposes of clarity. Importantly, these units are not different kinds of units (i.e., they do not work differently). Rather, they are simply units in different layers of the network. We use different names for the units in each layer (and different shapes in the figures) only to make them easier to distinguish.

relational role units into specific role-filler bindings. At the top of the hierarchy, localist proposition units (Ps) link RBs into whole relational propositions.

To represent the proposition *contains* (cup, coffee), PO units (triangles and large circles in Fig. 5.5) representing the relational roles *outside* and *inside*, and the fillers cup and coffee, are connected to semantic units coding their semantic features. RB units (rectangles) then conjunctively code the connection between roles and their fillers (one RB connects cup to *outside*, and one connects coffee to *inside*). At the top of the hierarchy, P units (oval) link sets of RBs into whole relational propositions. A P unit conjunctively codes the connection between the RBs representing *outside+cup* and the RB representing *inside+coffee*, thus encoding the relational proposition *contains* (coffee, cup). Each level of the representational hierarchy serves an important purpose. The semantic units capture the semantically rich (i.e., distributed) nature of human mental representations. The three layers of localist units make it possible to treat each level of the hierarchy as an independent entity for the purposes of mapping and inference (Hummel & Holyoak, 1997, 2003).

When a proposition enters working memory, role-filler bindings must be represented dynamically on the units that maintain role-filler independence (i.e., POs and semantic units; see Hummel & Holyoak, 1997). In models using synchrony of

firing as a binding tag, roles are dynamically bound to their fillers by synchrony of firing (see earlier). In models using systematic asynchrony of firing as a binding tag, roles and their fillers fire in direct sequence. Binding information is carried in the proximity of firing (e.g., with roles firing directly before their fillers).³

An important consequence of the approach is that it allows a solution to the problem of how the structured (i.e., symbolic) representations that underlie symbolic systems may be learned in the first place (as noted earlier, one of the most oft-levied criticisms of the symbolic account of cognition). DORA (*Discovery of Relations by Analogy*; Doumas et al., 2008) is an account of how children and adults learn novel relational concepts from examples and subsequently use those representations in the service of understanding and reasoning about the world. Unlike other models that represent and employ structured representations, DORA learns structured relational representations from unstructured (i.e., nonsymbolic and nonrelational) examples. DORA starts with unstructured representations of objects as simple vectors of features. When DORA compares two or more of these objects, it learns explicit representations of any properties they share. Because DORA can use time as a binding tag (see earlier), the resulting representations are effectively single-place predicates (represented in a distributed fashion) that can

be bound to novel arguments. DORA then combines sets of these predicates to form representations of complete multiplace relations (where each of the combined predicates serves as a role of the new relation). For example, DORA will learn predicates like *inside(x)* and *outside(y)* when it compares examples of different objects inside and outside one another (e.g., children outside a house and coffee inside a cup). DORA will then combine the *inside(x)* and *outside(y)* predicates to form the multiplace relation *contains(x, y)*. Importantly, this is precisely the learning trajectory that children follow when they learn relations (e.g., Smith, 1984). Thus, DORA provides an account of how structured representations can be learned from examples, and so it addresses one of the major criticisms levied at structured models of cognition.⁴

Based on a small set of basic principles (notably comparison-based learning and constructing multiplace relations from sets of single-place predicates), DORA accounts for many phenomena surrounding the development of relational thinking, the development of the shape bias, and the effect of labeling on relational category learning (e.g., Doumas & Hummel, 2010; Doumas et al., 2008; Sandhofer & Doumas, 2008; Son, Doumas, & Goldstone, 2010).

Strengths

Models based on symbolic-connectionist enjoy a range of strengths. Because they are structured (i.e., they have two representational degrees of freedom in that they solve the binding problem), symbolic-connectionist models support the flexible and powerful generalizations of traditional symbol systems. Predicates are free to vary in their arguments, and thus what is learned about a predicate in one context potentially generalizes to other contexts and other arguments (see later discussion). So, like symbolic models, symbolic-connectionist models can extrapolate beyond training examples. The structure sensitivity of symbolic-connectionist models has allowed them to account for a wide range of phenomena in higher order cognition, including analogy making and retrieval from long-term memory (Hummel & Holyoak, 1997), relational generalization and schema induction (Hummel & Holyoak, 2003), learning relational concepts (Doumas et al., 2008), object recognition and the role of attention in shape perception (Hummel, 2001; Hummel & Biederman, 1992), motivation (Sun, 2009), speech production (Chang, Dell, & Bock, 2006), explicit skill learning (Sun, Slusarz, & Terry, 2005), and

creative problem solving (Helie & Sun, 2010). There are also models of this sort that are able to learn structured (i.e., symbolic) representations from unstructured examples (Doumas et al., 2008).

Just as their structure sensitivity affords them the advantages of symbolic competence, so the distributed representations in symbolic-connectionist models afford them many of the strengths of traditional connectionist models. Like traditional connectionist models (as discussed earlier), symbolic-connectionist models offer a link between algorithmic models and possible neural underpinnings, allow natural automatic generalization, integrate representation and learning, and degrade gracefully with damage. Symbolic-connectionist models have been used to account for implicit skill learning (Sun et al., 2005), categorization, reflexive inference (Shastri & Ajjanagadde, 1993), and cognitive deficits due to brain damage (Morrison et al., 2004) and normal aging (Viskontas et al., 2004).

Weaknesses

Symbolic-connectionist models also have their share of weaknesses. One of the more serious shortcomings of symbolic-connectionist models is that they are weaker than purely symbolic models. For example, whereas symbolic models can deal with executive function and goal setting, representing and responding to negation and quantification (e.g., universal—for all—and existential—there exists), these phenomena have yet to be successfully modeled within symbolic-connectionist architectures. It remains unclear how (or even whether) symbolic-connectionist models will be able successfully account for them.

A second shortcoming of symbolic-connectionist models is that their representational assumptions (and thus their resulting representations) are more complex than traditional connectionist models. Although symbolic-connectionist models are connectionist in spirit, in that they are built out of collections of simple processing units that are highly interconnected, they include additional processing assumptions (such as sensitivity to temporal patterns of firing) that allow them to solve the binding problem (i.e., that provide them an additional informational degree of freedom comparable to that available to symbolic models). But whereas it might appear that symbolic-connectionist models make more nativist assumptions than traditional connectionist models (in that the former assumes an additional informational degree of freedom by which to

carry binding information), we would argue that this appearance is misleading. Symbolic-connectionist models make assumptions about learning rules and activation functions similar to those made by traditional connectionist models. The additional assumption that symbolic-connectionist models (at least those that use time to carry binding information) must make beyond traditional connectionist models is that units are organized in layers and are sensitive to what layers they are in.

Conclusions and Future Directions

An adequate account of human mental representations—and the human cognitive architecture more broadly—must account both for our ability to represent the semantic content of relational roles and their fillers, and for our ability to bind roles to their fillers dynamically without altering the representation of either. Traditional symbolic approaches to cognition fail to specify the semantic content of roles and their fillers—a failing that, as noted by the connectionists in the 1980s, renders them too inflexible to serve as an adequate account of human mental representations. Traditional distributed connectionist approaches have the opposite problem: They succeed in capturing the semantic content of the entities they represent but fail to provide any basis for binding those entities together into symbolic (i.e., relational) structures. This failure renders them incapable of relational generalization, which appears to be required for such human abilities as assessing similarity based on alignment (Goldstone & Son, Chapter 10), analogical reasoning (Holyoak, Chapter 13), and learning problem schemas (Bassok & Novick, Chapter 21).

By contrast, symbolic-connectionist models combine the strengths of both the symbolic and connectionist approaches. These models have the potential to produce representations that are neurally plausible, semantically rich, flexible, and meaningfully symbolic. Armed with these representations, the symbolic-connectionist approach may be able to provide a powerful foundation for understanding human cognition. Nonetheless, models to date have their limitations. Those models based on vector multiplication (using tensor products and other forms of conjunctive coding as the sole basis for role-filler binding) fail to capture the natural pattern of similarities among propositions. There remain many important aspects of human cognition that symbolic-connectionist models have not yet addressed, including planning, quantification, negation, and

other aspects of language use. It remains to be seen whether these are simply questions or represent fundamental limitations of the approach.

Notes

1. We say “in the limit” here because this statement assumes that the predicate is defined over variables open enough to take any kind of arguments, such as the x , y , and z in the larger... production rule. By contrast, a production rule defined over specific objects, such as the “me and my neighbor’s dog” rule, would not necessarily be expected to generalize automatically to all new arguments (although used as part of an analogy, it might be expected to generalize very substantially; see, e.g., Holyoak & Thagard, 1995; Hummel & Holyoak, 2003).

2. Note that this correspondence is not based on anything as trivial as the arguments’ locations within the parentheses: The same correspondence is also suggested by the propositions larger (battleship, cruiser) and smaller (housecat, Rottweiler)—a correspondence that also suggests that the semantics of the larger and smaller relations reside, not in the relations as holistic entities, but in their individual roles (Doumas & Hummel, 2005; Doumas, Hummel, & Sandhofer, 2008; Hummel & Holyoak, 1997, 2003).

3. Asynchrony-based binding allows role and filler to be coded by the same pool of semantic units, which allows a system to learn representations of relations from representations of objects (Doumas et al., 2008).

4. As noted by Holyoak (Chapter 13), DORA does not provide an account of what the features of relations are. Rather, it provides an account of how those features (assuming they exist) can be extracted from unstructured representations of objects and represented as explicit structures that can take arguments (i.e., as predicates).

Neurocognitive Methods in Higher Cognition

Robert G. Morrison and Barbara J. Knowlton

Abstract

The methods of cognitive neuroscience, notably functional neuroimaging and cognitive neuropsychology, are becoming increasingly important in efforts to understand the processes responsible for human higher cognition. Given the complexity of human thinking and reasoning, it is frequently the case that multiple theories can explain behavioral results. By utilizing the constraint of neural plausibility, some of these possibilities can be eliminated. These tools are thus beginning to help us to understand how thinking and reasoning actually occur in the brain. In this chapter we discuss a number of the techniques most frequently used to investigate higher cognition, including cognitive neuropsychology, scalp electroencephalography (EEG), functional magnetic resonance imaging (fMRI), and transcranial magnetic stimulation (TMS). We briefly survey a number of examples of how these techniques have contributed to our understanding of higher cognition, particularly the functions of the human prefrontal cortex.

Key Words: neuropsychology, neuroimaging, functional magnetic resonance imaging (fMRI), electrophysiology, event-related potentials (ERPs), prefrontal cortex

Introduction

For the past 40 years, neuroscience methods have played an increasingly important role in the study of cognition. It is now commonplace for cognitive scientists to connect cognitive processes to their underlying neural substrates. The explosive growth in the field of cognitive neuroscience, particularly in perception and memory, is blurring distinctions between cognitive psychology and neuroscience. Neuroscientists are now recognizing that higher cognition, including the study of thinking and reasoning, are also tractable areas for research, which could greatly benefit from attention to the constraint of neural plausibility.

The development of the field of cognitive neuroscience is a natural consequence of the fact that “cognition is what the brain does.” Recent years have seen unprecedented development in both the study of cognition and of the brain. The development

of neuroimaging techniques, chiefly functional magnetic resonance imaging (fMRI), has clearly accelerated this convergent growth. Because methodological developments have fueled advances in the cognitive neuroscience approach, this chapter is organized in terms of how different methodologies are informing the field.

Findings in cognitive neuroscience fall into two basic categories. In one category, researchers elucidate brain-behavior relationships; that is, they assign cognitive functions to specific brain regions or circuits. In the other category, neuroscience data are brought to bear in order to constrain cognitive theories, or they are used to provide a resolution between two theories that are both plausible based on behavioral data alone. This second category of findings is typically of more interest to cognitive scientists; however, the famous 19th-century neurologist Bernhard Von Gudden was wise to caution,

“Faced with an anatomical fact proven beyond doubt, any physiological result that stands in contradiction to it loses all its meaning... So, first anatomy and then physiology; but if first physiology, then not without anatomy” (as cited by Brodmann, 2006, p. 262). Thus, understanding the functional neuroanatomy of the brain is the first step in determining how the physical matter of the nervous system gives rise to human thought. Ultimately, this is one of the fundamental questions in life science. Thus, cognitive neuroscience is useful in that it provides additional methods for cognitive science, but it is also an important pursuit in its own right.

Methods of Cognitive Neuroscience

Building upon a long history of work in cognitive neuropsychology,¹ the methods of cognitive neuroscience are constantly evolving. In addition to functional neuroimaging techniques sensitive to the temporal dynamics or spatial localization of cognitive processes, researchers have also made extensive use of computational modeling to capture brain network architecture or functions, recently augmented by the methods of cognitive neurogenetics (see Green & Dunbar, Chapter 7). Here we introduce several of the techniques currently being used to study higher cognition, and we provide examples of their use (see Table 6.1 for a summary of methods).

Cognitive Neuropsychology

While modern “cognitive neuroscience” may have officially begun with the coining of the term in the late 1970s by Michael Gazzaniga and George Miller (D’Esposito, 2010), the precursors of this field can be traced to 19th-century studies of brain-damaged patients. The great controversy of the time was between *localizationism*, the view that specific cognitive functions could be ascribed to particular brain regions, versus an *aggregate field theory*, according to which cognitive abilities are distributed throughout the neocortex. Under the first view, restricted damage to specific brain regions should disrupt specific cognitive processes while leaving others intact. Under the second view, the extent of damage to the brain is more important than the location of damage, with all cognitive functions proportionately affected by damage. Some of the most compelling data from this period arguing for localizationism came from two patients studied by Paul Broca (Lee, 1981). These patients (Leborgne and Lelong) became unable to speak more than a few words. After the death of each patient, Broca

examined their brains and determined that for both patients the language difficulties were due to damage in the left inferior frontal lobe, a region now named Broca’s area (see Fig. 6.1). Interestingly, subsequent work has shown that patients with lesions limited to Broca’s area do not actually exhibit the kind of profound deficits in language production described in Broca’s original cases. Recent examination of Leborgne and Lelong’s brains with modern methods in fact demonstrate that the damage was much more extensive than originally described (Dronkers, Plaisant, Iba-Zizen, & Cabanis, 2007). Nevertheless, these case studies indicated that a complex cognitive function like language production could be selectively affected by brain damage that generally spared other functions.

Broca’s dissociation-based approach (see Fig. 6.2), which looks for commonalities in spared and impaired function with associated brain damage across subjects, has continued to be used in modern cognitive neuroscience. The power of the cognitive neuropsychological approach is that it can tell us whether a specific brain region is *necessary* for a particular cognitive function, and whether remaining regions are *sufficient* to support functions that are spared (i.e., single dissociation). In addition, even in situations where the location of damage is unclear, much can be learned about the organization of cognition by studying how it breaks down. For example, the apparent relative sparing of language comprehension in patients Leborgne and Lelong, despite their severe difficulties with language production, support models of language in which these abilities are independent. Another example is the distinction between declarative and procedural memory systems. The strongest evidence that memory is organized into such systems comes from the fact that amnesic patients are able to learn skills and procedures normally despite extremely poor memory for practice episodes (Cohen & Squire, 1980; Knowlton, Mangels, & Squire, 1996).

The neuropsychological approach depends on a careful analysis and characterization of behavior (see Feinberg & Farah, 2003). Dissociations between cognitive functions can be interpreted in different ways depending on the underlying psychological theory. Although a straightforward interpretation of the findings from Broca’s patients suggested a double dissociation between language production and comprehension, subsequent research has shown that similar patients have difficulty with comprehension based on grammar. It appears more accurate to describe these patients as “agrammatic.” To

Table 6.1. Summary of Experimental Methods in Cognitive Neuroscience

Temporal Resolution						
Method	Temporal Lag	Sampling Rate	Spatial Resolution	Advantages	Disadvantages	Methods and Examples
Cognitive neuropsychology (Behavioral Neurology)	NA	NA	10^{-3} – 10^{-2} m	Can access whether a particular brain region is necessary for a particular cognitive function; can be combined with structural and/or functional imaging and be used to test computational models	Depends on the “experiments of nature”; requires precise characterization of damage (structural imaging) and careful testing to establish dissociations	Feinberg & Farah (2003); Waltz et al. (1999); Morrison et al. (2004); Huey et al. (2009); Sonty et al. (2007)
Computed axial tomography (CT)	NA	Can be repeated over days to years	10^{-2} – 10^{-1} m	Excellent vascular detail; availability in all major medical/research centers	Poor detail except for vascular structures	
Structural magnetic resonance imaging (MRI, cortical thickness, VBM)	NA	Can be repeated over days to years	10^{-3} – 10^{-1} m	Excellent gray/white matter detail; can be used to measure cortical thickness or used with techniques like voxel-based morphometry (VBM) to make group comparisons; can be correlated with behavior	Claustrophobic; cannot currently be used in individuals with medical implants; difficult to use with infants and children	Raichle (1994); Fischl & Dale (2000); Ashburner & Friston (2000); Dumontheil et al. (2010); Rosen et al. (2002)
Diffusion tensor imaging (DTI)	NA	Can be repeated over days to years	10^{-3} – 10^{-1} m	Used to measure white matter integrity (DTI); can be correlated with behavior	Expensive; claustrophobic; difficult to use with infants and children	Filler (2009); Rogalski et al. (2009)
Single- or multi-unit recording	Instant	ms	10^{-5} – 10^{-3} m	Superior spatial and temporal resolution	Invasive! (animals and very selective brain-damaged humans); moderate startup and per-participant costs in animals	Humphrey & Schmidt (1990); Fuster & Alexander (1971); Cromer, Roy, & Miller (2010)

(Continued)

Table 6.1 Continued

Temporal Resolution						
Method	Temporal Lag	Sampling Rate	Spatial Resolution	Advantages	Disadvantages	Methods and Examples
Electrocorticography (ECOG)	Instant	ms	10^{-3} – 10^{-2} m	Good spatial and temporal resolution	Invasive! (very selective brain-damaged humans); high startup and per-participant costs	Miller et al. (2007); Canolty et al. (2006)
Scalp electroencephalography (EEG/ERP/ERO)	Instant	ms	10^{-2} – 10^{-1} m?	Noninvasive; excellent temporal resolution; low cost; can be used with children and infants	Undefined spatial resolution; sensitive to movement and eye artifacts	Luck (2005); Sauseng & Klimesch (2008); Knight et al. (1989); Vogel et al. (2005); Jung-Beeman et al. (2004); Kounios et al., (2006)
Positron emission tomography (PET)	2 m	?	10^{-2} – 10^{-1} m	Can be used either structurally or functionally; can be tuned to different metabolic processes; limited availability	Invasive (radiation); very expensive per-participant costs	Raichle (1983); Cabeza & Nyberg (2000); Villemagne et al. (2011)
Functional magnetic resonance imaging (fMRI)	1–2 s	250 ms - 1 s	10^{-3} – 10^{-1} m	Noninvasive; available at major medical/research centers; excellent spatial resolution	Expensive; loud and claustrophobic; cannot currently be used in individuals with medical implants; limited movement, poor participant contact, high per-participant cost	Brown, Perthen, Liu, & Buxton (2007); Raichle & Mintun (2006); Cabeza & Nyberg (2000); Kroger et al. (2002); Goel & Dolan (2004); Monti, Parsons, & Osherson (2009); Sonty et al. (2007)
Magnetoencephalography (MEG)	Instant	ms	10^{-2} – 10^{-1} m?	Noninvasive, provides high temporal resolution and moderate spatial resolution in one technique; can be used with children and infants	Not widely available in United States; high startup costs; moderate operating costs—much lower than fMRI	Hansen, Kringselbach, & Salmelin (2010); Ciesielski, Ahlfors, Bedrick, Kerwin, & Hamalainen (2010)

Near infrared spectroscopy (NIRS)	1–2 s	ms	10^{-3} – 10^{-2} m	Noninvasive; low-startup and low per-participant costs; can be used with infants and young children	Can only be used with cortical surface structures near scalp	Villringer & Chance (1997); Tsujii & Watanabe (2010)
Event-related optical signal (EROS)	100 ms	ms	10^{-3} – 10^{-2} m	Noninvasive; low-startup and low per-participant costs; can be used with infants and young children	Can only be used with cortical surface structures near scalp; very limited availability	Gratton et al. (1997)
Transcranial magnetic stimulation (TMS)	Instant	NA	10^{-3} – 10^{-2} m	Noninvasive virtual lesion method; relatively low cost but usually done with fMRI	Cannot be used with people with tendency to have seizures	Pascual-Leone, Bartres-Faz, & Keenan (1999); Tsujii et al. (2010)

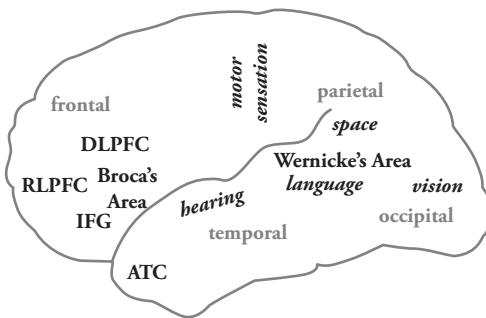

Fig. 6.1 Functional neuroanatomy in higher cognition. The human cerebral cortex is traditionally divided into four lobes based on neuroanatomical landmarks (e.g., the horizontal fissure). These lobes are then frequently further partitioned with respect to smaller anatomical divisions (e.g., prefrontal cortex [PFC], rostralateral PFC [RLPFC], dorsolateral PFC [DLPFC], inferior frontal gyrus [IFG], anterior temporal cortex [ATC]). However, sometimes brain regions are labeled with the name of the scientist who originally ascribed their function (e.g., Broca's or Wernicke's area), the type of information they process (e.g., auditory, sensation, visual), or by their dominant function (e.g., motor movement, language, spatial processing).

the extent that they can produce language, they will produce content words, but not function words that would indicate the use of grammar (Kean, 1977). Thus, more extensive examination of behavioral findings along with the development of new theoretical perspectives can lead to reinterpretations of neuropsychological data.

In the domain of thinking and reasoning, patients with frontal lobe damage are of interest because of the clear involvement of the frontal lobes in complex cognition (see also Holyoak, Chapter 13). Focal lesions to the frontal lobes (e.g., following a stroke) are very common; however, they are likely to be unilateral and restricted, making it likely that spared regions can take over lost functions. In addition,

the location and the extent of the lesions often vary between patients, making it difficult to generalize across cases (see Duncan & Owen, 2000). In investigations of neural mechanisms of reasoning, a great deal of attention has recently focused on patients with frontotemporal lobar degeneration (FTLD; e.g., Huey et al., 2009; Krawczyk et al., 2008; Morrison et al., 2004; Waltz et al., 1999; Zamboni, Huey, Krueger, Nichelli, & Grafman, 2008).² Although these patients are much rarer than those with focal frontal lobe damage, their damage is more encompassing of prefrontal cortex and can thus provide a good picture of its role in higher cognition.

FTLD can present with different clusters of symptoms depending on the regions of initial involvement (Mesulam, 2007; Miller, 2007). Although the disease ultimately progresses to involve multiple brain regions, in early stages it can affect specific regions of the brain more selectively. Those patients in the frontal-variant (also referred to as behavioral-variant) category exhibit executive problems early on in the disease course. Another group of patients, with early involvement in the left temporal lobe, exhibit deficits in semantic knowledge (i.e., semantic dementia). These two patient groups have been studied in the context of thinking and reasoning, as they exhibit a contrasting set of deficits. Using the technique of voxel-based morphometry to quantify the regional extent of damage, it is possible to correlate the extent of degeneration with specific cognitive abilities (Huey et al., 2009; Rosen et al., 2002). These studies have generally shown correlations between degeneration in the anterior frontal lobe and standardized tests of problem solving, whereas degeneration in other regions is strongly associated with other aspects of higher cognition. For example, degeneration in the dorsolateral prefrontal cortex

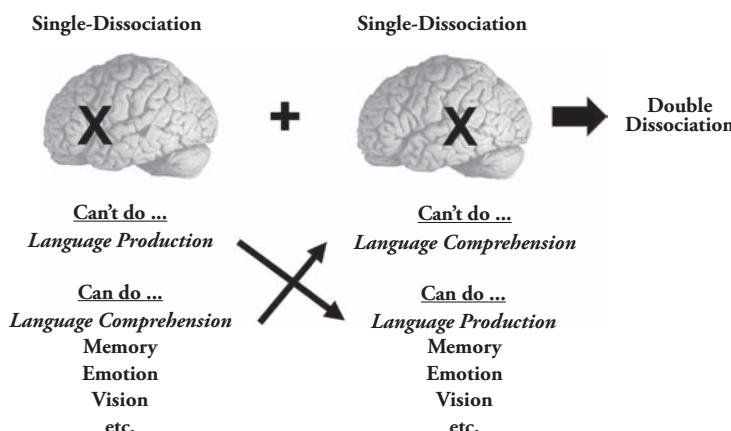

Fig. 6.2 Cognitive neuropsychology. Patient-based methods are typically based on the logic of single or double dissociations.

(DLPFC) is correlated with apathy, while degeneration in the right posterior temporal lobe is related to the patient's insight into his or her own behavioral problems (Zamboni et al., 2008).

Despite the widespread deficits in executive function shown by frontal-variant patients, there is also evidence that there is some selectivity in these deficits. For example, in tests of inductive and deductive reasoning, frontal-variant patients can perform within normal range when solving the problem requires only a single relation to be kept in mind (e.g., a Raven's Progressive Matrix problem that can be solved by considering a change across a single dimension, such as a shape getting larger across a row). However, when the subject must consider multiple relations simultaneously to find the answer (e.g., the shape is getting larger across rows and darker across columns), frontal-variant patients perform at chance levels. These results suggest that relational integration is one of the key contributions to reasoning made by the prefrontal cortex (Waltz et al., 1999).

In contrast to the performance of frontal-variant patients, those with temporal lobe involvement do not appear to have a deficit in relational integration. Rather, these patients exhibit deficits in using semantic knowledge to make inferences (Krawczyk et al., 2008; Morrison et al., 2004), while they are often able to reason about materials for which semantic content is not important, such as the Raven's Progressive Matrices test (Waltz et al., 1999). These results suggest that different neural circuits subserve reasoning about familiar versus unfamiliar domains. One interpretation of these findings is that reasoning based on familiar information necessarily uses the semantic knowledge system—in other words, it is difficult to reason with familiar entities as if they are arbitrary (see Evans, Chapter 8). In contrast, when there is an arbitrary relationship between items, a system for applying formal logical rules is engaged. Based on the results from FTLD patients as well as neuroimaging studies, interactions between frontal and temporal lobes are crucial for reasoning when semantic knowledge is relevant (Krawczyk et al., 2008, Luo et al., 2003; Morrison et al., 2004), whereas frontoparietal circuitry plays a major role in applying formal rules of logic to arbitrary relations (Hinton, Dymond, von Hecker, & Evans, 2010; Noveck, Goel, & Smith, 2004). Because the parietal lobes remain relatively intact in FTLD, these patients are able to solve deductive and inductive reasoning problems with

arbitrary content, particularly if they involve only a limited number of relations. With arbitrary relations, patients with frontal involvement perform poorly when they must consider multiple relations simultaneously in working memory (Waltz et al., 1999) or when activated semantic information competes during reasoning (Krawczyk et al., 2008; Morrison et al., 2004). The study of patients with FTLD has provided strong support for the idea that reasoning with semantically meaningful and arbitrary relations involves different neural circuitry.

Neuroimaging

Cognitive neuropsychology continues to yield new insights into the dissociable processes within the domain of reasoning. However, while this approach emphasizes dissociation, other approaches are needed to understand how regions act cooperatively. Neuroimaging approaches have a distinct advantage over cognitive neuropsychology in that they are noninvasive and involve relatively large numbers of healthy subjects, allowing greater generalizability of their findings. As cognitive neuropsychology depends on “experiments of nature,” there is unavoidable variability between patients in terms of lesion site or course of illness, which can make it difficult to make inferences about those regions responsible for observed deficits. Neuroimaging approaches, on the other hand, allow one to glimpse the intact brain at work. Neuroimaging methods vary with respect to whether they measure the structure or function of the nervous system; however, results from either type of method can be correlated with behavioral measures to provide valuable information about cognitive function. Functional methods can in turn either directly or indirectly measure neural activity. For instance, scalp electroencephalography (EEG) directly measures changes in voltage resulting from firing neurons, whereas functional magnetic resonance imaging (fMRI) indirectly measures neuronal activity by measuring increased blood flow to the area of the brain recently active. A further distinction is between methods that focus on spatial localization (e.g., fMRI) versus those that provide information on temporal dynamics (e.g., EEG).

STRUCTURAL NEUROIMAGING

Although neurologists are able to look at X-rays of the head to see damage to the skull, X-rays are inadequate to image soft tissue such as the brain. In 1974, brain imaging took a huge step forward with the development of computer axial tomography (CT or

CAT scan). This enhanced three-dimensional X-ray was able to resolve gray and white matter as well as blood and cerebrospinal fluid. As a consequence, neurologists were able to see the damage caused by tumors and different types of irregular blood flow (e.g., ischemia and aneurysms). This greatly facilitated cognitive neuropsychology because researchers did not have to wait until a patient died to know what areas of their brain were damaged. The development of magnetic resonance imaging (MRI), with its greater white/gray contrast and finer spatial resolution, allowed for precise volumetric measurement of different brain structures (Raichle, 1994). The state of the art in structural MRI allows researchers to measure cortical thickness (Fischl & Dale, 2000) or white matter integrity (Filler, 2009), correlating it with various types of behavior and even developmental change.

Comparisons can also be made across groups using techniques such as voxel-based morphometry (VBM; Ashburner & Friston, 2000), which allows researchers to spatially normalize brain images into a common stereotactic space, and then make voxel-by-voxel comparisons of the local concentration of gray matter between groups. This technique is particularly useful for demonstrating the similarities of cortical damage in different patients groups. For instance Rosen et al. (2002) used VBM to characterize structural differences in various subtypes of FTLD. Variability in a particular brain region can also be correlated with behavioral changes (see Huey et al., 2009).

In a recent developmental study of reasoning, Dumontheil, Houlton, Christoff, and Blakemore (2010) tested a large group of children using a relational reasoning task that shows major behavioral changes during adolescence. Using structural MRI with both cortical thickness and VBM analyses, they found significant reductions in gray matter but not white matter volume during adolescence in areas of prefrontal cortex functionally involved in relational reasoning. These results suggested that improvements in relational reasoning can be the result of decreases in the number of synapses, allowing for an increase in effective connectivity between brain regions necessary for reasoning.

Although structural MRI allows for excellent contrast between gray and white material, it does not directly measure the integrity of the tissue. In contrast, diffusion tensor imaging (DTI) can be used to appraise the integrity of white matter by using different settings during MRI image capture

(Filler, 2009). The analysis procedure appraises the characteristics of water in the tissue. Clinically, these methods have been used to diagnosis multiple sclerosis and recently have also been potentially helpful in detecting early stages of Alzheimer's disease (Rogalski et al., 2009). Importantly, white matter (the axons of myelinated neurons) connects different regions of the brain, and it is critical for both working memory (frontal/parietal network) and language (frontal/temporal network). Thus, it is likely that differences in connectivity as measured by DTI may be useful for appreciating individual differences in thinking, as well as development.

ELECTROPHYSIOLOGICAL FUNCTIONAL NEUROIMAGING

Single- and Multi-Unit Recording

Our understanding of many basic cognitive functions has been profoundly aided by studies using electrophysiological methods with nonhuman animals. In these studies microelectrodes are inserted into precise locations in the brain and can be used to directly record the firing of either single (i.e., single-unit recording) or small groups (i.e., multi-unit recording) of neurons (see Humphrey & Schmidt, 1990). This technique produces results with excellent temporal and spatial resolution—we know exactly when and where neurons are firing when a particular cognitive process is engaged. This information is particularly useful when cognitive processes can be clearly defined. For instance, if we would like to know what neurons respond to the spatial frequency of a visual pattern, we can place electrodes in various regions in primary visual cortex and locate neurons that fire to a particular spatial frequency, but not other frequencies. Similarly, we can ask whether there are cells that are specifically sensitive to face stimuli and not other complex visual objects.

Unfortunately, it is frequently difficult to isolate cognitive processes underlying thinking and reasoning with this same degree of precision. As Penn and Povinelli argue in Chapter 27, it is very likely that humans differ from even their nearest primate relatives in the nature of relational representations and processing. Despite these limitations, electrophysiology in the macaque monkey has provided some insight into the functions of the prefrontal cortex for higher cognition. Much of higher cognition, particularly System II or explicit processing (see Evans, Chapter 8), depends heavily on the working memory system for the maintenance

and manipulation of information (see Morrison, 2005). Seminal studies in the macaque by Fuster and Alexander (1971) demonstrated that neurons in prefrontal cortex selectively fire during the delay in delayed match-to-sample tasks, in which a monkey is required to match a target to a previously displayed sample object shown before a brief delay. In an elegant study using cortical cooling to temporarily deactivate connective fiber tracts, Fuster, Bauer, and Jervey (1985) went on to demonstrate that prefrontal neurons were not simple buffers for the temporary storage of information, but rather were responsible for maintaining the activity of neurons in posterior cortex, which actually coded for the information being maintained. Consistent with Cowan's (1995) conception of working memory as a process of selective attention, Fuster's finding illustrates one central "truth" of higher cognition—brain regions dynamically collaborate to accomplish complex processes.

Electrocorticography

The invasive nature of single- and multi-unit recording typically prevents its use in humans. One exception is in patients with intractable epilepsy. These patients frequently have surgery to remove parts of the brain (usually in the temporal lobe) responsible for initiating or propagating seizures. In preparation for surgical resection, patients frequently have electrodes placed directly on the brain under the skull and dura matter. In some cases electrodes capable of single- or multi-unit recording are even inserted into the cortex (i.e., depth electrodes). Patients are monitored for up to several weeks waiting for seizures to occur. During this period patients typically participate in a variety of cognitive studies, which allow researchers to correlate brain activity with function (see Miller et al., 2007). Although this provides an excellent opportunity for directly recording the activity of neurons in humans, caution must be exercised in interpreting results because of the pathology associated with epilepsy in these patients.

One recent example of how electrocorticography (ECOG) can be used to constrain cognitive models, demonstrated that different areas of cortex communicate with each other during behavioral tasks by precise timing of different populations of neurons firing at different frequencies (Canolty et al., 2006). It was hypothesized that these communication patterns may be regulated by GABAergic inhibitory neurons in the basal forebrain. In general, it

appears that local, domain-specific neural circuits communicate using high frequencies (e.g., *gamma*) while more distant cross-domain circuits use lower frequencies (e.g., *theta*; Canolty & Knight, 2010). These observations are consistent with those symbolic-connectionist accounts of higher cognition (see Doumas & Hummel, Chapter 5) that use temporal synchrony as a binding mechanism for representing explicit relational structures necessary for relational thinking and reasoning.

Scalp Electroencephalography

The ability to directly record electrical activity from the brain began long before the advent of single- and multi-unit recording. In 1929 Hans Berger first used electrodes on the scalp to record the summation of voltage changes associated with the firing of millions of neurons. This early method of neuroimaging showed rhythmic patterns associated with different states of consciousness. For instance, cycles of approximately 10 times per second (10 Hz, *alpha*) were detected in electrodes over the occipital lobe during sleep or periods when an individual's eyes were closed. The method of scalp electroencephalography (EEG) was used for many years to diagnose a number of different medical conditions, including epilepsy.

Event-Related Potentials

The true power of EEG for neuroimaging was not realized until computing advances allowed for large numbers of measurements to be summed (Galambos & Sheatz, 1962). The resulting event-related potentials (ERPs) can be time locked to particular events, such as the presentation of a stimulus, or a button press in response. Averaging many time-locked trials increases the signal-to-noise ratio, resulting in a smooth waveform with characteristic positive and negative peaks (see Fig. 6.3). Over thousands of experiments, researchers have associated many of these peaks with particular cognitive processes (For a detailed introduction to EEG/ERP methods, see Luck, 2005; Luck & Kappenman, 2012).

Typically, researchers compare ERPs from different within-subject conditions to isolate particular neural components; however, ERPs can also be used to compare different groups as well. Here we briefly consider two different studies showing the power of ERPs to elucidate the function of prefrontal cortex. In general, one important function of prefrontal cortex is to filter information. The filtering can either take the form of tonic gating, serving

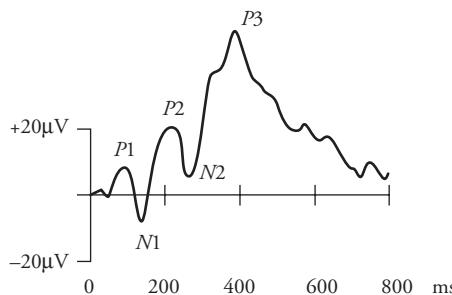

Fig. 6.3 Sample ERP. Averaging many trials from the same condition in an experiment improves the signal-to-noise ratio of time-locked EEG signal, resulting in an event-related potential with positive and negative peaks, which can sometimes be associated with particular cognitive processes.

to down-regulate sensory input from the outside world, and thereby avoiding distraction (Knight, Scabini, & Woods, 1989); or dynamic filtering to manage the contents of working memory for a current goal (Vogel, McCollough, & Machizawa, 2005). These are both essential aspects of executive functioning necessary for higher cognition that rely on prefrontal cortex.

Knight, Scabini, and Woods (1989; see also Knight & Graboweczyk, 1995) provided one early example of how ERPs can be used in conjunction with cognitive neuropsychology. They exposed patients with damage to DLPFC, or age- and education-matched control participants, to a sound recording of simple auditory clicks. These sounds produce positive deflections in the ERP within 30 ms of the click (P30). A group analysis revealed that patients and controls showed similar P30 ERPs when recorded from posterior electrode positions, whereas patients showed much more positive P30s than controls when the ERP was measured from parietal-, temporal-, or frontal-positioned electrodes. This pattern suggests that a functioning DLPFC serves to protect the higher cortical areas from sensory distraction by down-regulating signals.

A second ERP study investigating this issue explored how the ability to dynamically filter information can determine effective working-memory capacity. Numerous studies have linked individual differences in working-memory capacity with the ability to reason (Conway, Kane, & Engle, 2003). Vogel et al. (2005) used a delayed match-to-sample paradigm, similar to that used by Fuster in monkeys, in humans who were divided into two groups based on their individual working-memory spans (Conway et al., 2005). In Vogel et al.'s task participants had to remember the exact location and orientation

of several color bars over a delay. There were three different task conditions: (1) remember two bars of one color, (2) remember four bars of two different colors, or (3) remember two bars of one color and ignore two bars of a different color. Thus, the two latter conditions (2 and 3) had identical stimuli, with only the task differing. Vogel et al. isolated a contingent negative variation (CNV) in the EEG signal that began when the sample stimuli disappeared and persisted during the delay before participants were to respond to a target. The CNV thus appears to be an analog to the neural activity observed by Fuster using single-unit recording in nonhuman primates. Vogel and colleagues demonstrated that the CNV was modulated by working-memory load, with greater loads (remember-four) resulting in a more negative CNV than smaller loads (remember-two). However, they found that for people with low working-memory span, the remember-two and ignore-two condition produced the same CNV as the remember-four condition, while for high working-memory span people, the CNV for the remember-two and ignore-two condition looked like that for the remember-two condition. Thus, it appears that people with greater working-memory spans do not have greater working-memory capacities; rather, they simply manage the capacity they have more efficiently via dynamic filtering as regulated by prefrontal cortex.

Event-Related Oscillations

While the vast majority of EEG studies in cognitive neuroscience to date have used ERP analysis techniques, ERPs collapse the voltage data in such a way as to obscure the true nature of neuronal firing patterns. Clusters of neurons found in neural circuits tend to fire in oscillatory waves with characteristic frequencies. To capture this information, an increasing number of EEG studies in cognitive neuroscience have begun to employ what we term here event-related oscillation analyses (ERO; see Sauseng & Klimesch, 2008). These analyses are based on mathematical techniques (Fourier transform or wavelet analysis) that transform the recorded voltage changes into a frequency spectrum. Thus, researchers can estimate the relative populations of neurons firing at different rates. This is the type of analysis used in the ECOG study described previously (Canolty et al., 2006), but it can also be used with standard EEG recording as well.

Van Steenburgh et al. (Chapter 23) describe several different studies using time-frequency analysis to investigate the role of insight in problem

solving. In one study, Jung-Beeman et al. (2004) found two notable differences between problems that participants solved with or without insight. First, in problems solved with insight, they measured a sustained burst of low-alpha (around 10 Hz) EEG activity over the right parietal-occipital cortex beginning 1.5 seconds before the participant reported an answer. Low-alpha activity over visual cortex is understood to reflect visual sensory gating; thus, the brief deactivation of visual cortex may reflect a reduction of distracting sensory inputs needed in preparation for insight. Second, just 300 ms before answering, a burst of higher frequency gamma (30–80 Hz) activity over the right anterior temporal cortex was measured. The anterior temporal cortex is believed to be important for semantic integration, so it is likely that this burst is the signature for this cognitive process.

Although time-frequency analyses are frequently performed time-locked to stimuli or responses, they can also be used as a more general appraisal of cognitive state. In addition to the time-locked findings mentioned in the previous paragraph, Kounios et al. (2006) found that low-alpha EEG activity (8–10 Hz) prior to problem solving predicted whether a participant would solve the ensuing problem with insight, with greater alpha signifying a greater likelihood of a solution with insight. Likewise, many researchers have found that frontal asymmetries in low-alpha EEG activity also predict trait tendencies with respect to a general withdrawal or avoidance system (Davidson, 1993).

This type of analysis will likely prove increasingly useful as researchers in higher cognition seek to model the temporal dynamics of neuronal circuits. Changes in these dynamics have already been shown to provide parsimonious accounts for changes in reasoning associated with cognitive development (Morrison, Doumas, & Richland, 2011), aging (Viskontas, Morrison, Holyoak, Hummel, & Knowlton, 2004), and brain damage (Morrison et al., 2004).

SPATIAL FUNCTIONAL NEUROIMAGING

Spatial functional neuroimaging techniques make it possible to locate regions of activity in the brain with a greater level of precision than is possible with noninvasive electrophysiological techniques, such as EEG (see Table 6.1). Despite advances in source localization, there is nevertheless some ambiguity as to the brain regions that are contributing to an EEG signal because voltage is measured on the scalp, far from the many potential source generators. As a

result, a given pattern of electrical activity as measured on the scalp can arise from activation in many different areas of cortex. Techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) can be used to link cognitive functions with specific locations in the brain (see Cabeza & Nyberg, 2000). Both of these techniques measure biophysical changes associated with metabolic activity and exploit the fact that neural activity requires energy. Thus, locations where there is more neural activity should be the source of greater metabolic activity. Thus, unlike EEG these techniques provide an indirect measure of neural activity; however, the greater spatial resolution they provide has been a key factor in the growth of cognitive neuroscience.

Positron Emission Tomography

In the 1980s, positron emission tomography (PET) became the first widely used functional neuroimaging technique providing adequate spatial resolution (see Raichle, 1983). In the most commonly used PET procedure, blood flow is measured using a radioisotope of water. Participants must be injected with this radioactive material, but the short half-life (about 123 seconds) renders it relatively safe. Blood flow (and thus the water isotope) is increased to regions that are metabolically active, and it can be detected by sensors outside the head. Complex mathematics implemented in a computer are used to build a three-dimensional map of where the changes in metabolic activity are located in the brain. A similar method, single-photon emission computed tomography (SPECT scan) is frequently used diagnostically by neurologists to characterize potential brain damage in patients showing abnormal behavior. Early studies using the PET procedure studied memory and perception. For example, regions that were determined to be involved in vision based on recordings from neurons in animal models were shown to have increased blood flow during visual tasks. Confirmatory studies such as these provided support for the validity of the PET technique.

Although fMRI has since eclipsed PET for the purpose of localizing cognitive functions to particular brain regions, PET remains an important technique for examining the role of neurotransmitters in cognitive function. These can be radiolabeled so that the uptake of the specific neurotransmitter in different brain regions can be localized (e.g., Okubo et al., 1997). Using specialized isotopes, PET has also found important diagnostic applications, including

the early detection of Alzheimer's disease (e.g., Villemagne et al., 2011).

Functional Magnetic Resonance Imaging

There are several advantages to the use of functional magnetic resonance imaging (fMRI) compared to PET. Rather than using radiation, fMRI measures the oxygenation level of blood in particular regions of the brain, and it exploits the fact that a magnetic field is disturbed differently based on the amount of oxygen in the blood. Because there is more oxygenated blood in regions where there is more neural activity, the BOLD (blood oxygenation level dependent) signal can be used to indirectly assess relative activity of brain regions (see Fig. 6.4). With PET, the exposure to radiolabeled compounds limits the frequency with which subjects can be tested, thus making it difficult to test changes across time or practice in individuals.

A major advantage of fMRI is that it has far greater spatial and temporal resolution than PET (Brown, Perthen, Liu, & Buxton, 2007; Raichle & Mintun, 2006). The BOLD signal can resolve changes in regions as small as a cubic millimeter using some specialized techniques. This enables researchers to test more precise anatomical hypotheses than are possible with PET or EEG measures. fMRI also is more temporally precise than PET, although the hemodynamic response still takes many seconds to develop. With fMRI, it is possible

to measure BOLD signal associated with individual trials (Glover, 1999). This advance enabled a much wider range of experimental paradigms than were possible with PET. For example, one could intermix trials with varying demands or eliminate trials in which the subject made an error. However, it remains the case that fMRI cannot provide the kind of millisecond temporal resolution that is possible with direct neural activity measures such as EEG or ECOG.

Ongoing work using fMRI methods may be able to gain leverage on issues that have proved difficult to resolve through behavioral experimentation alone. For example, there have been two general approaches to understanding how humans solve reasoning problems (see Evans, Chapter 8). According to one view, humans reason based on innate logical rules. According to another view (see Johnson-Laird, Chapter 9), we form a mental model of the premises of a problem and then identify solutions by scrutinizing the model. If we assume that mental logic rules are linguistic and propositional in nature (Braine, 1998; Rips, 1994), one might expect that reasoning should engage left hemisphere regions that are active during syntactic processing. By the mental models view, solving problems that involve relations that can be represented spatially (taller-than, better-than) should activate visuospatial regions in the right hemisphere (Knauff, Fangmeier, Ruff, & Johnson-Laird, 2003; Knauff & Johnson-Laird,

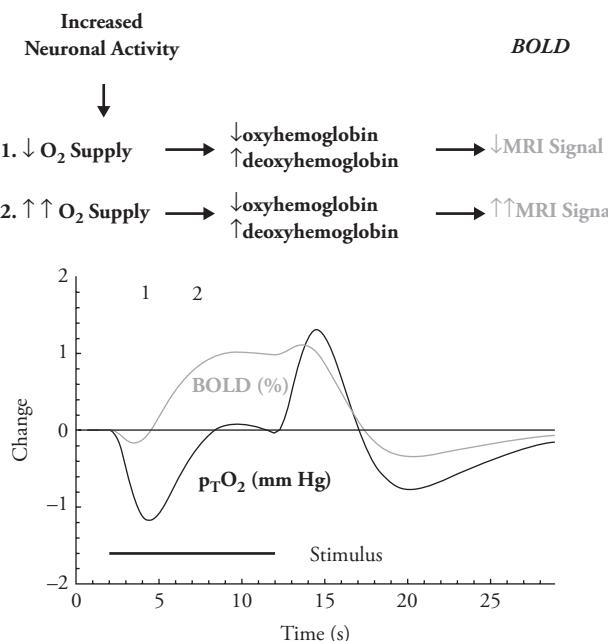

Fig. 6.4 Function magnetic resonance imaging (fMRI) is based on the hemodynamic response resulting from increases in metabolism in active neurons.

2002). At this point, existing fMRI data do not unequivocally support one view over the other, as the regions that are active during reasoning vary considerably depending on the task and the content of the reasoning problem. For example, solving syllogisms that are devoid of semantics such as (if P then Q, there is P, is there Q?) results in activation in left frontal-parietal pathways, whereas similar problems that use meaningful terms (If it is sunny, I ride my bike; I did not ride my bike today, is it sunny?) activate frontal and temporal lobe regions involved in semantic processing. Interestingly, when semantic knowledge or perceptual features of the problem are incongruous with the logical conclusion (If it is snowing, I ride my bike; I did not ride my bike today, is it snowing?), activation is also seen in right lateral midfrontal regions and the anterior cingulate (Goel & Dolan, 2003; Prado & Noveck, 2007), two areas that are implicated in cognitive control and conflict resolution. The fact that people often make errors when the logical conclusion of a problem is inconsistent with prior knowledge (the belief-bias effect, discussed later) can be viewed as a failure of engagement of these control circuits.

Overall, data from fMRI studies suggest that reasoning does not engage a dedicated neural circuit. Reasoning does not necessarily activate the right hemisphere regions involved in visuospatial processing, nor does it necessarily involve the same left hemisphere regions that are active during language processing (Kroger, Nystrom, Cohen, & Johnson-Laird, 2008; Noveck et al., 2004). However, these regions are engaged in some studies, supporting the possibility that rule application and visuospatial mental models can both support reasoning performance.

A view that is consistent with the mixed fMRI findings is that deductive reasoning involves a set of fractionated neural systems, each supporting different forms of relational reasoning (Goel, 2007). For example, although conditional reasoning (such as if-then problems) about unfamiliar information appears to rely on left frontoparietal regions, relational reasoning (e.g., Abe is to the left of Bill, and Bill is to the left of Charles; is Abe to the left of Charles?) relies in part on bilateral regions of the brain that have been implicated in visuospatial function, including the temporal-parietal-occipital junction (Goel & Dolan, 2004; Prado, Van Der Henst, & Noveck, 2010). Reasoning problems that involve semantically meaningful materials engage left temporal lobe storage sites for semantic information

(Goel, Buchel, Frith, & Dolan, 2000), consistent with the specific deficits in semantically meaningful problems exhibited by temporal-variant FTLD patients described earlier (Krawczyk et al., 2008; Morrison et al., 2004). The picture that appears to be emerging from these studies is that humans did not evolve a single reasoning system, but rather multiple systems suited to different problem domains are involved. Humans may have several reasoning systems at our disposal, including both rule-based mental logic and visuospatial mental models, and rely on whichever corresponding neural system is best suited for the problem (Prado et al., 2010).

Although fMRI studies to date do not seem to support any general theory of human reasoning, these studies together have consistently shown that deductive reasoning engages regions distinct from those involved in linguistic processing (Monti, Osherson, Martinez, & Parsons, 2007). While left hemisphere regions, including Broca's area in the inferior frontal gyrus (IFG), are often activated during deductive reasoning (Goel & Dolan, 2004), it is unclear if this is because language processing is required to understand the premises of a problem, or because these regions are generally important for syntactic processing that is common to both linguistic processing and logical reasoning. Based on fMRI approaches that allow the hemodynamic activity to be identified as the subject is processing different phases of the problem, it appears that although language areas in the frontal lobes are active for the initial interpretation of the premises, this activation quickly recedes to baseline, and nonlinguistic frontoparietal areas become active while the subject is actually solving the problem (Monti, Parsons, & Osherson, 2009). Thus, linguistic and logical rules used during reasoning appear to depend on distinct regions that occupy neighboring regions in left hemisphere, and fMRI data are at least making a good case that reasoning and thought can operate independently at the neural level. In addition, the existence of right hemisphere activation in several reasoning studies also suggests nonlinguistic processes may be engaged. For example, the involvement of right superior parietal lobule in these studies (Eslinger, et al. 2009; Goel & Dolan, 2003) is consistent with the idea that reasoning often involves the mental representation and manipulation of spatial information.

Although most fMRI studies of higher cognition have aimed to elucidate the various brain areas important for processing, there has been increasing

interest in understanding how these regions work together. In fact, the temporal dynamics of brain networks may be equally as important in higher cognition as simple activation. A dramatic example involving human language processing is a study by Sonty, Mesulam, Weintraub, Parrish, and Gitelman (2007), who used fMRI in conjunction with the cognitive neuropsychology approach. Patients with primary progressive aphasia (PPA; Mesulam, 2007; see also note 2), a neurodegenerative disease, show progressive loss of language functions, including the ability to name words and to appreciate the semantic relationships between concepts. Sonty et al. had patients with PPA, and age- and education-matched control participants, perform a semantic matching task (identify synonyms) and a letter-matching task (match nonword letter strings). Patients were less accurate than controls at the semantic task and slower on both tasks. Using fMRI, Sonty et al. found that several brain regions in the left hemisphere frequently associated with language (posterior fusiform gyrus, posterior superior temporal sulcus [Wernicke's area], IFG [anterior Broca's area], inferior parietal lobule, intraparietal sulcus, and ventral premotor cortex) were more active in the semantic than the letter task. Interestingly, these areas were not less active in patients than in controls, despite the poorer performance in patients. However, when Sonty et al. examined effective connectivity between these regions using dynamic causal modeling (DCM; Friston, Harrison, & Penny, 2003), a different story emerged. DCM uses a Bayesian decision algorithm to make estimates of how different brain regions affect each other via mono or polysynaptic interregional connections. Sonty et al. found that when patients were compared to controls, a significant decrease was found in connectivity between posterior superior temporal sulcus (Wernicke's area) and IFG (anterior Broca's area), and this decrease correlated with reduction in performance. Thus, in PPA it was not a change in activation *per se* that was responsible for changes in behavior, but rather the effectiveness of communication between areas. It is likely that connectivity patterns affect capabilities throughout higher cognition and may in part explain the dramatic individual differences and developmental patterns seen in cognitive abilities.

NEW METHODS FOR FUNCTIONAL NEUROIMAGING

Although EEG and fMRI currently dominate the neuroimaging methods used to study thinking

and reasoning, two new methods offer exciting possibilities for the future given their lower cost and better temporal resolution (relative to fMRI) and their superior spatial resolution (relative to EEG).

Magnetoencephalography

Like EEG, magnetoencephalography (MEG) directly measures neural activity; however, instead of measuring voltage, it utilizes the electromagnetic properties of the electrical charge associated with neurons to measure minute magnetic forces resulting from increases in neuronal firing (see Hansen, Krriegelbach, & Salmelin, 2010). According to Faraday's Law, magnetic forces exist perpendicular to current flow and as a result the magnetic forces do not spread as much as the voltage differences measured by EEG. Thus, the potential source generators for MEG signal are better constrained than those potentially responsible for EEG signal. Like EEG, MEG can be sampled with millisecond resolution. Also like EEG, the participant experience is quite noninvasive, allowing some participant movement during testing and good experimenter access to the participant. Like fMRI, MEG can also be used to examine when different brain regions tend to sequentially activate via DCM (Kiebel, Garrido, Moran, Chen, & Friston, 2009). As a result, MEG is rapidly becoming the preferred functional neuroimaging technique for imaging young children and infants. Thus, MEG will likely be important for understanding early changes in language and reasoning. For example, MEG has recently been used to compare 10-year-old children and adults in terms of the engagement of frontoparietal networks during working-memory processes (Ciesielski, Ahlfors, Bedrick, Kerwin, & Hamalainen, 2010). Even though the children and adults exhibited the same level of performance on an n-back task, differences in MEG signal in the two groups indicated that the children were relying on different neural mechanisms compared with adults.

Functional Optical Imaging

Functional near infrared spectroscopy (fNIRS) involves placing infrared light emitters and detectors on the scalp (see Villringer & Chance, 1997). The light penetrating the scalp is absorbed by oxy- and deoxyhemoglobin in the blood. The reflected wavelengths can then be measured, and the concentration changes as a result of neuronal activity can be estimated. Unlike fMRI, the NIRS response can measure both oxy- and deoxyhemoglobin,

with millisecond accuracy; however, just as with fMRI there is a delay in the beginning of the signal, because both techniques rely on measuring the hemodynamic response. NIRS equipment is relatively inexpensive, and unlike fMRI it costs very little to run the equipment. Thus, it is possible to run a larger number of participants in a study and thus potentially capture smaller behavioral effects. However, one problem with NIRS is that it can only detect neuronal activity in gray matter within approximately 1 cm of the scalp surface. While this limitation may prevent using NIRS to study the functions of subcortical structures, regions of the prefrontal cortex involved in working memory and reasoning are readily accessible using this technique. Like MEG, NIRS is being used in populations who cannot be tested in fMRI, including infants and young children.

An even more recently developed technique, event-related optical signal (EROS; Gratton et al., 1997), uses infrared light like fNIRS, but instead of measuring the hemodynamic response like fMRI it takes advantage of the light scattering qualities of neurons undergoing action potentials. Thus, EROS has a temporal latency (100 ms) closer to EEG and MEG than the multisecond latency of fMRI and fNIRS. Like NIRS, EROS can be sampled with millisecond frequency.

Tsujii and Watanabe (2010) recently used fNIRS to investigate the belief-bias effect, which has been explained using dual-process theory (Evans, Chapter 8). In this paradigm participants are asked to solve syllogisms in which the logical conclusions are either true (congruent) or not true (incongruent) about the world. The general finding is that participants are more likely to make reasoning mistakes when the logical conclusions are not factually correct—an effect that is enhanced when reasoning is speeded. Explanations based on dual-process theory argue that when resources (e.g., time) are limited, participants defer to a fast System I heuristic based on whether they believe the conclusion, rather than assessing whether it is logically correct. In contrast, when time is plentiful, participants use slower System II analytic processing. Tsujii and Watanabe used fNIRS to look at activity in right and left IFG, an area of the prefrontal cortex frequently associated with cognitive inhibitory functions, and an area they believed would be necessary to inhibit System I heuristic processes in order to choose the logically correct solutions when solving incongruent syllogisms. Their results were consistent

with this hypothesis. Specifically, they found that right IFG increased in activity on long-incongruent trials relative to short-incongruent trials, and that right IFG activity was correlated with the accuracy of individual participants on incongruent trials. These findings are broadly consistent with previous findings of right lateral prefrontal activation during incongruent trials (Goel & Dolan, 2003), and they extend these results in that they demonstrate a relationship between IFG activity and performance, and the ability to overcome belief-bias with time on each trial. The effects sizes in the Tsujii and Watanabe (2010) experiment were very modest, and they tested 48 participants in the study, something that would not have been feasible in an fMRI experiment due to expense.

Virtual “Lesions” Using Transcranial Magnetic Stimulation

Approaches such as EEG and fMRI seek to measure the output of the brain, and then correlate this activity with concurrent cognitive functions. Thus unlike cognitive neuropsychology, these approaches are unable to demonstrate whether this activity is necessary for the observed cognitive function. It is always possible that the activity that is measured is in fact supporting some incidental cognitive process. For example, activity associated with performance of a reasoning task could be related to incidental learning of the responses, or mental imagery, rather than the reasoning processes in question. Transcranial magnetic stimulation (TMS) allows the experimenter to alter function in a brain region and then measure the extent to which various cognitive functions are affected (see Pascual-Leone, Bartres-Faz, & Keenan, 1999). TMS relies on the fact that a magnetic field will induce an electric current orthogonal to the direction of the field. This induction is not impeded by the scalp or skull, so an electromagnetic coil held at the surface of the head can induce current in the brain tissue below. When TMS is administered as repetitive pulses, the effects of the current can be long lasting. In most experimental studies, TMS is used to disrupt function. However, if different stimulus intensities are used, it can also be used to enhance function. TMS given for extended periods over several sessions has been shown to be an effective treatment for some neurological and psychiatric disorders, as it appears to induce functional changes in activity (Wassermann & Lisanby, 2001).

Similar to the limitations of NIRS and EROS, a major disadvantage of the TMS technique is that

it is currently only possible to apply stimulation to regions on the surface of the brain that are accessible to the field generated by a coil. While thinking and reasoning certainly make use of subcortical structures, the frontoparietal network is clearly of great importance and accessible to TMS. For example, Tsujii et al. (2010) were able to follow up their NIRS study described previously using repetitive TMS to disrupt the region in the right IFG they found to be active when subjects needed to inhibit semantic-based heuristic processing to solve reasoning problems. As predicted, repetitive TMS applied to the right IFG interfered with performance on incongruent trials, thus enhancing the belief-bias effect.

TMS can be used in conjunction with neuroimaging techniques to examine whether regions of activation detected are in fact necessary for task performance. However, several important questions may be impossible to address with TMS, such as the interactions between cortical and subcortical structures in thinking (e.g., cortico-striatal loops) or the influence of emotion on thinking mediated by the amygdala.

Computational Modeling of Neural Systems

Computational modeling has greatly contributed to the development and testing of theories of thinking and reasoning at the computational and algorithmic levels of analysis (see, e.g., Doumas & Hummel, Chapter 5; Rips et al., Chapter 11; Buehner & Cheng, Chapter 12; Holyoak, Chapter 13; Koedinger and Roll, Chapter 40). Relatively little effort, however, has focused on understanding thinking and reasoning at the implementation level. Most implementation-level modeling of brain circuits has been based on connectionist architectures (e.g., Braver, Barch, & Cohen, 1999; O'Reilly, 2006), sometimes augmented with Bayesian decision rules. While these architectures and algorithms can capture many System I types of learning, they fail to capture many System II forms of thinking and reasoning that require explicit representation of relations (see Doumas & Hummel, Chapter 5). Notable exceptions include Anderson and colleagues (Anderson, Albert, & Fincham, 2005; Anderson et al., 2004) ACT-R model of problem solving, and Hummel and Holyoak's (1997, 2003) LISA model of relational reasoning.

ACT-R is a symbolic production system computer model of human cognition, including problem solving. ACT-R serves as a high-level programming language, including many basic assumptions about how cognition works but also allowing users to add

additional task-specific assumptions. ACT-R can make predictions for such indicators of task performance as response time or accuracy. Although ACT-R was not designed with brain architecture in mind, researchers have recently attempted to map several of ACT-R's basic functions to brain areas, and then to use this information to match fMRI activation patterns to the functioning of the model as it solves a complex problem, such as the Tower of Hanoi (see Bassok & Novick, Chapter 21). In a series of studies that attempted to isolate cognitive processes in ACT-R with relatively simple tasks, Anderson et al. (2005) associated a posterior parietal brain region with changes in problem representation, a prefrontal brain region with retrieval of task-relevant information, and an area in primary motor cortex with programming of manual responses.

Hummel and Holyoak's LISA model (1997, 2003; see also Doumas & Hummel, Chapter 5, and Holyoak, Chapter 13) is a symbolic-connectionist model that aims to provide a unified account of analogical retrieval, mapping, inference, and relational generalization. LISA solves the relational binding problem by a form of dynamic binding implemented via temporal synchrony. Temporal synchrony is a fundamental property of neural circuits, as evidenced by the rhythmic oscillations evident in raw EEG signals. The use of temporal synchrony as a binding mechanism was first demonstrated via single-cell recording in cat visual cortex (Gray, Engel, Konig, & Singer, 1992), and it has been proposed as a general binding mechanism in the brain (see Singer, 1999). LISA uses temporal synchrony to bind relational representations in working memory. Specifically, propositional structures like *chase* (cat, mouse) are "thought about" in LISA by firing semantic units capturing what it is to chase, and to be a cat, at the same time; and conversely firing units capturing what it is to be chased, and to be a mouse, at the same time, but out of synchrony with *chase* (cat). See Morrison, Doumas, and Richland (2011) for a recent detailed description of LISA's functioning using these types of representations.

While the early papers on LISA remained agnostic regarding the neural substrate of different functions in the model, cognitive neuroscience studies provide a basis for some conjectures (see Fig. 6.5). Based on the previously discussed study by Fuster, Bauer, and Jervey (1985), it appears likely that DLPFC is involved in activating representations for objects and relations that are maintained in posterior cortex (Fig. 6.5b). This process

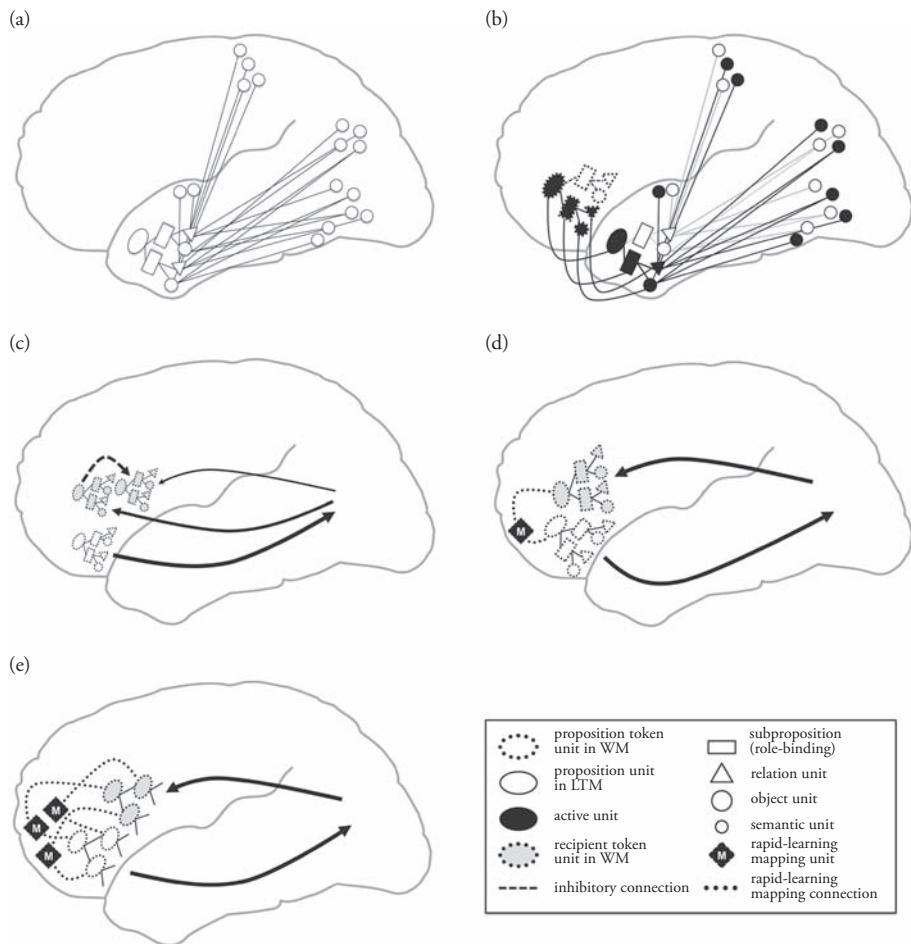

Fig. 6.5 LISA in the brain. (a) Networks responsible for relational representations in long-term memory are likely located in anterior temporal cortex, with their distributed semantic units found in regions responsible for sensation and perception, language, and spatial processing. (b) Thinking about a proposition (e.g., *loves* (Bob, Debbie)) in LISA entails forming dynamic proxy units (Duncan, 2001) in prefrontal cortex (PFC). LISA fires separate subpropositions (e.g., *lover+* Bob) and their connected object (e.g., Bob) and relation (e.g., *loves*) units synchronously. These units pass activation to their static counterparts in long-term memory, effectively bringing long-term memory representations into active working memory (Cowan, 1995; Fuster et al., 1985). Subpropositions for a given proposition alternate being activated in working memory through a process of reciprocal activation and inhibition (i.e., black-and-white units in figure would oscillate out of synchrony with one another). (c) An analog's activation is computed by the rapid-learning mapping units by integrating (over time) the activations of all propositions in that analog. Because of the distributed nature of representations in LISA, more than one potential recipient analog may initially be activated. The probability that a given analog will be retrieved from long-term memory is proportional to its activation divided by the sum of the activations of all analogs. (d) During the pattern of synchronous firing, activation spreads through semantic units in posterior regions of the cortex and gradually activates analogous units in the recipient. Once again dynamic proxy units form in prefrontal cortex. Rapid-learning mapping units in prefrontal cortex (Assad et al., 1998; Cromer, Machon & Miller, 2010) track synchronously active units between the driver and recipient analogs via Hebbian learning and thus learn analogical mappings. Although in this figure only proposition units are shown connected via a rapid-learning mapping unit, all dynamic proxy units in prefrontal cortex (i.e., proposition, subproposition, object, relation) are hypothesized to connect to analogous units via these mapping-unit neurons. (e) Higher order relations (propositions taking propositions as fillers) activate more anterior regions of prefrontal cortex (e.g., Kroger et al., 2002), most likely because of the greater need to track analogical mappings via rapid-learning mapping units.

likely also requires the involvement of IFG to inhibit competing representations (Cho et al., 2010). LISA assumes that propositions are stored in long-term memory as conjunctive codes, perhaps in anterior temporal cortex (Morrison et al.,

2004), with the hippocampus serving to form and later retrieve the conjunctive codes. The process of analogical mapping appears to be dependent on rostralateral prefrontal cortex (Fig. 6.5d; Bunge, Helskog, & Wendelken, 2009; Bunge, Wendelken,

Badre, & Wagner, 2005; Nikitin & Morrison, 2011). The role of the rostralateral prefrontal cortex (RLPFC) in reasoning appears to increase with the complexity of the task-relevant relations (Fig. 6.5e; Kroger et al., 2002). The anterior cingulate is also important for conflict monitoring, particularly in preparation of a decision concerning mapping (Cho et al., 2010; Kroger et al., 2002; Kroger et al., 2008).

The Role of the Frontal Lobes in Human Intelligence

A consistent finding across the range of methodologies employed in cognitive neuroscience is that the frontal lobes play a crucial role in high-level cognitive abilities (Cabeza & Nyberg, 2000; Duncan & Owen, 2000). But while the role of the frontal lobes in intellectual function is fundamental, it is also circumscribed. Intelligence has been typically understood as being of two different forms: crystallized intelligence, including semantic knowledge; and fluid intelligence, which supports abstract reasoning, especially in novel situations. Fluid and crystallized intelligence are differentially affected by aging and brain damage, indicating different neural substrates. Whereas patients with degenerative disease involving the temporal lobes exhibit impaired knowledge of concepts and categories (Krawczyk et al., 2008; Miller, 2007; Morrison et al., 2004), patients with frontal lobe involvement show deficits in problem solving (Holyoak & Kroger, 1995). Frontoparietal circuits are active during fMRI scanning while subjects perform fluid reasoning tasks, such as the Raven's Progressive Matrices (Kroger et al., 2002; Prabhakaran, Smith, Desmond, Glover, & Gabrieli, 1997). It appears that people with a high degree of fluid intelligence further engage regions including the DLPFC and posterior parietal lobule when problems become more complex, whereas individuals with low fluid intelligence scores activate these regions more than those with high fluid intelligence when solving easier problems but do not show this increase when problems become more complex (Perfetti et al., 2009). It is as if moderately difficult problems "saturate" this frontoparietal system in those with low fluid intelligence. High fluid intelligence may be characterized by the ability to effectively engage these circuits.

The comparative anatomy of the frontal lobes, and the fact that they are more highly developed in humans than in other animals, supports the role for the frontal lobes in cognitive abilities that

are most highly developed in humans (Robin & Holyoak, 1995). The posterior part of the frontal lobes includes motor cortical regions, while more anterior, prefrontal regions have more abstract functions. Given the large size of the prefrontal cortex, it seems likely that different subregions have different functions. While there are distinct cytoarchitectonic subregions, these regions are heavily interconnected, suggesting cooperation.

Data from neuroimaging studies often show a great deal of convergence in terms of the regions that are activated in the prefrontal cortex. A number of different tasks involving cognitive control, which includes processes such as resolving response conflict, generation, working-memory manipulation, and categorization, all appear to activate a common set of regions in the lateral prefrontal cortex, dorsal anterior cingulate, and often the premotor cortex (Duncan & Owen, 2000). An increasingly popular method used to define circuits is to assess functional connectivity by measuring the correlation of BOLD signal in different brain regions (Cole & Schneider, 2007). For example, activity in the DLPFC and the anterior cingulate is correlated during task performance, and also when the subject is at rest and not performing any task. These findings indicate that these regions are interconnected and comprise part of a functional network for cognitive control. This network may subserve some process that is common to a diverse set of tasks requiring cognitive control. On the other hand, it may be that this network supports several different functions. If the latter is the case, it may prove difficult to pinpoint the cognitive functions of the prefrontal cortex because these circuits contribute flexibly to cognition.

The cognitive control network comprises a large area of cortex. According to one characterization of the prefrontal cortical control network, there is a hierarchical organization of lateral prefrontal cortex such that the more caudal regions, such as premotor cortex, are involved in response selection based on sensory stimuli, whereas more anterior regions, such as the DLPFC, are necessary when the appropriate response depends on the context. When action depends on retrieved episodic memories, the most anterior regions of the lateral cortex, including the frontal pole, are activated. By this view, the successive layers exert control over each action plan (Koechlin, Ody, & Kouneiher, 2003). In this way, behavior can be modified based on varying levels of complexity that depend on the task demands (Robin & Holyoak, 1995).

In addition to a cognitive control network, other prefrontal regions appear to be activated under other circumstances. Medial and orbital regions appear to be engaged when tasks have emotional or social components (Price, Carmichael, & Drevets, 1996). In addition, the RLPFC, the most anterior part of the prefrontal cortex, appears to have functions distinct from those of lateral prefrontal cortex. A major topic in the cognitive neuroscience of the frontal lobe is the delineation of the contribution of the RLPFC (Bunge et al., 2009; Christoff, Ream, Geddes, & Gabrieli, 2003). As discussed in the hierarchical model of cognitive control, this region becomes important when information retrieved from episodic memory is necessary for forming an action plan. This region is frequently engaged during episodic memory retrieval (Lepage, Ghaffar, Nyberg, & Tulving, 2000), but it is also active while solving reasoning problems that do not have much of a memory retrieval component. According to one view, the RLPFC becomes engaged when the problem requires the integration of multiple relations (Cho et al., 2010; Wendelken & Bunge, 2010); while according to another view, this region becomes engaged when the relations are sufficiently abstract (Christoff, Keramatian, Gordon, Smith, & Madler, 2009). As with the lateral regions, the RLPFC may play multiple roles in cognition. An important direction for future studies is the meta-analysis of neuroimaging data in order to identify commonalities in activation patterns across studies.

Conclusions and Future Directions

Methods in contemporary cognitive neuroscience range from those that have been in use for more than a century (cognitive neuropsychology) to those still undergoing development today. While each technique is better suited to address certain types of questions than others, convergent evidence from multiple methods has been most effective in moving theory forward. Because of the importance of the frontal lobes in complex cognition, their relative accessibility is a boon to researchers using techniques that are limited to the cortical surface. As a more complete understanding of the workings of the prefrontal cortex emerges, perspectives on the nature of thinking will be constrained, or perhaps new perspectives will arise.

Understanding how the brain implements human thinking and reasoning is just in its infancy. The next 10 years promise to be very exciting as the field develops with the use of new methods

and analysis techniques. We believe that the fundamental challenge to this pursuit is to move beyond localist conceptions of brain function toward an understanding of how brain networks develop and operate. Thinking and reasoning are the pinnacles of human cognition and doubtless draw on many different cognitive functions. Understanding how these cognitive functions are harnessed is critical to a fuller understanding of human thought. To get to this point, we believe cognitive neuroscience needs to continue to develop in three core areas.

Cortical Connectivity

Methods for studying when and how brain regions communicate with each other are at the heart of this greater pursuit. Techniques like dynamic causal modeling have provided a way to assess connectivity using fMRI data at a macrodynamic scale; however, we need techniques to study how brain regions communicate at the temporal scale of the timing of neurons. Fortunately, methods such as EEG and MEG and possibly NIRS or EROS provide opportunities to examine real-time temporal dynamics.

Integration of Spatial and Temporal Functional Imaging

While methods like EEG and MEG provide great hope for investigating the temporal dynamics of brain circuits, they have intrinsic limitations for understanding where signals are originating in the brain. Ultimately, researchers interested in understanding brain dynamics will have to develop methods to use spatial localization techniques, such as fMRI, NIRS, or EROS, to target regions of interest, which will help to provide confidence in source localization using EEG and MEG.

Neurocomputational Approaches

Given the complexity of neural systems, we will certainly need principled ways of generating hypotheses about how they function in the service of thinking and reasoning. Computational modeling has been the great friend of thinking and reasoning in the past, helping us to develop and test models at the algorithmic and representation levels of analysis. In the coming years models will need to evolve to achieve realistic neural plausibility and thereby help to make predictions about how neural circuits work together in the service of higher cognition. This will almost certainly involve a merging of different approaches, including symbolic, connectionist, and Bayesian representations and algorithms.

Acknowledgments

The authors would like to thank Keith Holyoak and Slava Nikitin for helpful comments on an earlier draft of the chapter and the American Federation of Aging/Rosalinde and Arthur Gilbert Foundation and the Loyola University Chicago Dean of Arts and Sciences for their generous support (RGM) during the preparation of this manuscript.

Notes

1. Terminology in cognitive neuroscience is frequently rather confusing because of the interdisciplinary origins of the field. In this chapter we use the term “cognitive neuropsychology” to refer to studies of brain-damaged patients, which are frequently based on the logic of single or double dissociations (see Fig. 6.2). Cognitive neuropsychology should not be confused with the field of clinical neuropsychology, which is based on the psychometric appraisal of cognitive function. The cognitive neuropsychology approach is also sometimes referred to as “behavioral neurology.”

2. Frontotemporal lobar degeneration (FTLD) is the newer nomenclature for a syndrome previously referred to as frontotemporal dementia (Miller, 2007). The umbrella of FTLD also frequently includes patients diagnosed with primary progressive aphasia (PPA; Mesulam, 2007). Patients primarily with damage in anterior to dorsolateral frontal cortex are typically referred to as either frontal-variant or behavioral-variant and have symptoms consistent with traditional frontal lobe syndromes (i.e., disinhibition, poor judgment, loss of motivation, executive and working-memory deficits). Patients with damage in anterior temporal cortex, particularly the temporal poles, are frequently referred to as temporal-variant, semantic dementia, or semantic-subtype PPA. Patients diagnosed with FTLD have a range of different postmortem pathologies, including Pick’s disease, cortical basal degeneration and sometimes Alzheimer’s disease.

Mental Function as Genetic Expression: Emerging Insights From Cognitive Neurogenetics

Adam E. Green and Kevin N. Dunbar

Abstract

Following the decade (or two) of the brain, a new effort is underway to integrate insights about the biology of mental function that have been gained at parallel levels of description, in molecular genetics, cognitive neuroscience, and psychology. Integrative cognitive neurogenetic research promises new contributions to our understanding of how genes affect the mind by shaping the brain. These contributions include research into psychological functions that do not readily lend themselves to animal models. Despite the complex pathway from genetic variation to changes in psychological functions and behavior—the effects of any one gene depend on its interaction with other genes and with the environment—molecular-genetic data have the potential to inform psychological function in unique ways. We review work on working memory, attention, long-term memory, and language that illustrates this emerging potential.

Key Words: cognitive neurogenetic, intermediate phenotype, imaging genetic, cognitive neuroscience, molecular genetics

Introduction

As the focus of psychological inquiry has shifted to physical characteristics of the human brain, especially with the advent of direct, *in vivo* assays of brain function, some of the spirit has gone out of the long debate between dualism and materialism. And if we accept the materialist premise that the physical brain constitutes the mind, a consequence is that the genome, which directs the brain's physical construction, must shape mental function. An established behavioral-genetic literature has demonstrated that genes strongly influence human cognition, emotion, and subjective experience, often in ways that depend critically on the environment (Caspi et al., 2003; Turkheimer, Haley, Waldron, D'Onofrio, & Gottesman, 2003). Recently, a new research area has taken root at the intersection of psychology, neuroscience, and molecular genetics (Goldberg & Weinberger, 2004; Green et al., 2008; Meyer-Lindenberg & Weinberger, 2006). A major

motivation for this "cognitive neurogenetic" research has been to relate genetic variation to brain function, especially as a window into genetic susceptibility to psychiatric disorders (Goldberg & Weinberger, 2004; Meyer-Lindenberg & Weinberger, 2006; Tan, Callicott, & Weinberger, 2008; see Bachman & Cannon, Chapter 34). While we address some of this foundational work, the review presented in this chapter primarily emphasizes the potential of molecular genetics to inform our understanding of mind-brain relationships more generally in healthy populations. We focus on the role of the cognitive neurogenetic approach in helping to explain psychological functions that we all have in common as well as differences in mental efficacy between individuals.

This chapter is intended as a psychologically oriented primer rather than an exhaustive review. Our goal is to provide a reference for recent developments in cognitive neurogenetics as a starting point for those with a primary interest in psychology to learn more

Table 7.1. Some psychological phenotypes, associated brain-based intermediate phenotype, and putative genes of influence

Psychological Function	Intermediate Phenotype	Implicated Genes
Working memory	DLPFC efficiency and functional connectivity	Dopamine-related: <i>COMT, DAT1</i>
Attention		
Alerting	Thalamic activity	Noradrenaline-related: <i>ADRA2A, NET</i>
Orienting	Parietal activity	Acetylcholine-related: <i>CHNA4, CHRNA7</i>
Executive control	Anterior cingulate activity	Dopamine-related: <i>COMT, DAT1, MAO-A</i>
Long-term memory (encoding and retrieval)	Hippocampal activity Hippocampal and parahippocampal volume Hippocampal N-acetyl-aspartate	Synaptic plasticity-related: <i>BDNF, Prion</i> Dopamine-related: <i>COMT</i> Metabotropic signaling cascade-related: <i>ADCY8, CAMK2G, GRM3, PRKACG</i>
Language	White matter volume and connectivity	Neurotrophic factor-related: <i>PLXNB3, BDNF</i>

about how genetic data are being incorporated into each of several key research areas in psychology. We briefly introduce conceptual issues and then review the extant literature, dividing our review into four areas of experimental psychology: working memory, attention, long-term memory, and language. For quick reference, Table 7.1 lists some genes and associated brain characteristics relevant to the cognitive neurogenetics of these areas of psychology. We take a decidedly cognitive approach to divvying up mental function, and it is worth noting that this is a chapter concerned with relatively modular cognitive operations in a book with the broader charter of thinking and reasoning. While cognitive neurogenetics aspires toward more integrated phenotypes, extant work has focused on specific cognitive operations. Nonetheless, cognitive operations like memory, attention, and language are largely the constituents of thinking and reasoning, so a review of this literature can inform the central questions this volume addresses. In the discussion we assess the logic, benefits, and obstacles that attend cognitive neurogenetic inquiry.

Back to Bases

Before we begin our review, it may be useful to discuss in general terms the sort of molecular-biological

sequence of events that can lead from genes to cognition. Human beings are made up of cells that have a nucleus and within the nucleus there are chromosomes, which contain genes that are the basic units of inheritance (human beings have 23 pairs of chromosomes, which contain roughly 30,000 genes in total). Each gene consists of a sequence of DNA on a chromosome. The process of expressing the information encoded in gene sequences begins with transcription of DNA into RNA, and then continues by means of complex cellular machinery to produce proteins that sustain cells and direct them to perform particular functions. This is what is often referred to as the central dogma of molecular biology. While there are many nuances concerning what exactly constitutes a gene and how genes are transcribed, the fundamental property of genes that is relevant for cognitive neurogenetics is that genes are made from subunits called *nucleotides*. Each nucleotide is made of a sugar and phosphate and a chemical base. There are four different bases—adenine (A), thymine (T), guanine (G), and cytosine (C)—that determine the functional identity of the nucleotide in which they occur. These nucleotides are the fundamental structural and coding elements of DNA. The DNA itself consists of a pair of strands that wind around each

other in the form of a double helix. Because of the charges on the bases and the structure of the helix, only an A on one strand of the helix can match to a T on the other strand, and only a G on one strand can match to a C on the other strand.

A key distinction in genetics research is between the phenotype, which is the observable behavior, and the genotype, which is the underlying genetic coding. As molecular-genetics research has progressed toward mapping entire sequences of nucleotides on a gene, it has been discovered that only some of the DNA is expressed. Indeed, the actual functions of most genetic sequences remain unknown. Furthermore, individuals can have different sequences of nucleotides yet have similar phenotypes. Nevertheless, between-human variations in the sequence of nucleotides within the DNA of a gene can lead to differences in protein transcription that can ultimately have bearing on the complex machinery of the mind. These variations in nucleotide sequence are called polymorphisms. Single nucleotide polymorphisms (SNPs) involve variation of just one nucleotide in a sequence and are relatively common (e.g., an A might be substituted for a T, or a G for a C). Polymorphic variations that have been linked to variation in cognitive phenotypes are a major target of investigation in cognitive neurogenetics. This work will be the primary focus of our review.

Molecular Genetics in Cognitive Neuroscience

To what extent can molecular-genetic data further the broad goal of cognitive neuroscience to understand the mind mechanistically? There are at least three potential benefits of incorporating such data into cognitive neuroscience studies: (1) to tell us more about the brain by providing insight into molecular-biological machineries that contribute to the building of neural systems and implementation of cognitive function; (2) To tell us more about the mind, by providing a new source of explanatory variance (genetic variation) to test hypotheses about psychological mechanisms (e.g., to test whether putatively separate psychological mechanisms are associated with distinct sets of genes); and (3) to tell us more about sources of individual differences by characterizing genetic variables, which are less susceptible to confounding factors (e.g., motivation, prior experience/knowledge, cognitive and emotional state) that are often difficult to remove from standard cognitive neuroscience studies (see Fig. 7.1).

INTERMEDIATE PHENOTYPES

Cognitive neurogenetics takes an *intermediate phenotype* approach (Tan et al., 2008), in that it seeks to link observable psychological phenotypes to polymorphic loci in the genome by way of neural phenotypes (intermediate between genotype and psychological function) that are detectable through brain-based investigation. Intermediate phenotypes are the same neural structures and functions that are the typical object of cognitive neuroscience studies (Goldberg & Weinberger, 2004; Meyer-Lindenberg & Weinberger, 2006). Critically, intermediate phenotypes may be more amenable to genetic investigation than behavioral phenotypes (Goldberg & Weinberger, 2004; Tan, Callicott et al., 2008), the key idea being that they are physiologically more proximate to gene expression than are overt behaviors (Blackwood et al., 2001; Goldberg & Weinberger, 2004; Meyer-Lindenberg & Weinberger, 2006; Tan, Callicott et al., 2008). In contrast, behavior is a more distant, final common pathway—and hence presumably more variable as an outcome measure (Caspi & Moffitt, 2006; Meyer-Lindenberg & Weinberger, 2006; Tan, Callicott et al., 2008).

INTERPRETIVE HAZARDS

There is considerable complexity at each link in the chain of associations from single polymorphism to brain activity to psychological function. Appropriate interpretation requires cognizance of some key conceptual issues, including pleiotropy, polygenicity, and false-positive genetic association. Many of the genes that are relevant to psychological function are *pleiotropic*, that is, they contribute to many functions (Kovas & Plomin, 2006). For example, a gene that influences a general feature of brain structure is likely to influence multiple brain functions that depend on this feature (e.g., the brain-derived neurotrophic factor [*BDNF*] gene is thought to influence the development of white matter connections throughout the brain). Adding to the complexity many psychological functions are influenced by multiple genes and/or multiple variations within a gene, a phenomenon known as *polygenicity* (Fisher, 2006). Furthermore, genes can exert considerable influence on each other (Fisher, 2006). For example, as we will see, there is evidence that human working memory function is shaped by several interacting variations in genes that influence dopamine signaling. Thus, multiple complementary and convergently focused studies are likely to be required to fully understand causal gene-to-phenotype (and gene-to-intermediate phenotype) relationships in detail.

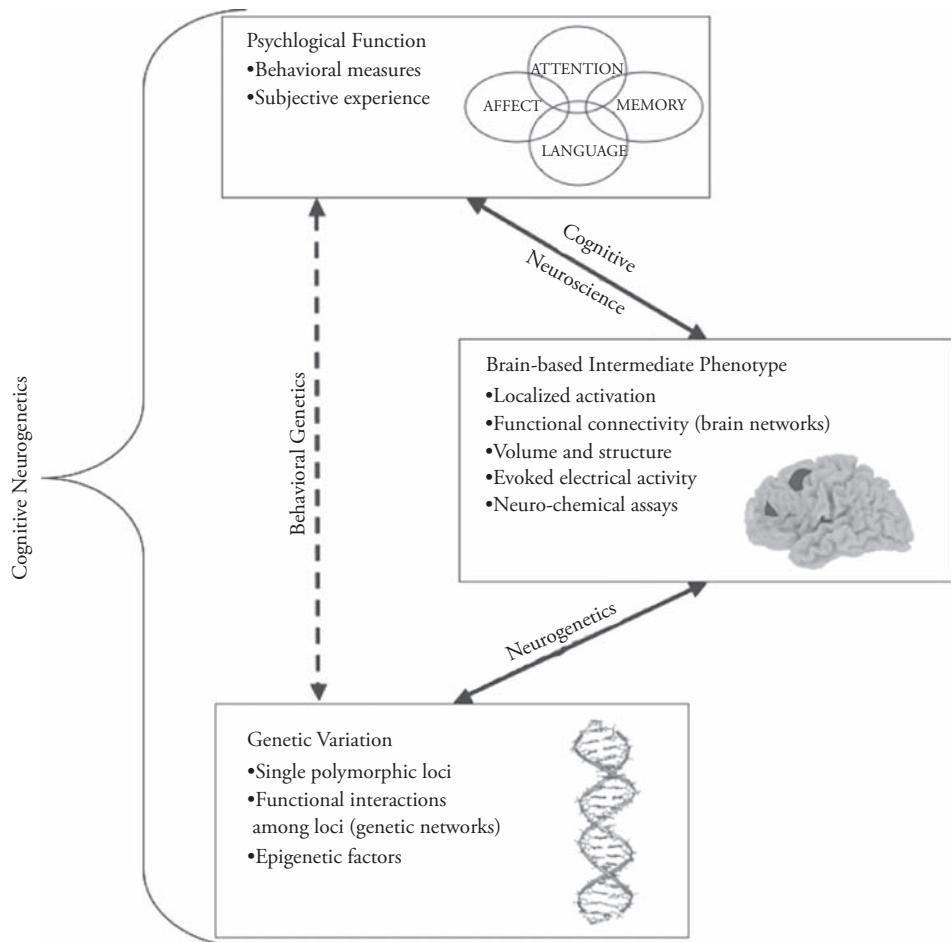

Fig. 7.1 Integrating cognitive neuroscience and molecular genetics through the intermediate phenotype approach of cognitive neurogenetics. As applied to cognitive neuroscience, cognitive neurogenetics seeks to identify links between psychological functions and points of variation in the genome via intermediate neural characteristics that (1) are associated with the psychological function and (2) vary as a function of the genetic variation. This cognitive neurogenetic approach incorporates standard cognitive neuroscience methods to characterize psychological functions in terms of their underlying neural substrates (intermediate phenotypes), and genetic analysis to determine whether specified genetic variables are associated with these intermediate phenotypes. This approach also typically involves behavioral-genetic analysis in order to test whether behavioral measures of the psychological function of interest are influenced by the specified genetic variable. A relationship between genetic variation and an intermediate phenotype, even in the absence of a brain-behavior association can be informative; this sort of finding can identify neural effects of genetically determined differences that would not be observed in standard cognitive neuroscience.

From a methodological perspective, an issue requiring caution in the study of genetic associations is the potential for “false positive” findings (Type I errors) owing to the multitude of genes (and polymorphisms) that can be investigated for a given psychological function. This issue is potentially compounded for cognitive neurogenetics research because neuroimaging datasets involve sampling from multiple points in the brain, heightening the potential risks of multiple comparisons and increasing the necessity of statistical rigor if true gene–brain-cognition associations are to be identified. Illustrating the importance of interpretive

caution in genetic association is the fact that early studies of behavioral and clinical phenotypes found the proportion of phenotypic variance accounted for by a single genetic variant was as much as 10%–20%, whereas subsequent meta-analyses suggested that the true figure is typically closer to 0.1%–1% (Flint & Munafò, 2007). Importantly, strategies such as choosing the genes and neuroanatomical regions of interest *a priori* focusing on genetic variants with a known functional significance, using rigorous statistical criteria, replication, and meta-analyses can reduce the risk of making Type I errors. The intermediate

phenotype approach, when constrained by carefully targeted anatomical hypotheses, has the potential to reduce the risk of Type I error (as compared to the use of behavioral or clinical phenotypes; Meyer-Lindenberg et al., 2008) but cannot eliminate this risk. A point of particular emphasis for cognitive neurogenetics studies should be increased statistical power through large sample sizes.

EPIGENETIC INFLUENCES

Points of variation within DNA have been the primary targets of cognitive neurogenetic investigation, and this emphasis is reflected in our review. However, in addition to this research, exciting molecular-genetic data have emerged, which concern variations not in the genome itself, but in the chromosomal structures that scaffold DNA and can influence its transcription. Such “epigenetic” variations, while not encoded within genes, do exhibit heritability (see Qiu, 2006, for a brief overview) and have consequences for genetic expression in development, protection against disease, and psychological functions (Masterpasqua, 2009; McGowan & Szyf, 2010). Intriguingly, epigenetic research promises insights into mechanisms by which elements of our external environment—physical, social, psychological, and otherwise—produce changes in gene expression. Extant epigenetic research has had a largely clinical focus. While our focus here is primarily nonclinical, an introduction to the concepts and promise of this emerging area is worthwhile because the use of epigenetic data in cognitive neurogenetics is likely to expand.

Epigenetic effects depend on the way that DNA is bound to the chromosomes that carry it. Chromosomes are largely composed of protein units called *histones*, around which strands of DNA are wrapped in convoluted loops. In aggregate, histones and their bound DNA strands are called *chromatin*. Each histone has a tail, which protrudes out from the histone protein. These tails can be bound to a methyl group (methylation), a phosphate group (phosphorylation), or an acetyl group (acetylation). Methylation, phosphorylation, and acetylation alter chromatin structure, thereby influencing the availability of bound strands of DNA to be transcribed to RNA. These alterations modify protein production and, at least in some cases, are brought on by environmental influences.

One of the clearest examples of epigenetic processes at work relates to the question of why identical twins become different over time. Given that these twins are extremely alike at the level of

genotype, how is it that they should differ, sometimes greatly, in phenotype? Fraga and colleagues (2005) investigated the methylation and acetylation of histones in monozygotic twins. These researchers discovered little difference in young twins, but in older twins found large methylation and acetylation differences, which were shown to affect genetic expression. Similar studies using animal models have obtained similar results that indicate that environmental factors as diverse as maternal bonding, diet, smoking, and social interactions can all change the expression of genes in an epigenetic manner (see Relton & Smith, 2010, for a review). Work has been undertaken to draw links between epigenetic variables and neural intermediate phenotypes related to cognition, primarily in clinical populations (Canli et al., 2006; Dulac, 2010; Graff & Mansuy, 2008, 2009; Riccio, 2010). As cognitive neurogenetic models become more complete, it will also be important to characterize interactions between genetic and epigenetic variables in the genesis of healthy cognitive function.

Complex Cognition and Working Memory

The emergence of cognitive neuroscience over the past two decades has enabled novel insights into the most advanced reaches of human mental function (see Morrison & Knowlton, Chapter 6). Data from cognitive neuroscience studies, combined with data from animal research and lesions studies, have reliably identified prefrontal cortex (PFC) as neural substrate for the most complex, “high-level” cognitive operations (Green, Kraemer, Fugelsang, Gray, & Dunbar, 2010; Green, Kraemer, Fugelsang, Gray, & Dunbar, in press; Kane & Engle, 2002; Ramnani & Owen, 2004). Brain networks within PFC—operating in connection with other regions—mediate component demands of complex cognitive tasks. A strong heritability of prefrontal gray matter volume (~80%), and a strong predictive relationship between prefrontal gray matter and general intelligence, indicate that there are genetic influences on PFC-mediated cognition (Bouchard & McGue, 1981; Gray & Thompson, 2004; Thompson et al., 2001). Indeed, many of the most complex prefrontally mediated cognitive traits, including IQ (Allen et al., 2005; Dick et al., 2007; Le Hellard et al., 2009), executive function (Apud et al., 2007; Barnett, Heron, Goldman, Jones, & Xu, 2009; Bishop, Fossella, Croucher, & Duncan, 2008; Egan et al., 2001; Joober et al., 2002; Malhotra et al., 2002; Pezawas et al., 2004; Rybakowski, Borkowska, Skibinska, & Hauser, 2006;

Tan, Nicodemus et al., 2008; Tsai et al., 2008; Waldman et al., 2006), and even creativity (Dunbar, 2008; Reuter, Roth, Holte, & Hennig, 2006), have been linked to specific genetic polymorphisms. This evidence for genetic influence, combined with strong brain-imaging characterization of brain networks underpinning PFC-mediated tasks, suggests that the PFC may be a suitable target for the application of molecular-genetic methods to cognitive neuroscience. Indeed, a growing body of findings has begun to inform mechanistic understanding of molecular-genetic influences on brain networks that mediate complex cognition.

Working memory is a well-characterized form of complex cognition that appears to be central to a range of higher cognitive functions. Working memory refers to the ability to maintain and manipulate information in short-term memory while resisting interference (Baddeley, 2003). It is related to a number of high-level capacities such as reasoning, and its neural substrate overlaps that of intelligence (Gray, Chabris, & Braver, 2003; Just & Carpenter, 1992). Networks of brain areas, including dorsolateral prefrontal cortex (DLPFC) and hippocampus, have been reliably associated with visual and verbal working memory systems, and several tasks have been developed to study individual differences in working memory capacity (Nystrom et al., 2000; Smith & Jonides, 1998; Turner & Engle, 1989). Working memory capacity, and patterns of underlying brain activity, show strong heritability (Koten et al., 2009). Molecular-genetic approaches have focused on genes that influence the dopamine system. This focus stems from a rich clinical literature, especially work in schizophrenia, which has implicated disordered dopaminergic function in pathological impairment of working memory (Cools & Robbins, 2004; Goldberg et al., 2003; Meyer-Lindenberg & Weinberger, 2006; Weinberger et al., 2001; see Bachman & Cannon, Chapter 34).

A dopamine-system-related gene that has been frequently studied for its possible effects on working memory is the catechol-*O*-methyltransferase (*COMT*) gene. *COMT* encodes the COMT enzyme, which catabolically terminates the activity of dopamine in all dopaminergic synapses. In PFC, COMT enzymatic activity is thought to be particularly important for determining dopamine availability because the dopamine reuptake transporter protein, which helps to clear dopamine from the synaptic cleft, shows sparse expression in PFC relative to striatal areas (Lewis et al., 2001; Matsumoto et al.,

2003). Much investigation has therefore targeted a common polymorphism that is known to influence the enzymatic activity of COMT. An evolutionarily recent G-to-A mutation, causing a valine (Val)-to-methionine (Met) substitution at codon 158 of the *COMT* gene on chromosome 22q11, results in relatively reduced COMT enzyme activity. Thus, Met allele carriers have relatively low COMT enzyme activity and have higher dopamine availability as a result, whereas Val allele carriers have relatively increased COMT activity and lower dopamine availability (Lotta et al., 1995).

Some insight into the effects of this polymorphism on the operation of working memory networks has been gained through analysis of brain-based intermediate phenotypes, especially brain activity assessed by neuroimaging. An association of the *COMT* Met allele with better working memory performance has been reported (Barnett et al., 2009; Diaz-Asper et al., 2008; Egan et al., 2001; Goldberg et al., 2003), but the behavioral data have been inconsistent (Barnett, Scorielis, & Munafo, 2008; Bertolino, Blasi et al., 2006; Bruder et al., 2005; Ho et al., 2006; Tsai et al., 2003). Relatively more consistent has been the brain-based finding that the Met allele is associated with indices of greater neural efficiency during working memory tasks (i.e., less recruitment of working memory-associated brain areas for equal behavioral performance; Egan et al., 2001; Mattay et al., 2003; Tan et al., 2007). The inconsistency of the behavioral data highlights the potential utility of the brain-based intermediate phenotype approach for investigating effects of genetic variability that may be obscured at the behavioral level by compensatory factors (e.g., motivation) but visible at the brain level, which is putatively more causally proximate to variations in the genome. The history of psychiatric genetics, which has indicated poor predictive value of initial findings and the tendency for effect sizes to diminish as more studies are published (Flint & Munafo, 2007), suggests continued caution. Nonetheless, the effect of the *COMT* Val158Met polymorphism on brain-based working memory intermediate phenotypes has emerged as one of the best replicated findings in the cognitive neurogenetic literature (Apud et al., 2007; Bertolino, Blasi et al., 2006; Bilder, Volavka, Lachman, & Grace, 2004; de Frias et al., 2009; Egan et al., 2001; Ho et al., 2006; Malhotra et al., 2002; Mattay et al., 2003; Meyer-Lindenberg et al., 2005; Meyer-Lindenberg & Weinberger, 2006; Sambataro et al., 2009; Savitz, Solms, &

Ramesar, 2006; Tan et al., 2007; Winterer & Weinberger, 2004).

One plausible hypothesis that has been proposed to explain the mechanism by which *COMT* and other dopamine-system-related genes influence the function of brain networks involved in working memory centers on the signal-to-noise ratio of dopaminergic signaling within PFC (Apud et al., 2007; Bertolino et al., 2006; Savitz et al., 2006; Winterer et al., 2006; Winterer & Weinberger, 2004). This hypothesis posits that binding at dopamine D1 and D2 receptors affects the signal-to-noise ratio in PFC by modulating the excitatory release of glutamate from pyramidal cells (likely through modulation of Na⁺ channel opening; Rotaru, Lewis, & Gonzalez-Burgos, 2007), and possibly by modulating the inhibitory release of GABA from interneurons (Winterer et al., 2006). In short, the higher the D1/D2 activation ratio, the stronger the excitatory signal, and the better the inhibition of noise in the surround. This is important for working memory, which requires the maintenance of an informational signal over time and inhibition of distractor noise. At levels of dopamine availability that facilitate optimal working memory function, D1 binding in PFC is high relative to D2 binding. However, when dopamine availability is decreased, as it is decreased in Val carriers relative to Met carriers, the D1/D2 ratio is reduced. Thus, the *COMT* Val allele plausibly contributes to a diminished signal-to-noise ratio in PFC and consequently less efficient working memory function.

A related hypothesis, the tonic–phasic hypothesis (de Frias et al., 2009), posits that the low enzyme activity Met allele leads to enhanced tonic dopamine activity in PFC, promoting sustained cognitive representations in working memory, whereas the Val allele leads to reduced tonic but enhanced phasic dopaminergic activity in subcortical regions, putatively supporting greater cognitive flexibility. These hypothesized mechanistic accounts are supported by the finding that the *COMT* Val allele is associated with less efficient activation and reduced functional connectivity in a network of brain regions associated with working memory function, especially DLPFC (Apud et al., 2007; Bertolino, Blasi et al., 2006; Bilder et al., 2004; de Frias et al., 2009; Egan et al., 2001; Ho et al., 2006; Malhotra et al., 2002; Mattay et al., 2003; Meyer-Lindenberg et al., 2005; Meyer-Lindenberg & Weinberger, 2006; Sambataro et al., 2009; Savitz et al., 2006; Tan et al., 2007; Winterer & Weinberger, 2004).

Analysis of dopamine-related performance, however, shows that more dopamine does not always mean better working memory performance. Rather, research in animals and humans has demonstrated that an inverted U-shaped function better describes the relationship between working memory performance and dopamine availability (Cools & Robbins, 2004). Cognitive neurogenetic data concerning the effects of *COMT* on working memory are consistent with this inverted U-shaped function and have added some new insights. Treatments that increase dopamine availability in PFC reduce neural efficiency during working memory in Met allele homozygotes, who have relatively high baseline dopamine availability. Conversely, these treatments improve working memory efficiency in Val homozygotes, whose baseline dopamine availability is lower (Apud et al., 2007; Mattay et al., 2003; Meyer-Lindenberg et al., 2005).

Investigations of *COMT* have provided promising insights regarding the neural mechanisms that may influence working memory. However, it is essential to resist envisioning the association between gene and phenotype (or gene and intermediate phenotype) as a one-to-one relationship (because of pleiotropy and polygenicity; Fisher, 2006; Flint & Munafò, 2007). More comprehensive methodological approaches can be taken to engage the multiplicity of the genotype-intermediate phenotype relationship by examining multiple polymorphisms taken together as predictors of specific neural characteristics (Bertolino, Blasi et al., 2006; de Quervain & Papassotiropoulos, 2006; Meyer-Lindenberg, Nichols et al., 2006; see Fig. 7.2).

For example, Meyer-Lindenberg and colleagues (Meyer-Lindenberg, Nichols et al., 2006) employed a step-wise analysis to examine the combined effect of SNPs at three different loci in the *COMT* gene on neural activity during an N-back working memory task. Consistent with previous findings, Val allele load (0, 1, or 2 Val alleles) at the Val158Met SNP was predictive of prefrontal activation as measured by functional magnetic resonance imaging (fMRI). However, exploratory multipolymorphic analysis indicated that the strongest predictor of prefrontal activation was actually a combination of variants that included all three loci within the *COMT* gene. This analysis also revealed a complex, nonadditive interaction between the Val158Met SNP and one of the other *COMT* SNPs (a P2 promoter region SNP).

These findings point to the complexity of the effects of genotype on brain activity and behavior.

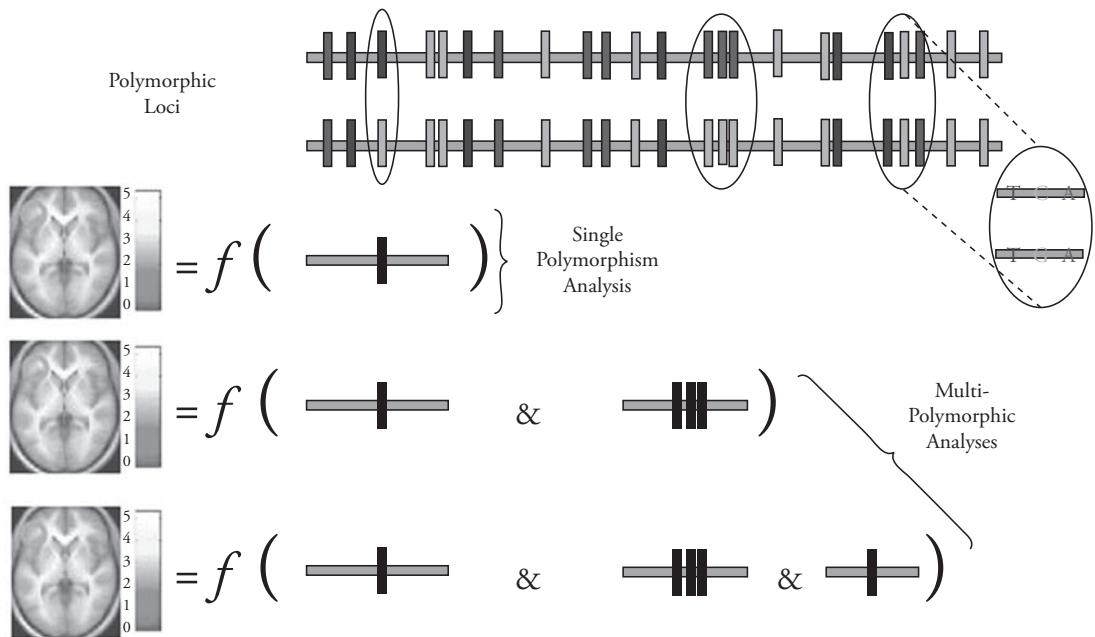

Fig. 7.2 Multipolymorphic analysis. Multiple polymorphic sites in the genome influence a psychological phenotype and its underlying brain activity (brain-based intermediate phenotype). The combined, complexly interactive contributions of these polymorphisms influence neural activity and cognitive function. Most cognitive neurogenetic research to date has focused on variation at individual polymorphisms. These findings are instructive, particularly where only one candidate polymorphism has been implicated by prior findings. However, a growing number of cognitive neurogenetic studies are testing the association of variations at multiple polymorphisms with brain-based intermediate phenotype(s). The figure illustrates a generic multipolymorphic analysis. Polymorphic loci are indicated within two example DNA sequences (where the upper sequence differs from the lower sequence). Brain activity in a region of interest is predicted as a function of one, two, or three of these polymorphisms. Development of multipolymorphic analyses will help construct a better understanding of the complex genetic “networks” that contribute to cognitive brain function and human psychology. See color figure.

Although they generally require larger sample sizes, approaches that consider multiple genetic variations can capture larger fractions of phenotype and intermediate phenotype variance (Nackley et al., 2006) and will be essential to the development of behavioral genetics and cognitive neurogenetics.

Variation in other dopamine-system-related genes has also been linked to working memory performance and related brain function. For example, dopamine transporter (*DAT1*) genotype appears to be associated with response accuracy and activity in frontal, striatal, and parietal regions during working memory tasks (Stollstorff et al., 2010). A separate study indicated that *DAT1* variation influences DLPFC and cingulate activity (Bertolino et al., 2006) during working memory, and that these *DAT1* effects interact with the effects of *COMT* genotype (Bertolino, Blasi, et al., 2006). In a strong example of vertically integrating genetic, molecular-biological, and neural data, Bertolino and colleagues

(Bertolino et al., 2009) have linked variation in the dopamine receptor D2 (*DRD2*) gene to the expression of a particular type of postsynaptic D2 receptor, ligand binding at this receptor, and functional connectivity between striatum and PFC during working memory tasks.

Variations in a number of non-dopaminergic genes also influence the function of working memory networks, including the e4 allele of the apolipoprotein E (*APOE*) gene, which is a risk factor for Alzheimer’s disease (Filbey, Slack, Sunderland, & Cohen, 2006; Wishart et al., 2006), and variations in the glutamate receptor metabotropic 3 (*GRM3*) gene (Egan et al., 2004; Marenco et al., 2006). *GRM3* genotype is associated with DLPFC efficiency and its functional connectivity with parietal cortex (Tan et al., 2007). This finding was revealed by a region-of-interest-based fMRI approach, a useful strategy for minimizing multiple comparisons of brain regions and thus reducing Type I error. Moreover

GRM3 genotype was found to interact with *COMT* genotype, such that homozygosity for the *COMT* Met allele ameliorated the effects of the less efficient *GRM3* genotype (Tan et al., 2007). Variations in the G-protein signaling 4 (*RGS4*) gene, which influences G-protein-linked signal transduction in multiple neurotransmitter systems, have also been implicated in working memory performance as well as functional connectivity and local gray and white matter volume in a network of working memory-related brain regions (Buckholtz et al., 2007).

Polymorphisms in additional brain-expressed genes have been associated with variations in parietal and frontal activity, hippocampal structure and activity, latency of ERP-measured P300 response, and with functional coupling between DLPFC and hippocampus during working memory tasks (Bath & Lee, 2006; Callicott et al., 2005; Cerasa et al., 2010; Egan et al., 2003; Jansen et al., 2009; Reuter et al., 2008; Schofield et al., 2009; Wolf, Jackson, Kissling, Thome, & Linden, 2009). A growing literature surrounding the *BDNF* gene, thus far primarily studied in relation to episodic memory, may prove especially fruitful for insights into working memory and its neural underpinnings (Cerasa et al., 2010; Nagel et al., 2008; Schofield et al., 2009). New behavioral-genetic and cognitive neurogenetic findings related to working memory seem likely to continue emerging rapidly. However, replication of extant findings rather than expansion, will be most effective in establishing a solid understanding of the molecular-genetic mechanisms that support working memory function in PFC.

Attention

Attention is related to working memory. While lower level attention processes (e.g., orienting attention to a surprising noise) can be clearly distinguished from working memory, attention at the executive level (e.g., deciding which of several noises is most important to attend) often is not easily distinguishable from working memory. Tasks that measure working memory (e.g., the N-back task) rely on executive attention, and tasks that measure executive attention, including those discussed later, rely on working memory. Executive control of attention is a major component of working memory theory (Baddeley, 2003; Engle, 2002), and there is overlap between the instantiations of these constructs at the neural level (Kane & Engle, 2002). As such, it is reasonable to predict that a largely shared set of genetic factors impacts these two cognitive phenotypes.

Like working memory, the brain systems related to attention are among the most well characterized and most reliably identified in the cognitive neuroscience literature (Raz & Buhle, 2006). Brain imaging has related attention to large-scale neural networks that are active during attentional tasks and are anatomically overlapping with regions that, when damaged, produce attentional deficits (Mesulam, 1981; Posner & Petersen, 1990). Posner and Petersen proposed that the neural architecture of attention comprises a system of three anatomical networks, which mediate initial alerting of the attentional system, orienting to stimuli, and executive attention, respectively.

Cognitive neurogenetic approaches have been used to test and inform the model of separate attentional networks by examining whether individual differences in distinct components of attention are associated with distinct genetic polymorphisms. Dopaminergic genes have been a focus of this research because of the high levels of expression of dopamine receptors in the anterior cingulate cortex (ACC) and other regions that have been implicated in attention.

The Attention Network Test (ANT) provides a well-validated behavioral measure for parsing the components of attention (Fan, McCandliss, Sommer, Raz, & Posner, 2002) and has been important in establishing the cognitive neurogenetics of attention (see Fig. 7.3). The executive attention measure of the ANT shows about 77% test-retest reliability and a heritability of 89% (Fan, Wu, Fossella, & Posner, 2001). A behavioral-genetic study showed modest associations of executive control of attention with common variants in genes, including the monoamine oxidase-A (*MAO-A*) and the dopamine D4 receptor (*DRD4*) genes (Fossella & Posner, 2004). Neuroanatomical characterizations of brain activity during performance of the ANT (Fan & Posner, 2004) revealed dissociable networks for the three putative components of attention as well as evidence that individual differences in the activation of cingulate cortex correlates with variation in the *MAO-A* gene (Fan, Fossella, Sommer, Wu, & Posner, 2003). This *MAO-A* finding has subsequently been independently replicated and extended (Meyer-Lindenberg et al., 2006).

Because the executive component of attention is an important aspect of working memory (Baddeley, 2003; Engle, 2002), it is not surprising that common genetic variants are associated with both working memory and executive attention.

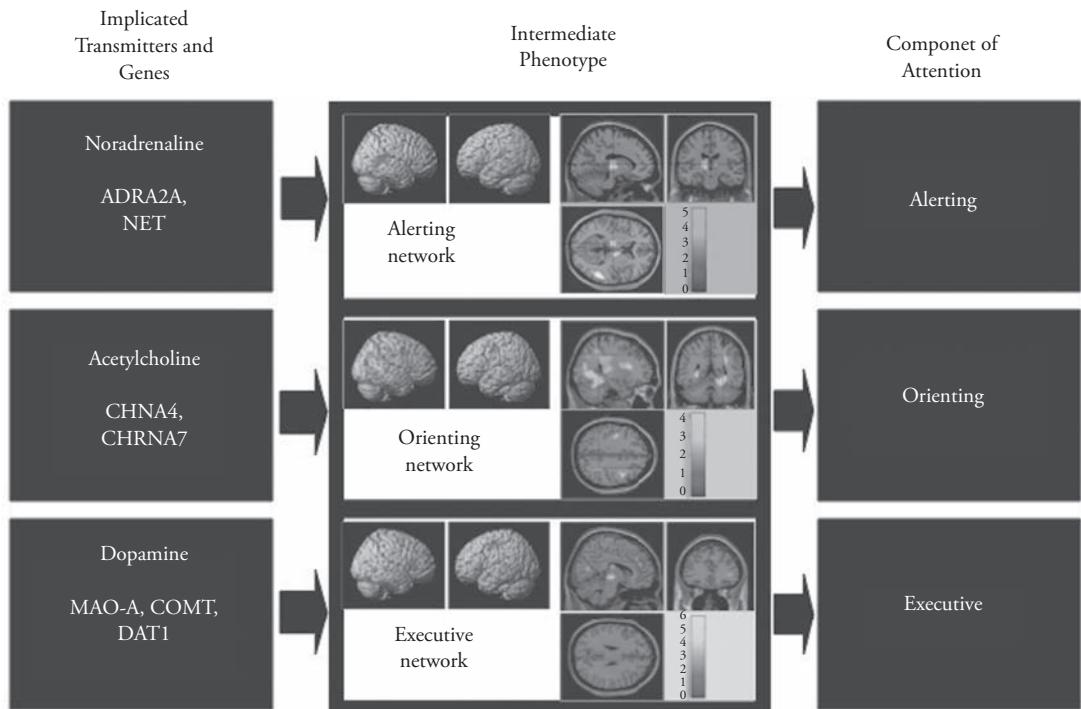

Fig. 7.3 Parsing components of attention in cognitive neurogenetic studies with the Attention Networks Test (ANT). Variations in a set of candidate genes have been correlated with behavioral performance or brain activity for distinct components of attention using the ANT. To generate candidate genes for cognitive neurogenetic studies—in this case for studies on attention—it is important to rely on multiple sources of converging evidence. First, neuroimaging and lesion data pointed to separable neural networks that carry out different aspects of attention. Secondly, pharmacological manipulations demonstrated that noradrenergic modulation can influence the efficiency of the alerting network, while cholinergic modulation and dopaminergic modulation can influence orienting and executive control of attention, respectively. With regard to neural intermediate phenotypes, brain networks were identified where attention-related activity overlaps with patterns of gene expression. It was hypothesized that variation in gene sequence should correlate with individual differences in neural activity associated with components of attention. In the case of executive control of attention, hypotheses of this kind have been supported for brain regions that are targets of dopamine innervation such as the frontal midline, lateral prefrontal areas, and basal ganglia. See color figure.

For example, during tasks that demand executive attention, *COMT* Met allele carriers show relatively decreased activity in ACC and perform better (Blasi et al., 2005; Krabbendam et al., 2006; Winterer et al., 2006), suggesting that the Met allele is associated with more efficient neural processing during such tasks. However, as with working memory, the data relating polymorphic variation to behavior have been less consistent than the data linking polymorphic variation to individual differences in neural intermediate phenotype (Reuter, Ott, Vaitl, & Hennig, 2007), again indicating the value of the brain-based intermediate phenotype approach. For example, Blasi et al. (2005) demonstrated that the effect of *COMT* genotype on ACC activation is strongest at the highest levels of executive attentional demand. The effects of *COMT* genotype on executive attention

have been framed under the dopamine signal-to-noise hypothesis (Winterer et al., 2006; Winterer & Weinberger, 2004), and increased levels of noise have been demonstrated in Val allele carriers surrounding peaks of activation in ACC and elsewhere in PFC (Winterer et al., 2006). Extraction of *COMT* protein from cadaverous human tissue (Tunbridge et al., 2007) and a recent study of *COMT* attentional effects in toddlers (Voelker, Sheese, Rothbart, & Posner, 2009) suggest that the *COMT* enzymatic activity and the posited cognitive effects of *COMT* genotype may increase substantially from early childhood to adulthood.

Variants in dopamine-system-related genes other than *COMT* also affect the operation of attentional brain networks as a function of candidate genetic variants. Early, and still somewhat contradictory findings have begun to implicate several other

dopamine-system-related polymorphisms in the executive component of attention based on performance measures, evoked potentials, and functional imaging of ACC activation (Birkas et al., 2006; Fan et al., 2003; Fossella, Green, & Fan, 2006; Fossella et al., 2002; Passamonti et al., 2008; Passamonti et al., 2006; Rueda, Rothbart, McCandliss, Saccomanno, & Posner, 2005).

While dopamine-system-related genes have been associated with the executive component of attention, a number of genes that are not directly involved in the dopamine system have been associated with the orienting and alerting components of attention and their associated brain networks. These include genes associated with the glutamatergic (Gallinat et al., 2007), GABA-ergic (Porjesz et al., 2002), serotonergic (Fallgatter et al., 2004), and cholinergic (Begleiter & Porjesz, 2006; Espeseth et al., 2006; Parasuraman, Greenwood, Kumar, & Fossella, 2005; Winterer et al., 2007) systems. Cholinergic-system-related genes are neurophysiologically plausible candidates because of the role of acetylcholine in activating parietal attention networks in response to salient stimuli (Davidson & Marrocco, 2000; Sarter & Bruno, 1997). Indeed, both nicotinic and muscarinic acetylcholine receptor genes have been associated with attentional alerting as indexed by individual differences in response time, as well as brain-based intermediate phenotypic measures obtained by electrical recording, and brain imaging of alerting tasks (Begleiter & Porjesz, 2006; Espeseth et al., 2006; Greenwood, Lin, Sundararajan, Fryxell, & Parasuraman, 2009; Parasuraman et al., 2005; Winterer et al., 2007). These findings, juxtaposed with those implicating dopamine-system-related genes in the executive component of attention (and working memory), reinforce the separable networks model of attention (Posner & Petersen, 1990; Posner, Rothbart, & Sheese, 2007; Raz & Buhle, 2006) and enrich this model by identifying separable genetic influences that bear upon distinct brain networks.

Long-Term Memory

Long-term, declarative memory is a major focal area for neuroscience research. Whereas attention and working memory generally operate over brief durations, long-term memory requires neural mechanisms and networks that can represent information over extended durations. Thus, mechanistic models of memory that incorporate long-term changes in synaptic strength have gained empirical

and theoretical traction. Synaptic plasticity as a mechanism of memory has been supported by findings at the cellular and systems level (C. Chen & Tonegawa, 1997; Silva, 2003). The molecular pathways mediating synaptic plasticity and the neural architecture mediating memory function have been characterized in some detail (Chen & Tonegawa, 1997; Lamprecht & LeDoux, 2004). Furthermore, genetic investigation of memory performance has revealed roughly 50% trait heritability (McClearn et al., 1997). Thus, research on long-term memory is well suited for cognitive neurogenetic approaches.

A growing body of work evaluates the role of the *BDNF* gene, which encodes the BDNF protein. This protein shows high levels of brain expression in hippocampal regions (Murer, Yan, & Raisman-Vozari, 2001), which are critical for long-term memory function (Gabrieli, 1998). Evidence from animal models indicates that BDNF-mediated long-term potentiation (LTP) in the hippocampus facilitates memory formation (Poo, 2001). In human cells, the Met allele of a common Val-to-Met substitution polymorphism at codon 66 of the *BDNF* polypeptide is associated with diminished BDNF secretion (Chen et al., 2004; Egan et al., 2003). This effect is likely due to disrupted trafficking of the BDNF protein through the secretory pathway within the cell (Chen et al., 2004; Egan et al., 2003), which may result from decreased interaction between BDNF and the cytoplasmic trafficking protein, Sortillin (Chen et al., 2005).

Because *BDNF* genotype has been implicated as an influence on synaptic plasticity in hippocampus (Goodman et al., 1996; Kang & Schuman, 1995; Poo, 2001), a number of studies have begun to ask whether the role of *BDNF* can be related to models of memory in which cellular plasticity is a core mechanism. Structural brain imaging has shown that the Met allele is reliably associated with reduced hippocampal and parahippocampal volume in healthy adults (Bueller et al., 2006; Ho et al., 2006; Pezawas et al., 2004; Szeszko et al., 2005), although these effects may be due to global effects of the *BDNF* Val66Met polymorphism on brain volume (Toro et al., 2009). *BDNF* Met allele carriers show poorer cognitive performance on tasks such as episodic recall of scenes and events (Dempster et al., 2005; Egan et al., 2003; Hariri et al., 2003) that typically rely on hippocampal activation. Some evidence indicates that verbal memory tasks, such as remembering lists of words, do not show strong effects of *BDNF* genotype (Bath & Lee, 2006), possibly because they are less reliant on hippocampal mechanisms (Bath & Lee, 2006;

Egan et al., 2003). However, at least one study has identified impaired performance among healthy Met allele carriers across a range of verbal memory tasks (Ho et al., 2006). The Met allele has also been associated with decreased hippocampal engagement at both the encoding and retrieval stages of episodic memory (Bath & Lee, 2006; Callicott et al., 2005; Hariri et al., 2003; Hashimoto et al., 2008), and decreased hippocampal levels of n-acetyl-aspartate, a measure of in vivo synaptic activity (Callicott et al., 2005; Egan et al., 2003).

Although the cellular pathways related to *BDNF* and synaptic plasticity are attractive candidates for translational research on cognitive mechanisms, memory is a complex, multiphasic process. As such, it is affected by a variety of genetic factors that exert mechanistic effects on a range of processes, including not only storage but also encoding and retrieval. These genetic effects are observable in the operation of a network of brain regions that is centered on the hippocampus but depends on connectivity with frontal and midbrain regions. An expanding literature has begun to characterize the effects of a number of specific candidate genes on several components of the networks that support memory. These include genes whose protein products, like *BDNF*, are linked to synaptic plasticity, such as the *CPEB* gene encoding the cytoplasmic polyadenylation element-binding protein (Vogler et al., 2009) and the *PRNP* gene encoding prion (Papassotiropoulos, Wollmer et al., 2005). Individual differences in memory performance have also been linked to variation in the *DISC1* gene, a schizophrenia susceptibility factor (Callicott et al., 2005), and schizophrenia-linked alleles at three polymorphisms of the neurotrophin receptor (*NTRK-3*) gene have been associated with differences in hippocampal activity during episodic encoding (Ottness et al., 2009).

As in the working memory and attention literatures, genes that influence dopaminergic signaling have been implicated. Met genotype at the *COMT* Val158Met SNP has been associated with stronger hippocampal activation during encoding and retrieval of remembered information (Bertolino, Rubino, et al., 2006; Krach et al., 2010) and with better declarative memory performance in adults and children (Bertolino, Rubino et al., 2006; de Frias et al., 2004; Diamond, Briand, Fossella, & Gehlbach, 2004). *COMT* Met allele load also correlates with a putatively advantageous decrease in the functional coupling of hippocampal and

ventral-lateral prefrontal cortex activity (Bertolino, Rubino et al., 2006). Dorsal and orbital prefrontal regions show stronger functional coupling with hippocampus among Met homozygotes, which was linked to successful encoding in a verbal memory paradigm (Schott et al., 2006). This *COMT*-related prefrontal intermediate phenotype was differentiated from an effect of *DAT1* genotype on midbrain and ACC activation during the same verbal memory task, possibly indicating a role for *DAT1* in the rapid, phasic midbrain activity that is associated with memory demands (Schott et al., 2006).

Neurotransmitter-related polymorphisms not directly related to dopamine have also been associated with memory performance and the function of memory-relevant neural systems. These include variations in the serotonin-2A receptor (*5-HT2A*) gene (de Quervain et al., 2003; Papassotiropoulos et al., 2005) and the alpha2b-adrenergic receptor (*ADRA2B*) gene, which has been specifically linked to emotional memories and amygdala activation during encoding (de Quervain et al., 2007; Rasch et al., 2009).

Several insights into genetic factors that affect the molecular- and systems-level implementation of memory have arisen from studies of a panel of genes that influence memory-related cellular signaling and synaptic plasticity. de Quervain and Papassotiropoulos (2006) targeted a specific cluster of genes expressed within a cellular signaling cascade that includes the metabotropic glutamate receptor and the adenylyl cyclase enzyme. A large group of behaviorally tested participants was assigned genotype "scores" based on their genotype at seven polymorphisms in this genetic cluster. Thirty-two participants whose behavioral performance was similar were selected for an fMRI study. This approach enabled the researchers to isolate the effects of genotype on intermediate phenotype while controlling for other factors related to behavioral performance that might influence brain activity (e.g., motivation). Genotype scores that correlated with greater hippocampal and medial temporal activity in fMRI participants were also associated with better memory performance among non-fMRI participants.

These researchers similarly demonstrated the effect of a polymorphism in the calmodulin-binding transcription activator 1 (*CAMTA1*) gene on medial temporal and hippocampal activity during a task of episodic memory retrieval (Huentelman et al., 2007). This *CAMTA1* polymorphism was first identified as

a candidate by a high-density genome-wide scan of 502,627 SNPs on a DNA microarray (frequently referred to as a “gene chip”) to screen for SNPs that were predictive of memory performance among a large sample of behaviorally tested participants (Huentelman et al., 2007). A tyrosine-to-cytosine substitution in the *KIBRA* gene was also a predictor of better episodic association memory in this population. At the neural level, *KIBRA* genotype influences the efficiency of memory-related hippocampal activation (Papassotiropoulos et al., 2006) as well as hippocampal volume and functional coupling between hippocampal and cingulate cortices (Emery et al., 2009). These effects are putatively due to an effect of KIBRA, a novel cytoplasmic protein, on synaptic plasticity that supports long-term potentiation in hippocampus (Emery et al., 2009; Papassotiropoulos et al., 2006). DNA microarray analysis of the kind utilized in this and related research (Potkin et al., 2009) is a powerful tool for identifying candidate polymorphisms in broad swaths of the genome, and it is likely to have great impact on future cognitive neurogenetic investigation. In addition, the strategies employed by Papassotiropoulos et al. further demonstrate the usefulness of considering multiple polymorphisms in the investigation of single cognitive phenotypes in order to begin engaging the extensive polygenicity of human cognitive traits (de Quervain & Papassotiropoulos, 2006; Rasch, Papassotiropoulos, & de Quervain, 2010).

Language

Understanding the underpinnings of language function has been a topic of great interest in cognitive neuroscience, and it has great importance for informing the treatment of language disorders. However, language processing has received relatively little attention in the cognitive neurogenetics literature, despite a relatively well-delineated neural architecture (Binder et al., 1997; Hickok & Poeppel, 2007). The genetics of language function have been approached through linkage studies, which have yielded important results concerning the chromosomal loci of language-related genes (Bishop, 2001; Fisher & DeFries, 2002; Fisher, Lai, & Monaco, 2003). Structural imaging has demonstrated high heritability of gray matter volume in prefrontal language areas as compared to other prefrontal regions (Thompson et al., 2001). However, only a few of cognitive neurogenetic investigations have sought to tie language-related brain networks to specific genes implicated in language function. In

particular, more work is needed to identify molecular-genetic and systems-level mechanisms that contribute to variation in normal, nondisordered language processing.

Much of the research performed to date has focused on a point mutation in the forkhead box P2 (*FOXP2*) gene, a transcription factor that regulates genes involved in neural development. *FOXP2* contains evolutionarily recent amino-acid changes that may have arisen with the advent of human spoken language (Enard et al., 2002; Fisher et al., 2003; Lai, Gerrelli, Monaco, Fisher, & Copp, 2003). Variation in the *FOXP2* gene has been linked to a rare language disorder in family studies among patients and their unaffected relatives (Fisher et al., 2003; Lai, Fisher, Hurst, Vargha-Khadem, & Monaco, 2001). Variation in *FOXP2* genotype has been associated with gray matter density in several areas involved in language production as well as language reception and comprehension (Belton, Salmond, Watkins, Vargha-Khadem, & Gadian, 2003; Watkins et al., 2002). People with the nondisordered (normal) *FOXP2* genotype showed stronger recruitment than affected siblings in Broca’s area and inferior prefrontal regions associated with language comprehension during both overt and covert verb generation (Liegeois et al., 2003).

A novel candidate polymorphism, rs1006737 in the alpha 1C subunit of the L-type voltage-gated calcium channel (*CACNA1C*) gene, which has been previously implicated in impaired verbal fluency in bipolar disorder, has recently been shown to affect inferior frontal gyrus activity during a semantic fluency task in healthy participants and to affect performance of a more demanding semantic fluency task performed outside the scanner (Krug et al., 2010). The same group of researchers has demonstrated that inferior frontal and right middle temporal activation, and out-of-scanner semantic fluency performance, decrease in healthy participants concomitant with increasing numbers of the schizophrenia-risk-associated T allele of the rs35753505 SNP of the neuregulin 1 (*NRG1*) gene (Kircher et al., 2009). These researchers have also shown an association between genotype at rs1018381 of the schizophrenia-linked dysbindin 1 (*DTNBP1*) gene and neural efficiency in ACC and superior and middle temporal gyrus (Markov et al., 2009), as well as an association between Val allele load at the *COMT* Val158Met SNP and left inferior frontal activity (Krug et al., 2009), during their semantic fluency task.

Additional insight into the cognitive neurogenetics of language has come from an investigation of the *PLXNB3* gene, which is expressed predominantly in the brain and encodes Plexin B3, a potent stimulator of neurite growth (Rujescu et al., 2007). Two candidate polymorphisms on the *PLXNB3* gene were used to define three distinct haplotypes. Carriers of the most evolutionarily recent haplotype scored highest for verbal intelligence and showed the greatest whole-brain white matter volume (Rujescu et al., 2007). Genetic influences on neurite growth and white matter connectivity have also been implicated in normal language-related variation in studies examining the effects of *BDNF* genotype on verbal cognition (Egan et al., 2003; Ho et al., 2006). In addition, the *CACNA1C* gene has been implicated in mediation of synaptic plasticity via the encoded calcium receptor's role in a second messenger cascade (Moosmang et al., 2005; White et al., 2008), and the *NRG1* gene is linked to white matter myelination (Nave & Salzer, 2006). These initial findings provide a starting point for future investigations to directly evaluate whether molecular-genetic determinants of white matter connectivity and efficacy account for variance in functional brain-based measures of language.

Conclusions and Future Directions

Connecting variations in the genome to individual differences in human brain function is not only an endeavor for clinicians. This approach has begun to inform cognitive neuroscientific models of variation among healthy individuals. It is early yet, but coalescing themes can be discerned in data. Mental abilities such as working memory and attention that are characterized by fast, nimble responses to dynamic stimuli, seem to be most influenced by genetic variables related to neurotransmitter signaling (e.g., dopamine transmission), a relatively rapid-fire form of communication in the brain. By contrast, long-term memory seems to show a relatively strong influence of genes (e.g., *BDNF*) that shape long-duration synaptic connections between neurons. Meanwhile, early returns from the cognitive neurogenetics of language implicate genes (e.g., *FOXP2*) that guide construction of the developing brain. These broad themes may become more definite under closer scrutiny, and with further aggregation of data, or they may dissolve into finer-grained hypotheses delineating individual causal pathways from genes to brain to cognition.

New Data, Familiar Theory

Molecular-genetic data can contribute to cognitive neuroscience in multiple ways. They are a source of key constraints on the mechanisms that mediate a given psychological function, providing a qualitatively different measure with which to test hypotheses. This function is similar to the way in which neural data have helped inform cognitive science by providing empirical constraints, which help to test competing hypotheses about the implementation of a cognitive function. Molecular-genetic data can also be used to identify causes of individual variation (specific genes and gene–environment interactions), which can both help to explain such variation, and to remove unwanted variation from cognitive and brain-based investigations that take genotype as a covariate (Green et al., 2008). Genetic variation can be leveraged to parse and inform between-group differences in neural structure and function that correlate with genetic variables of interest. This use of genetic research is similar to the way that cognitive neuroscience data help to parse and inform individual differences in psychological constructs (e.g., intelligence, personality, clinical status). Brain-based indices are now taken to be physical markers of individual differences in cognitive function and to contain new information about mechanism not visible in behavior alone, sometimes even in the absence of behavioral differences (Gray et al., 2005). The potential exists for cognitive neurogenetic data to identify even deeper-lying markers and to establish the scaffolding for a vertical integration of all data concerning a cognitive function, extending from psychological phenotype down through biomolecular implementation and genomic coding.

Such potential can be glimpsed in the literature that is developing around a number of the genetic variants reviewed here. In these cases, cognitive neuroscience in humans has pointed toward neural systems and characteristics that support a particular cognitive function (e.g., hippocampal plasticity in declarative memory), and candidate genetic variants (e.g., the *BDNF* Val66Met polymorphism) have been selected that are plausibly related to the identified neural systems. As neural and behavioral effects (e.g., differential hippocampal activation and memory performance) come to reliably implicate molecular-genetic mechanisms “downstream” of the targeted genetic variants (e.g., putatively differential trafficking and secretion of *BDNF*), this information will be used to inform and constrain subsequent models and predictions.

More immediately, genetic data provide an additional level of analysis to complement and inform traditional cognitive neuroscience questions. For example, in the attention literature, the use of genotypic dissociations to enrich behavioral and neural dissociations between types of attention is a relatively well-developed demonstration of the utility of genetic data in cognitive neuroscience.

Indications for Future Research

Much as cognitive neuroscientific data have enriched earlier behavioral models of the mechanisms supporting psychological function, one might expect a similar enrichment of cognitive neuroscience over the next 20 years with the incorporation of genetic data. However, an understanding based on genetic dissociations, or gene–brain associations, without careful regard for psychological theory, will not be enough. The ubiquity and strength of gene-environment interactions requires that a complete description also account for the environment. The environment includes any contextual effects on gene function whether these be other genes, developmental influences, or the wider social-psychological milieu (Caspi & Moffitt, 2006; Fisher, 2006). In addition, as new candidate polymorphisms continue to be identified, meaningfully integrating this information with the cognitive neuroscience literature will require more than fragmentary associations with individual cognitive tasks. Grouping these associations in principled ways, and testing genetic effects on underlying cognitive constructs—constrained by predictions based on brain regions known to underlie those constructs—will be essential to finding constellations of meaning on a horizon already crowding with new and sometimes seemingly contradictory genetic associations. Thus, psychological theory and psychometric expertise will be more indispensable, not less, for channeling an influx of a new type of data toward the familiar goal of understanding how properties of mind are constituted physically (Plomin, 2000).

NOT JUST IMAGING

Full development of a young field will depend on the use of multiple cognitive neuroscience methods—not just brain imaging—in order to overcome the inherent limitations of any single method. For example, measuring the effects of cholinergic-system-related gene variation on electrical oscillation patterns in the brain (e.g., Begleiter & Porjesz, 2006, or the effects of serotonin-system-related genetic

variation on neural error processing at the millisecond scale (e.g., Fallgatter et al., 2004), requires direct sensitivity to electrical activity, which fMRI and other brain-imaging methods cannot provide. In addition, agonist and other chemical treatment studies in clinical and healthy populations, cadaverous tissue expression assays, temporarily induced lesion studies, and other brain-based methods will help to provide breadth and convergence of data to grow the field and strengthen its core findings. For this reason we prefer the more comprehensive term, *cognitive neurogenetics*, to the more focused term, *imaging genetics*.

RULES OF THUMB

At least four specific prescriptive indications for future investigations can be gleaned from the early history of cognitive neurogenetics.

1) Use large sample sizes, much larger than typical sample sizes for MRI, PET, and EEG. Much, if not most, cognitive neurogenetic work to date has been underpowered to accurately reject the null hypothesis (Green et al., 2008). De Geus and colleagues propose a rule of thumb of at least 10 participants in the smallest genotype group (de Geus, Goldberg, Boomsma, & Posthuma, 2008), which will often require sample sizes in the hundreds. Higher numbers of participants are also required in order to employ DNA microarray analyses in studies of brain-assayed participants.

2) Adhere to psychological theory and psychometric rigor. Points of emphasis here include the use of cognitive tasks with strong construct validity, the use of latent variables comprising multiple theoretically related tasks to represent a psychological construct, and replication of effects on closely related tasks within and between laboratories.

3) Seek integration with molecular-genetic and molecular-biological data. In particular, what is known about regional brain expression and protein-level effects (e.g., enzymatic activity) of a genetic variation should constrain a priori hypotheses about brain characteristics targeted for investigation as intermediate phenotypes. As much as possible, all the levels of measurement in a particular study (e.g., genotype, transmission/binding, neural activity, brain structure, cognitive performance) should be integrated into a single model to test directional predictions about the effects of genetic variation on downstream variables and the effects of downstream variables on each other.

4) Take a systems approach that begins to engage the complexity of genetic networks (variations in different genes and multiple polymorphisms in the same gene) and their effects on networks of multiple, networking brain regions.

A PATH-ANALYTIC APPROACH

A statistical framework that begins to address these indications (although imperfectly) is path-analytic mediation modeling. Path-analytic mediation models have traditionally been applied to investigate relationships between genetic and environmental variables (e.g., Munafo, 2006). Somewhat surprisingly, however, they have not yet been widely used to test whether relationships between genes and cognition are mediated by intermediate neural phenotypes. Cognitive neurogenetic studies have typically examined pairwise relationships (e.g., gene-brain and gene-cognition correlations), but pairwise relationships cannot test statistical mediation. Thus, they cannot test whether variation in a neural intermediate phenotype variable mediates the effect of a genetic variable on a cognitive variable. We have recently constructed a path-analytic mediation model that is directional from gene to brain to cognition, using data collected from 160 genotyped fMRI subjects who performed the multisource interference (MSIT) task of executive attention (Green, Kraemer, DeYoung, Fossella, & Gray, unpublished data). This model indicates an effect of *COMT* genotype on MSIT performance that is mediated by activity in a group of frontal brain regions.

Beyond testing neural mediation hypotheses, path-analytic mediation models in cognitive neurogenetics have several attractive attributes. (1) They conceptually articulate the expression pathway (gene-to-brain-to-cognition) in a clear and integrated way that is consistent with directional/causal hypotheses. This is appropriate because, with the possible exception of epigenetic influences, genetic effects generally cause neural and cognitive effects, not vice versa. (2) They can incorporate multiple intermediate phenotype variables simultaneously (e.g., activity in multiple brain regions). This is useful because cognitive functions usually involve multiple co-contributing regions and structures. (3) They can expand to include additional variables and complexity as new data inform existing models (e.g., new evidence concerning epigenetic moderator variables). (4) They organically incorporate latent variables comprising shared variance between multiple measures (e.g., multiple cognitive tasks which, together, represent an underlying psychological construct).

To achieve sufficient statistical power, path-analytic mediation requires sample sizes that may appear dauntingly large by the standards of brain-imaging research, which relies on methods that are expensive and time consuming. This is likely why mediation models have not been widely used in cognitive neurogenetics to date. The requirement of a large sample is a considerable challenge in practice; however, it is not a problem in principle. Moreover, this requirement reflects the broader reality that progress in cognitive neurogenetic research will require large-scale data collections.

In Sum

For cognitive neuroscience, the promise of molecular genetics is one of growth from characterizing the “where” and “when” of mental function toward new questions of “whence” and “how,” using a new set of powerful tools that can reveal mechanistic insights at the level of fundamental biology. While this promise is still largely unproven, and interpretive hazards require great caution, the research reviewed here suggests some emerging proof of concept and grounds for measured optimism.

Acknowledgments

The authors wish to thank M.I. Posner, J. Fossella, J. Gray, M. Munafo, and C. G. DeYoung, whose consultation contributed much to the manuscript.

Dual-Process Theories of Deductive Reasoning: Facts and Fallacies

Jonathan St. B. T. Evans

Abstract

The psychology of reasoning was dominated by the deduction paradigm from around 1960 to 2000, in which untrained participants are asked to assess the validity of logical arguments. As evidence of logical error and content-dependent thinking amassed, the paradigm has shifted recently with more emphasis on probabilistic and pragmatic processes. This chapter is focused particularly on the dual-process theories that arose from traditional studies of deductive reasoning but that now form part of a more general set of theories of higher cognition. It is argued that the “received” view of dual-process theory, which was established around 2000, actually incorporates a number of false beliefs and fallacies, which are discussed in this chapter. While dual-process theory rightly remains the focus of much current research, it is important to understand and avoid these fallacies.

Key Words: deductive reasoning, dual-process theory, inference

Introduction

The idea that there are two fundamentally different kinds of thinking has been proposed for centuries by numerous philosophers and psychologists. In many cases, such dual-process theories have been developed in ignorance of the similar ideas of both earlier and contemporary authors (Frankish & Evans, 2009). In postwar psychology, the earliest dual-process theory seems to have been that developed by Reber (1993) founded in his long program of research into implicit and explicit learning, which started in the 1960s. Reber was probably the first to suggest that implicit and explicit processes were derived from two distinct cognitive systems, one ancient and animal-like and the other recently evolved and distinctively human, an idea echoed in much later writing (Epstein, 1994; Evans, 2010; Evans & Over, 1996; Stanovich, 1999; Stanovich, 2004). Numerous dual-process theories of social cognition were also proposed in the early 1980s, including both the ideas that (a) social knowledge

may take an implicit form (e.g., stereotypes) that influences behavior independently of consciously accessible beliefs, and (b) information may be processed in an automatic or shallow manner, or in a controlled and effortful way (for recent reviews, see Deutsch & Strack, 2006; Lieberman, 2007; Smith & DeCoster, 2000, Smith & Collins, 2009).

In this chapter, I focus mostly on the theories that have arisen from research in the study of deductive reasoning, although the fallacies I shall identify may be seen in other fields in which dual-process theories are discussed. The psychology of deductive reasoning is a major tradition that dates from the early 20th century and which was intensively studied from the 1960s to date. It was built around the deduction paradigm (see Evans, 2002) in which participants are asked to assume the truth of some premises and decide whether a conclusion follows necessarily from them. Normally, participants are used who have no training in logic and none is provided by the experimenter. This paradigm derives from

a logicist tradition in philosophy and psychology which assumed that logic must be built into the mind in order to allow rational thought to take place (Henle, 1962; Inhelder & Piaget, 1958). As evidence of logical error and content-dependent thinking amassed, however, the foundations of the paradigm were gradually undermined, to the point where a distinct shift to a new paradigm psychology of reasoning appears to have occurred in the past 10–15 years. The inheritors of the deductive reasoning tradition now use a range of methods and draw on pragmatic and probabilistic accounts rather than logical processing (see Evans, *in press* for an account of the paradigm shift; also Oaksford & Chater, 2010 for many recent examples of studies based on the new paradigm). However, the deduction paradigm is still used, though interpreted somewhat differently, as we shall see later.

Dual-process theories in the deductive reasoning field have been around since the 1970s and until recently were developed independently and in ignorance of dual-process theories in social psychology and other fields. Nevertheless, the features typically attributed to the two kinds of thinking, which I shall call type 1 and type 2 in this chapter, are very similar to those proposed by authors in other fields (Evans, 2008). In Table 8.1, I list a set of the typical attributes in what I am going to call the “received” view of dual-process theory, based broadly on the writing of various authors during the 1990s. All dual-process theories seem

to contrast the idea of fast, automatic, low-effort and high-capacity processes (type 1) with slow, controlled, high-effort and low-capacity processes (type 2). The idea that type 1 thinking is unconscious and type 2 thinking is conscious has been a recurring theme in many accounts from Reber onward. The distinction between conscious and nonconscious processing has been particularly emphasized by social psychologists (e.g. Wilson, 2002) and was a feature of the earlier dual-process theory of reasoning (Wason & Evans, 1975). It has also been suggested that type 1 thinking operates preconsciously so that it precedes, shapes, and biases conscious type 2 thinking (e.g. Evans, 1989). The relationship of consciousness to dual-process theory is, however, rather more complex than implied by the received view. Consideration of this issue is beyond the scope of this chapter, but I have discussed it in detail elsewhere (Evans, 2010, Chapter 7).

The notion that type 2 reasoning involves explicit rule following, whereas type 1 processing relies on associative, experiential learning has been proposed by a number of authors writing across different fields of dual-process theory (Evans & Over, 1996; Sloman, 1996; Smith & DeCoster, 2000). Moreover, for historical reasons (see next section) there has been a strong association between type 1 processes and cognitive biases on the one hand, and type 2 processes with normatively correct reasoning on the other (see, for example, Evans, 1989; Stanovich, 1999). The same association is reflected in recent

Table 8.1. “Received” View of Dual-Process Theories of Reasoning and Higher Cognition, as It Emerged c. 2000

Type 1 Processes	Type 2 Processes
Unconscious, preconscious	Conscious
Rapid	Slow
Automatic	Controlled
Low effort	High effort
High capacity	Low capacity
Associative	Rule based
Intuitive	Deliberative
Contextualized	Abstract
Cognitive biases	Normative reasoning
Independent of cognitive capacity (IQ, WMC)	Correlated with individual differences in cognitive capacity
System 1	System 2

application of dual-process theory to the study of judgment and decision making by Kahneman and Frederick (2002). Stanovich (1999) particularly emphasized the distinction between contextually dependent type 1 processes and abstract, decontextualized type 2 thinking, talking of a *fundamental cognitive bias* to contextualize all information. In his empirical research program with West, Stanovich also demonstrated a strong association between cognitive ability (as measured mostly by SAT scores) and type 2 processing, while also showing that type 1 processes were broadly independent of such measures (Stanovich & West, 2000b).

Perhaps the most important feature of the received view of dual-process theory is that type 1 and 2 processes can be attributed to two distinct cognitive systems, now widely known as System 1 and 2 following the use of these terms by Stanovich (1999). This idea actually emerged from a combination of proposals made by several earlier authors (Epstein, 1994; Evans & Over, 1996; Reber, 1993). The two-system theory added a number of other features to the list shown in Table 8.1, in that System 1 was proposed to be an old system, which evolved early and shares many of its features with animal cognition, whereas System 2 was proposed to be recently evolved and either unique to humans or very distinctively developed in our own species. I have recently developed these concepts within a two-minds (rather than two-system) theory (Evans, 2010), but I will not discuss them in this chapter because the focus is on the more restricted dual-process theory. I will, however, discuss the idea that type 1 thinking can be allocated to just one system and type 2 thinking to another.

Having explained the received view of dual-process theory, I must now comment that both experimental research and theoretical analysis have moved on a lot in the past decade in such a way that it now appears many of the attributes listed in Table 8.1 are in some

ways suspect if not outright fallacious. However, even among dual-process researchers, awareness of some of these issues is not as high as it might be. So in the later part of this chapter, I am going to discuss a number of fallacies that I believe to be associated with research on dual process (see Table 8.2). Note that I use the term “fallacy” rather loosely here: Some of the points in Table 8.2 refer to genuine inferential errors, whereas others are simply false beliefs. All result in mistaken interpretation or application of dual-process theory, however. I hasten to add that it is not my purpose to reject the fundamental type 1 and 2 distinction. So I will precede my discussion of the “fallacies” with two other sections. In the first I will sketch a brief history of the psychology of deductive reasoning and show how the dual-process theory developed. This is important both to understanding how contemporary research on dual-process theory is conducted, as well as explaining the origin of some of the fallacies. In the following section, I will present the experimental and neuroscientific evidence which I believe should compel us to take the type 1 and 2 distinction seriously. Finally, I shall discuss the fallacies that require us to think much more carefully about the way in which we discuss dual processes and conduct research upon them.

Deductive Reasoning and the Origins of the Dual-Process Theory of Reasoning

The earliest studies of deductive reasoning were published prior to World War II and used classical (Aristotelian) syllogisms (Wilkins, 1928; Woodworth & Sells, 1935). Such syllogisms are comprised of two premises and a conclusion that may or may not follow logically from the premises. These early studies provide a foretaste of what was to come in the modern study of the topic. Participants were shown to endorse many fallacies, that is to say that conclusions followed logically when they did not. They were also shown to be systematically

Table 8.2. Some Fallacies Associated With Dual-Process Theories of Thinking and Reasoning

-
1. All dual-process theories are essentially the same

 2. There are just two systems underlying type 1 and 2 processing

 3. Type 1 processes are responsible for cognitive biases; type 2 processes for normatively correct responding

 4. Type 1 processing is contextualized, whereas type 2 processing is abstract

 5. Fast processing indicates the use of a type 1 rather than type 2 process

biased by both the linguistic form of the syllogisms and the believability of the content (see Evans, Newstead, & Byrne, 1993 for a detailed review of research on syllogistic reasoning). Despite these early findings, the logicist ethos of the 1960s saw the launch of a large program of research employing the deduction paradigm.

While a U.S. tradition continued to focus mostly on people's ability to evaluate classical syllogisms, the British psychologist Peter Wason extended the paradigm with ingenious tasks of his own invention, the most famous of which is the four-card selection task (Wason, 1966). This task went beyond the deduction paradigm by involving hypothesis testing, but it still used formal logic as a normative reference. It has been studied by the same research community as those employing the deduction task proper and traditionally treated by reviewers as part of the same field (e.g. Evans, 2007a; Evans et al., 1993; Manktelow, 1999). The standard abstract task involves four cards lying on a table, on whose exposed sides might be the values

A D 3 7

Participants are told that each card has a capital letter on one side and a single-digit number on the other. They are also told that the following rule applies to these four cards and may be true or false:

If there is an A on one side of the card, then
there is a 3 on the other side of the card.

Their task is to identify those cards, and only those cards, which must be turned over in order to decide whether the rule is true or false. Given this task, most people choose the A card and a number of others choose the A and the 3. Wason argued that neither choice was logically correct: Participants should turn over the A and the 7. The reason is that only by discovering a card with an A on one side that did *not* have a 3 on the other could one prove the rule false, and only these cards could lead to such a discovery. Wason also discovered that the task can be easy to solve when framed with realistic content (see Wason & Johnson-Laird, 1972). Researchers became fascinated with both the difficulty of the abstract task and the apparent ease of certain realistic versions, with the result that study of human reasoning was dominated by the task for the next 25 years or so (see Evans & Over, 2004, Chapter 5, for a review).

From the 1970s onward, psychologists also started to study conditional inference, which uses

the deduction paradigm proper. The focus of interest has been on what philosophers term "elimination inferences" (conditional introduction inferences have been relatively neglected; see Over, Evans, & Elqayam, 2010). There are four of these as follows:

Modus Ponens (MP)	If p then q; p, therefore q
Denial of the Antecedent (DA)	If p then q, not-p, therefore not-q
Affirmation of the Consequent (AC)	If p then q, q, therefore p
Modus Tollens (MT)	If p then q, not-q therefore not-p

Interest in the study of conditional inference has gradually increased to the point where it is nowadays more commonly studied than the selection task, although not necessarily with deductive reasoning instructions. Of the four inferences, two (MP, MT) are logically valid and two (DA, AC) considered to be classical fallacies. Early studies soon established (a) that the fallacies are commonly endorsed (in common with findings on syllogistic reasoning) and (b) that while MP is endorsed with near 100% frequency, the other valid inference MT is far from obvious, with endorsement rates of around 60%–70%.

Explaining these findings became an issue of the major debate between two rival accounts of deductive reasoning which took place mainly in the 1980s. One tradition, known as "mental logic" was introduced to cognitive psychologists by Martin Braine (1978), although Jean Piaget's theory of formal operations was a precursor in developmental psychology (Inhelder & Piaget, 1958). According to this view, people have a set of logical rules built into their minds to permit reasoning, which proceeds as a kind of mental proof. Well-developed mental logic theories are presented by Braine and O'Brien (1998b) and Rips (1994). While standard logic has a rule for Modus Tollens, these authors suggested that mental logics do not, in order to account for the relative difficulty of the inference. Instead, MT could be derived by error-prone indirect reasoning procedures. Endorsement of the fallacies, DA and AC, was attributed to a mechanism outside of mental logic, namely that of pragmatic implicature. The rival theory, based on mental models, was launched by Johnson-Laird (1983; see also Johnson-Laird & Byrne, 1991). According to this theory, people do not require any logical rules in their heads to perform deductive reasoning. Instead, they operate a simple semantic principle: a deduction is valid if

there are no counterexamples to it. In this theory, logical possibilities are represented by mental models that may be fleshed out or eliminated as reasoning proceeds. People are deductively competent in principle but fallible in practice, as they have limited working memory capacity with which to consider models and are subject to a number of processing biases (see Johnson-Laird, Chapter 9, for a detailed account of research on mental model theory).

The mental model theory also gave an account of the basic phenomena of conditional inference (Johnson-Laird & Byrne, 2002). Initially, people consider explicitly only one mental model “*p & q*,” which allows MP but not MT to be easily drawn. To draw MT, people must “flesh out” models representing other possibilities, such as “not-*p* and not-*q*.” The endorsement of fallacies could result from superficial processing or biconditional representation in which the possibility “not-*p* and *q*” is excluded. It is interesting to note that although neither mental logic nor mental model theories were formulated as dual-process accounts, each makes proposals that can easily be mapped on to the type 1 and 2 distinction. Both proposed fast, low-effort (type 1) processes: immediate inference with built-in rules like MP, or formulation of and inference from initial mental models. Equally, both proposed effortful, error-prone (type 2) processes: indirect reasoning procedures or fleshing out of implicit mental models.

While mental model theory became a major paradigm in the 1980s and 1990s, this was also the heyday of the Wason selection task, especially in its realistic form. Theorists debated whether facilitatory versions reflected Darwinian algorithms for social exchange and hazard avoidance (Cosmides, 1989; Fiddick, Cosmides, & Tooby, 2000), acquired pragmatic reasoning schemas (Cheng & Holyoak, 1985; Holyoak & Cheng, 1995), or domain-general procedures based on either decision theoretic principles (Manktelow & Over, 1991; Oaksford & Chater, 1994) or pragmatic relevance (Sperber, Cara, & Girotto, 1995). In my view, these debates were never satisfactorily resolved. However, they did contribute to the downfall of the deduction paradigm in its traditional form, as all of these theorists emphasized the nonlogical nature of the cognitive processing involved.

The first explicit dual-process theory emerged in the 1970s in the context of the original abstract version of the selection task. Wason had conducted a number of experiments with the selection task

in which the erroneous patterns persisted and in which 10% or less of participants gave the correct solution. He found participants to be resistant to various “therapies” he devised to encourage insight into the task and concluded that they were fundamentally irrational, as he never doubted the logical standard for rationality (see Evans, 2002). However, this thinking was challenged when a very simple method of facilitating logical selections on the task was discovered. This involved putting a negation into the second part of the conditional statement. Suppose for the same set of cards shown earlier the rule was as follows:

If there is an A on one side of the card, then there is NOT a 3 on the other side of the card.

Now, the correct choice is A and 3 because a card with these values would falsify the claim. And this is what most participants also select, turning a very difficult problem into an easy one (first shown by Evans & Lynch, 1973; there have been many later replications as reviewed by Evans, 1998). The tendency to select cards named in the rule was termed “matching bias” and created a theoretical puzzle for Wason. He had already shown, in other research on the task, that participants gave verbal justifications for their choices that seemed to reveal the degree of insight that these choices suggested. But no one mentioned matching bias as a cause of his or her selections.

Wason and I collaborated on two papers to try to understand what was going on (Wason & Evans, 1975; Evans & Wason, 1976). In the first of these we gave both the hard affirmative and easy negative version to participants and asked them to write verbal justifications for their choices. We found, first of all, a strong matching bias on both tasks regardless of the order in which we presented them. We also found that participants always gave a justification consistent with their choices. So if they received the negative rule first and chose the correct (and matching) cards, they would say they were trying to falsify the statement. But when given the affirmative rule second, this apparent insight disappeared and with it the correct choices. Now they said they were trying to prove the statement true. And, of course, no one gave matching bias as the reason for his or her choices. Wason and Evans concluded that an unconscious type 1 process (matching) was responsible for the choices, while conscious type 2 processes were simply post hoc rationalizations, a conclusion supported by a different method in our second paper.

The original Wason and Evans study has also been replicated recently in essential respects by Lucas and Ball (2005) whose findings broadly supported the original conclusions.

A question left hanging by the 1975 paper was whether explicit reasoning (type 2 processing) did more than simply rationalize card choices on this task. Dual-process accounts typically propose a competition between two processes in determining the actual behavior observed. But for a long time it seemed as though card choices on the selection task might simply reflect the attention that was paid to individual cards. For example, using a computer-presented version of the task, Evans (1996) asked participants to point the mouse to cards they were thinking of selecting, thus measuring card inspection times. It was found that much more time was spent inspecting cards that were subsequently selected, suggesting that the “reasoning” observed was mostly to justify preconsciously cued selections. Although the mouse-pointing method was criticized (Roberts, 1998), all essential findings were replicated using eye-movement tracking by Ball et al. (2003). However, a recent reanalysis of this study (Evans & Ball, 2010) has cast new light on the issue. While matching cards are inspected for much longer amounts of time, they are not always selected, especially in cases where such choices would be hard to justify. This finding accords with other evidence that reasoning does, in fact, affect choices on the task (Feeney & Handley, 2000; Handley, Feeney, & Harper, 2002).

The other main origin of the dual-process theory in the study of deductive reasoning came from the study of syllogistic reasoning and the phenomenon of “belief bias.” The belief bias paradigm provides perhaps the prototypical dual-process finding in the field of deductive reasoning because in contrast with the selection task, it appeared clear from the start that both type 1 and 2 processes were influencing the decisions made. Belief bias is the tendency to judge the validity of a logical argument on the basis of whether one agrees with the conclusion. When strict deductive reasoning instructions are employed, the believability of the conclusion is irrelevant, and so its influence is considered to be a cognitive bias. The effect was first demonstrated by Wilkins (1928), but subsequent research was marred by methodological problems. The modern study of the topic is usually considered to start from the paper of Evans, Barston, and Pollard (1983), who established the basic phenomena with all relevant

controls (replicated many times since; for a recent major study see Klauer, Musch, & Naumer, 2000). The paradigm involves asking people to evaluate syllogisms (three term problems, with two premises and a conclusion) in each of four categories: valid-believable, valid-unbelievable, invalid-believable, and invalid-unbelievable. Thus, conclusions might be supported by logic or by belief or neither. Evans et al. found that participants approved valid conclusions 89% of the time when they were believable but only 56% when unbelievable. Invalid conclusions were accepted only 10% of the time when unbelievable, but an astonishing 71% of the time when they accorded with prior belief. Thus, there were three reliable effects: (a) a preference for valid over invalid conclusions, (b) a preference for believable over unbelievable conclusions, and (c) a belief by logic interaction (more belief bias on invalid arguments). On the basis of protocol analysis and other measures, Evans et al. concluded that there was a *within-participant* conflict between belief and logical reasoning. The same person might go with logic on one problem, but belief on another.

It is interesting to note that dual-process theories arose originally from a more descriptive approach in which both logical and nonlogical factors were observed to influence behavior in these tasks—described as the two-factor theory of reasoning (Evans, 1982). It was only later that they were explicitly linked to “analytic” (type 2) and “heuristic” (type 1) processes (Evans, 1989). Both matching bias and belief bias were seen as nonlogical factors in the two-factor approach. While this chapter is concerned mostly with explanations in terms of two types of cognitive processing, it should be noted that recently there has been some reversion to the two-factor approach, mostly due to a revival in the popularity of mathematical modeling (Beller, Bender, & Kuhnmnnch, 2005; Dube, Rotello, & Heit, 2010; Klauer, Beller, & Hutter, 2010). These recent models treat logical form and prior belief as two *sources* of evidence that influence reasoning responses and have provided convincing support for this claim. A dual-source model is not necessarily a dual-process model, though, as a single type of cognitive process could be influenced by more than one source of evidence. Hence, I will focus here on more cognitively oriented work.

One feature of the protocols collected by Evans et al. (1983) was consistent with those of Wason and Evans (1975): no one mentioned the believability of the conclusion as a reason for his or her decision.

So once again, we have a case where an apparently unconscious type 1 process (belief bias) conflicts with logical reasoning. Even though it is apparently less dominant than matching bias is on the selection task, people once again appear to be unaware of this process and able to rationalize the choices they make. It is on these empirical observations that the dual-process theory of deductive reasoning was formed. Perhaps unsurprisingly, the explanation of cognitive biases exclusively in terms of unconscious or preconscious type 1 processing (Evans, 1989) was the main focus of such research for many years after. Although I now consider that conclusion a mistake that has been corrected in recent writing (Evans, 2006b; 2007a), the case for dual processes made by these early studies remains compelling. It seems that people's choices on these tasks are partly a function of explicit reasoning and partly caused by cognitive biases of which they are unaware.

Evidence for the Reality of the Type 1 and 2 Distinction in the Psychology of Reasoning

Dual-process theories of reasoning, as indicated in the previous section, were developed during the main period of traditional study of deductive reasoning, c. 1960–2000. This was reflected in some of the language originally used, as in the description of logical versus nonlogical factors, or the contrast of the role of logic and belief in syllogistic reasoning. However, it is important to note that not only has dual-process theory adapted to the new paradigm psychology of reasoning, but it has flourished within it (see Evans, *in press*). Dual-process theorists no longer refer to type 2 processing as logical, and the association of type 2 processing with normatively correct solutions has been specifically deemphasized in recent writings (Evans, 2007a; Stanovich, 2010). Nevertheless, the history of these theories has strongly influenced the *received* view of dual-process theory and the persistence of some of the fallacies listed in Table 8.2, which I discuss in the next section.

Dual-process theories are open to criticism on the grounds that the features listed in Table 8.1 are not reliable indicators of two kinds of processing or even consistently correlated with one another. For this reason, recent authors have focussed the debate about the type 1 and 2 distinction on the issue of whether working memory is involved (see Evans, 2003; 2008). By "working memory" I mean a singular, central, and capacity-limited resource of the kind discussed by Baddeley (2007) and as implied

by the large program of work that measures *working memory capacity* and correlates it with many cognitive functions (Barrett, Tugade, & Engle, 2004). Defined in this sense, the contemporary view is that type 2 processing requires and taxes working memory, whereas type 1 processing does not.

As an example, suppose I ask you whether the following statement is believable: "If an animal is a dog, then it has a tail." You might be inclined very quickly to say "yes" without any conscious effort—a rapid, intuitive type 1 response. But if instead I ask you, is it *necessarily* true that "If an animal is a dog, then it has a tail" you might, after reflection, answer no. In the second case you would attempt to call counterexamples to mind: You might think of a breed of dog that has no tail, for example, or consider the possibility that a dog has its tail amputated due to an accident. Reflective thinking of this kind, with consideration of counterexamples (see Johnson-Laird, Chapter 9), requires use of working memory, which makes it a slower and more effortful type 2 process. In fact, recent evidence (Verschueren, Schaeken, & d'Ydewalle, 2005; Oberauer, Geiger, Fischer, & Weidenfeld, 2007) suggests that we may use both associative (type 1) and reflective (type 2) processes when we reason with such conditional statements.

If type 2 processing requires access to working memory, then it explains a number of the features listed in Table 8.1 as being typical of this kind of thought; for example, it is going to be relatively, slow, sequential, high effort and low capacity compared with type 1 thinking, which can bypass working memory. It also explains why type 2 processing is thought to be strongly correlated with measures of cognitive ability. Working memory capacity (WMC) is generally measured by counting the number of items that can be held in short-term memory while simultaneously performing a cognitive task. However, individual differences in WMC are closely correlated with those measured by tests of general intelligence (Colom, Rebollo, Palacios, Juan-Espinosa, & Kyllonen, 2004). Hence, the observation that reasoning ability is closely linked to SAT scores (Stanovich, 1999; Stanovich & West, 2000b), themselves a close correlate of IQ, can readily be interpreted as reflecting the load that type 2 processing puts on working memory.

There are essentially three methods that can be used to test the hypothesis that there are type 2 processes loading working memory, competing or combining with type 1 processes that do not. The

first is to demonstrate that individual differences in cognitive capacity (WMC, IQ, SAT, etc.) *differentially* correlate with behaviors that are attributed to type 1 and 2 processes in standard dual-process accounts of reasoning tasks. The second is to show that performing a reasoning or decision task under a concurrent working memory load *selectively* disrupts type 2 processing. The third method exploits the fact that type 2 processing is generally slower than type 1 processing. So again, we may expect selective disruption of type 2 processes if people are given little time to think—the so-called speeded-task method. Research studies using all three methods appear to support the validity of the type 1 and 2 distinction.

There is a potential problem with the correlational method, however, that should be acknowledged at the outset. The general approach assumes that behaviors dependent upon type 2 processing will be strongly and significantly correlated with cognitive capacity and those based on type 1 processing will have little or no correlation. As an example, Stanovich and West (1998) observed that the small minority of participants who succeed in solving the standard abstract version of the Wason selection task were of exceptionally high IQ. However, when tested on a realistic, deontic version of the task known to be much easier (see Cheng & Holyoak, 1985), there was little correlation with cognitive ability. This was interpreted as evidence that type 2 processing was needed for abstract reasoning, but that the realistic version was facilitated by pragmatic cues of a rapid, automatic (type 1) nature. The problem with the logic here is that a process that uses working memory but does not tax it much may fail to produce a correlation with WMC or one of its correlates in a given sample of people. In fact, Newstead et al. (2004) later showed that with lower ability samples, performance on the deontic selection task *does* correlate substantially with IQ. Even if the correct answer is pragmatically cued on this task, it still requires the ability to follow and comply with a fairly demanding set of instructions, and surely this aspect, at least, loads upon working memory. This raises the issue of whether there are any responses that can be attributed purely and unambiguously to type 1 or 2 processing. Recent research has also complicated the picture in another regard. Whereas earlier studies showed mostly (but not entirely) that individual differences in ability correlated with finding the normatively correct solution to reasoning and

decision problems (Stanovich, 1999), there is now evidence that a substantial range of cognitive biases in decision tasks may be independent of such measures (Stanovich & West, 2008).

The fact that high-ability people can show cognitive biases should not necessarily be seen as evidence against dual-process theory (see discussion of fallacy 3 later). However, it does show how complex the individual differences method is. Stanovich (1999, 2009a, 2009b) has argued that rational performance requires a combination of both sufficient cognitive capacity and a rational thinking disposition. The latter is partly a matter of personality, as measured by scales such as Need for Cognition (Cacioppo & Petty, 1982) but also a function of instructions and context. I will consider two examples, which seem to require retention of a dual-process approach. Stanovich and West (2008) show that some cognitive biases can be resisted by participants of higher cognitive ability provided that a within- rather than between-participant design is adopted. For example, the conjunction fallacy (Tversky & Kahneman, 1983) involves participants judging, in some circumstances, that $P(A \& B)$ is greater than $P(A)$, a logical impossibility. When asked to rate the probabilities in separate groups, cognitive ability is of no help. In a within-participant design, however, high-ability participants may notice the logical inconsistency in their rating of the two outcomes and hence be able to correct it.

Other recent evidence supporting the dual-process approach involves causal conditional inference. This involves study of the four conditional inferences, described earlier, using “if p then q” statements that are realistic and about which people hold prior beliefs of causality. When such materials are used, the endorsement rates for both the valid (MP, MT) and fallacious (DA, AC) inferences may be substantially affected. For example, the tendency to endorse MP can drop well below 100% when people do not believe that p will lead to q in particular conditional statement (e.g. George, 1995; Stevenson & Over, 1995). More generally, when causal conditionals are used, people are substantially influenced by whether p is regarded as a *sufficient* cause for q (affects MP, MT) and as a *necessary* cause for q (affects DA, AC; see Thompson, 1994, 2000). Similar results are found when people are asked to rate the equivalent subjective probabilities: $P(q|p)$ and $P(p|q)$ (e.g., Dieussaert, Schaeken, & d'Ydewalle, 2002). When strict deductive reasoning instructions are employed, as they often are, we can

regard these findings as another form of belief bias. People's prior beliefs about the causal relations are apparently competing with their attempt to follow the instructions and reason deductively.

It has been suggested that the endorsement of conditional inferences is based on nothing more than the subjective conditional probability of the conclusion given the minor premise (Oaksford, Chater, & Larkin, 2000), in which case a dual-process account of causal conditional reasoning would not be required. However, if this were the case, then it should make no difference whether the conditional statement was presented. Consider this DA inference:

If the Bank of England raises interest rates, then the UK inflation rate will decrease.

Suppose the Bank of England does not raise interest rates. Does it follow that the UK inflation rate will not decrease?

If people judge this inference purely on their prior beliefs about causal relations in the economy, then they should give the same answer when the conditional statement is omitted. If, however, they are making an attempt to reason according to instructions, then the fallaciousness of the DA inference should lower their expressed confidence in the conclusion. In a recent study, Klauer et al. (2010) showed that it does make a substantive difference with such inferences whether the conditional statement is present. In a detailed modeling exercise they showed that both the logical form of the inference and prior beliefs influenced the conclusions drawn, in line with a dual-process account.

The dual-process theory is also supported by a recent study of causal conditional inference in my own laboratory (Evans, Handley, Neilens, Bacon, & Over, 2010). We presented such inferences either with pragmatic reasoning instructions (rate the belief in the conclusion given the premises) or with strict deductive reasoning instructions (assume the premises are true and decide whether the conclusion is logically necessary). This is fairly typical of the use of the deduction paradigm within the contemporary psychology of reasoning. It is no longer administered to test people's native logical abilities, but rather as a means of enforcing the need for type 2 processing to deal with a novel and difficult task. In this case, we found that participants of higher IQ were better able to inhibit the influence of belief on their reasoning, but only when deductive reasoning

instructions were given. Under pragmatic instructions, both groups were equally influenced by beliefs. This strongly supports Stanovich's (2009a) argument that both sufficient cognitive ability and a disposition for critical thinking are required for effective type 2 override of type 1 responding. De Neys et al. (2005a, 2005b) similarly found that while higher ability participants are influenced by prior knowledge on such tasks, they will inhibit counterexamples that come to mind which would otherwise block a valid inference. They also showed that reasoning is more belief based when a concurrent working memory load is administered to block type 2 processing.

Turning to the belief bias effect in syllogistic reasoning, there are a number of reported findings consistent with the dual-process theory. Very strong deductive reasoning instructions can reduce but not eliminate the effect (Evans, Allen, Newstead, & Pollard, 1994). When prior belief and logical validity are put into conflict, the ability to inhibit beliefs is greater for those of higher cognitive ability (Stanovich, 1999) but declines sharply in old age (Gilinsky & Judd, 1994). Belief bias is substantially larger when people are forced to respond quickly in a speeded task (Evans & Curtis-Holmes, 2005) or when a concurrent working memory load is administered (De Neys, 2006). These results suggest that belief bias is the result of a rapid type 1 process that provides a default response that may or may not be inhibited and overridden by type 2 reasoning. This conclusion, in turn, is supported by several studies using neural imaging methods. For example, on belief-logic conflict problems, a region in the right prefrontal lateral cortex, associated with inhibitory executive processes, tends to be activated but *only* when the participant gives the answer that favors logic over belief (Goel & Dolan, 2003; Tsujii & Watanabe, 2009).

To summarize, it is difficult to see how a single-process account can be given of the accumulated experimental evidence on deductive reasoning. Even those who advocate a built-in mental logic for reasoning (Braine & O'Brien, 1998a; Rips, 1994) have found the need to augment this with a variety of proposals about nonlogical pragmatic influences, whereas mental model theorists have proposed a mechanism of pragmatic modulation to account for the effects of prior knowledge and belief on deductive inference (Johnson-Laird & Byrne, 2002). It is also clear that attempts to account for behavior in entirely nonlogical terms (Oaksford & Chater,

2007) do not accord with the evidence. The evidence shows that participants do make an effort at deductive reasoning—depending upon their ability and instructions given—and that the logical form of the arguments influences their decisions. In the belief bias paradigm, for example, the validity of the argument appears to compete with the believability of the conclusion, and neural activity differentiates the cases where one or the other wins. On the selection task, people focus on matching cards, but their decisions about them still depend on their logical status (Evans & Ball, 2010). The proposal that type 2 processing is heavily dependent on working memory is supported by converging evidence from studies of individual differences in cognitive capacity, as well as those employing speeded tasks and working memory loads.

Some critics have suggested that type 1 and 2 processing might lie at the ends of a continuum rather than represent distinct types of processing (e.g. Newstead, 2000; Osman, 2004). However, it is hard to see how this can be reconciled with the evidence discussed here. For example, why do patterns of neural activity switch to a different part of the brain when type 2 processing is suggested by the answer given? Although there have been comparatively few imaging studies of reasoning to date (see Goel, 2008 for a recent review), there is extensive evidence from social neuroscience that there are two distinct neural systems underlying implicit and explicit forms of social judgment (Lieberman, 2003, 2007). The pattern of activation and mutual inhibition of these systems is precisely incompatible with the idea that there is just one functional system activated to different degrees (Lieberman, 2009). But even leaving aside the neuroscience, many experimental findings are interactive in nature: cognitive ability, working memory loads, speeded tasks, and instructional manipulations have all been shown *selectively* to affect responses attributed to type 1 and 2 processing.

While the evidence for dual processing remains strong, there are a number of problems with the received view of the theory described at the outset of this chapter. This has led to several fallacies that affect the thinking of both advocates of the theory and its increasing band of critics. It is to these that I now turn. In discussing the fallacies I will refer to not only the core dual-process theory of reasoning whose origins have been traced here but also rather more broadly to dual-process theories in cognitive and social psychology generally.

Fallacies in the Received View of

Dual-Process Theory

Fallacy 1: All Dual-Process Theories Are Essentially the Same

There are many dual-process theories in the cognitive and social psychological literature, but in the *received* view, they tend to be lumped together as incorporating generally the set of features listed in Table 8.1. Some reviewers sympathetic to dual-process theories have sought to integrate a large number of such accounts within a single framework (Evans, 2003; Smith & Collins, 2009; Smith & DeCoster, 2000; Stanovich, 1999). At the same time, critics of dual-process and dual-system theories tend to write as though faults in one account are a problem for all (Gigerenzer & Hoffrage, 2007; Keren & Schul, 2009; Osman, 2004). For example, problems with dual-system theories (see later) can be used as a stick with which to beat all dual-process theories.

As the very least we should distinguish the following: (a) dual-mode theories, (b) dual-type theories, and (c) dual-system theories. In practice, these often get confused. The proposal that there are two *modes* of processing does not necessarily imply that there is more than one kind of cognitive mechanism involved. The proposal of two *types* of thinking does, in the terminology that I am going to use here. It may appear, for example, that the discovery of cross-cultural differences in thinking style (Nisbett, Peng, Choi, & Norenzayan, 2001) must be related to dual-process theories in cognitive and social psychology. Such research indicates that East Asians have a more holistic style of thinking, whereas Westerners are more analytic. But this cannot reflect a type 1 and 2 distinction of the kind I have been discussing in this chapter. First, we can safely assume that all humans share broadly the same cognitive architecture. Second, the research shows that when people move to the other culture, their thinking style accommodates within a matter of months. Attempts to reconcile these findings with dual-process theory include (a) the idea that the tendency to intervene on default intuitions with reflective reasoning may be culturally dependent (Evans, 2009), and (b) the proposal that thinking styles reflect two different kinds of reflective (type 2) thought (Buchel & Norenzayan, 2009).

The same issue arises in social psychology, where authors have distinguished between fast, superficial, and slow reflective ways of processing social information as in the ELM (Petty & Wegener, 1999)

and heuristic-systematic models (Chen & Chaiken, 1999). Some reviewers have treated these theories as similar to type theories (Smith & DeCoster, 2000), whereas others have clearly treated them as mode theories (Evans, 2009; Strack & Deutsch, 2004). There are many ways of engaging in deliberative reasoning, which include being slow and careful, or quick and lazy (see fallacy 5). The type/mode distinction is also clearly reflected in the psychometric approach of Stanovich and West (2000a; Stanovich, 1999). In this work, types of processing are distinguished by cognitive capacity, in the way described earlier, clearly linking type 2 processing to working memory. But the same researchers show that when cognitive ability is factored out, residual variance can be predicted by thinking styles. In more recent writing, Stanovich has emphasized the importance of measuring rational thinking dispositions independently of cognitive ability to get a full picture of someone's capacity for rational decision making (Stanovich, 2009b). Thus, a distinction between people who are applying their cognitive faculties effectively or not is one of modes, not types. And unlike types, modes of processing do indeed seem to lie at two ends of a continuum.

Dual-system theories extend type theories by making specific proposals about the underlying cognitive mechanisms responsible for type 1 and 2 processing. But there are different kinds of dual-system theory as well. Some have a specific domain of reference, such as learning (Sun, Slusarz, & Terry, 2005), reasoning (Sloman, 1996), or social cognition (Lieberman, 2003) to which the authors wish largely to restrict them. The received System 1 and 2 theory, however, implies something that applies much more generally to the mind as a whole (encouraged by such authors as Epstein, 1994; Evans & Over, 1996; Reber, 1993; Stanovich, 1999, 2004). The various authors of the wider theory commit themselves to many similar features, broadly as those listed in Table 8.1. However, it is evident that dual-process theories of particular tasks and paradigms can dispense with many of these added features. If we use working memory involvement as our definition of type 2 processing, for example, we do not need to specify that it is conscious, recently evolved, and distinctively human. Dual-system or two-mind theories (Evans, 2010) are asserted at a higher theoretical level and for a broader purpose: to seek to explain, for example, why dual-process theories are proposed for so many different cognitive tasks. This distinction of level is important. If

critics, for example, find dual-system theories to be vague or unfalsifiable, these features cannot automatically be carried over to more specific and limited dual-process accounts.

Even among dual-process researchers, difference in cognitive architecture between different theories went unnoticed until quite recently. I coined terms "default-interventionist" and "parallel-competitive" to distinguish the two main categories (Evans, 2007b, 2008). Some theories are explicitly parallel, proposing that associative (type 1) and rule-based (type 2) processes operate in parallel, each having a say (Sloman, 1996; Smith & DeCoster, 2000). More commonly, however, dual-process accounts of reasoning and decision making propose that rapid type 1 processes provide a default intuitive response, which may or may not be moderated by subsequent intervention with deliberative, type 2 reasoning (Evans, 2006b; 2007a; Kahneman & Frederick, 2002; Stanovich, 1999, 2009a). It is hard to distinguish these two architectures simply by observing two competing sources of variance (Evans, 2007b), so we need to find indirect means of doing so. It can also be argued that there is room for both kinds of theory in different applications and that the actual architecture of the mind includes different type 1 processes that operate *both* in parallel with and prior to the operation of type 2 thinking (Evans, 2009). However, it is also clear that parallel and sequential models have been applied to the explanation of the same phenomena.

Fallacy 2: There Are Just Two Systems Underlying Type 1 and 2 Reasoning

Dual-process theorists have only themselves to blame for spreading the idea that there are two distinct systems in the mind responsible for type 1 and 2 processing (Epstein, 1994; Evans & Over, 1996; Reber, 1993; Stanovich, 1999), commonly known as System 1 and 2. However, prior to the recent critical attack of Keren and Schul (2009), problems with the two-system idea had already been identified and discussed within the dual-process camp (Evans, 2006a, 2009; Stanovich, 2004, 2009a). The problem lies with the word "system," which suggests a singular and well-defined mechanism. It is more appropriate, in my view, to refer to a two-minds hypothesis, to distinguish the idea that there are forms of cognition which are ancient and shared with other animals, and those that are recently evolved and distinctively human (Evans, 2010). In a two-minds theory, each mind can have

access to multiple systems, in a meaningful sense of that term.

Consider first the idea that there is a System 1 responsible for type 1 processing. There are several kinds of processes that meet the type 1 criteria: associative processes involved in learning and retrieval of implicit knowledge; processes attributed to cognitive modules such as the language acquisition device; preconscious and pragmatic processes that retrieve explicit knowledge for processing through working memory; procedural processes that were once explicitly rehearsed and have become automatic through practice. Is there one system for all of these? Beyond that, is there one system that performs all automatic processing, such as face recognition, memory retrieval, stereotyping, and many others? Of course not. However, dual-process and dual-system theorists have been unspecific about the scope and parameters of System 1 and have at times attributed various different kinds of type 1 process to it. Recognizing this problem, Stanovich (2004) dispensed with the term “System 1” in favor of “TASS”: the set of automated subsystems.

System 2 seems to have a better case for being a system. It is, after all, part of the definition of type 2 processing that it is *singular*, operating in a slow, sequential manner that taxes working memory and allows hypothetical thinking about one possibility at a time (Evans, 2007a). However, is the System 2 that engages in explicit hypothesis testing for Sloman, which intervenes with rational decision making for Kahneman, and which overrides belief bias with abstract reasoning for Evans, just the same system? In fact, is System 2 responsible for all the many cognitive tasks whose performance is correlated with working memory capacity? If so, what exactly is this mighty System 2: working memory, the conscious mind, a homunculus? To assert that either System 2 or working memory is a single system that does reading, reasoning, learning, decision making, and so on is vacuous. So while there is good evidence that there is a type 2 form of cognition, attributing it to a single System 2 does not make a lot of sense. The solution that should be explored, in my view, is the idea that there are multiple *type 2 systems* (Evans, 2009; Samuels, 2009), just as there are multiple type 1 systems. The key difference is that type 2 systems compete for a single central working memory system which they utilize *among other resources*. The evidence suggests that there is not even a single type 2 system for reasoning, as different reasoning tasks recruit a wide variety of brain

regions, according to the exact demands of the task (Goel, 2008).

I think of type 2 systems as ad hoc committees that are put together to deal with a particular problem and then disbanded when the task is completed.¹ Reasoning with abstract and belief-laden syllogisms, for example, recruits different resources, as the neural imaging data indicate: Only the latter involve semantic processing regions of the brain. It is also a fallacy to think of “System 2” as a conscious mind that is choosing its own applications. The ad hoc committee must be put together by some rapid and preconscious process—any feeling that “we” are willing and choosing the course of our thoughts and actions is an illusion (Wegner, 2002). I therefore also take issue with dual-process theorists (e.g., Kahneman & Frederick, 2002; Sloman, 1996) who assign to System 2 not only the capacity for rule-based reasoning but also an overall executive role that allows it to decide whether to intervene upon or overrule a System 1 intuition. In fact, recent evidence suggests that while people’s brains detect conflict in dual-process paradigms, the conscious person does not (De Neys & Glumicic, 2008; De Neys, Vartanian, & Goel, 2008).

Fallacy 3: Type 1 Processes Are Responsible for Cognitive Biases; Type 2 Processes for Normatively Correct Responding

One of the most important fallacies to have arisen in dual-process research is the belief that the normativity of an answer (see Chater & Oaksford, Chapter 2) is diagnostic of the type of processing. Given the history of the dual-process theory of reasoning, one can easily see how this came about. In earlier writing, heuristic or type 1 processes were always the “bad guys,” responsible for cognitive biases (e.g. Evans, 1989). In belief bias research, authors often talked about the conflict between “logic” and “belief,” which are actually dual *sources*, rather than dual processes. Evans and Over (1996) defined “rationality2” as a form of well-justified and explicit rule-based reasoning that could only be achieved by type 2 processes. Stanovich (1999; Stanovich & West, 2000a) in his earlier reviews of his psychometric research program emphasized the association between high cognitive ability, type 2 processing and normative responding. Similarly, Kahneman and Frederick (2002) associate the heuristics of Tversky and Kahneman with System 1 and successful reasoning to achieve normatively correct solutions to the intervention of System 2.

The problem is that a normative system is an externally imposed, philosophical criterion that can have no direct role in the psychological definition of a type 2 process. We may, of course, believe that the brain is adaptive and has evolved in such a way as to make us instrumentally rational, that is, likely to achieve our goals. However, theorists with this approach are sharply divided as to whether a normative theory is required to capture this kind of adaptation (Oaksford & Chater, 2007) or not (Gigerenzer, 2004). Within the psychology of reasoning, the view that there is an in-built mental logic in the form of inference rules (Braine & O'Brien, 1998a; Rips, 1994) is nowadays a minority position, and even these theorists propose substantial variation from standard logics, as well as a host of performance factors. In any case, if type 2 processes are those that manipulate explicit representations through working memory, why should such reasoning necessarily be normatively correct? People may apply the wrong rules or make errors in their application. And why should type 1 processes that operate automatically and without reflection necessarily be wrong? In fact, there is much evidence that expert decision making can often be well served by intuitive rather than reflective thinking (Gigerenzer, 2007; Gladwell, 2005; Klein, 1999; Reyna, 2004) and that sometimes explicit efforts to reason can result in worse performance (Reber, 1993; Wilson & Schooler, 1991).

Reasoning research somewhat loads the dice in favor of type 2 processing by focusing on abstract, novel problems presented to participants without relevant expertise. If a sports fan with much experience of following games is asked to predict results, he or she may be able to do so quite well without need for reflective reasoning. However, a participant in a reasoning experiment is generally asked to do novel things, like assuming some dubious propositions to be true and deciding whether a conclusion necessarily follows from them. In these circumstances, explicit type 2 reasoning is usually necessary for correct solution, but certainly not sufficient. Arguably, however, when prior experience provides appropriate pragmatic cues, even an intractable problem like the Wason selection task becomes easy to solve (Cheng & Holyoak, 1985), as this can be done with type 1 processes (Stanovich & West, 1998). It is when normative performance requires the deliberate suppression of *unhelpful* pragmatic cues that higher ability participants perform better under strict deductive reasoning instructions (De

Neys, Schaeken, & d'Ydewalle, 2005b; Evans et al., 2010).

Hence, fallacy 3 is with us for some fairly precise historical reasons. In the traditional paradigms, researchers presented participants with hard, novel problems for which they lacked experience (students of logic being traditionally excluded), and also with cues that prompted type 1 processes to compete or conflict with these correct answers. So in these paradigms, it does seem that type 2 processing is at least necessary to solve the problems, and that type 1 processes are often responsible for cognitive biases. But this perspective is far too narrow, as has recently been recognized. In recent writing, I have attributed responsibility for a range of cognitive biases roughly equally between type 1 and type 2 processing (Evans, 2007a). Stanovich (2009a, 2010) similarly identifies a number of reasons for error other than a failure to intervene with type 2 reasoning; for example, people may reason in a quick and sloppy (but type 2) manner or lack the necessary "mindware" for successful reasoning.

Fallacy 4: Type 1 Processing Is Contextualized, Whereas Type 2 Processing Is Abstract

Fallacy 4 arises for similar historical reasons to fallacy 3. Belief bias has always featured strongly in dual-process accounts of reasoning, and Stanovich (1999) went so far as to identify contextualization as the fundamental cognitive bias. It does appear that our thinking is automatically contextualized when we are given a reasoning problem which cues prior knowledge, and that participants of higher ability may be better able to inhibit the influence of such context. Interestingly, autistic people are *less* influenced by belief bias in conditional reasoning (McKenzie, Evans, & Hanoch, 2010), probably because their reasoning was not contextualized to start with. In the pre-2000 work on dual-process theory, abstract and logical reasoning became linked with type 2 processing, whereas contextualized and biased reasoning was attributed to type 1 processing, supporting both fallacies 3 and 4.

The signs that something is wrong with this idea have been with us for some time. For example, it has become evident that there is not one but *two* belief bias effects in syllogistic reasoning (Evans, Handley, & Harper, 2001; Klauer et al., 2000; Oakhill, Johnson-Laird, & Garnham, 1989). The first, which we might call a type 1 belief bias (i.e., based on a type 1 process), is a general response bias to say "yes" to conclusions that accord with prior

belief and “no” to those that do not. The type 2 bias affects the process of reasoning such that people search selectively for counterexamples to unbelievable conclusions. These two biases account, respectively, for the main effect and the interaction effect observed in the data. That is, the type 1 bias produces overall preference for believable conclusions, whereas the type 2 bias selectively affects invalid inferences. More recently, there is evidence that beliefs influence causal conditional inference in two similar ways. People are partially influenced by the degree of association between minor premise and conclusion (as suggested by Oaksford et al., 2000) but also by the explicit consideration of counter-examples that come to mind (Verschueren et al., 2005; Weidenfeld, Oberauer, & Hornig, 2005) in line with the general principles of mental model theory (Johnson-Laird, 1983; Johnson-Laird & Byrne, 1991). A recent study suggests that the type 1 belief bias dominates MP and AC inferences, whereas the type 2 effect is stronger for DA and MT (Evans et al., 2010).

A little reflection will reveal why it must be fallacious to equate type 2 processing with abstract, decontextualized thought. Bearing in mind that type 2 processing involves putting a load on working memory—and is not a mental logic—it is evident that much (indeed most) of the contents that pass through our working memories are forms of explicit belief and knowledge that are semantically rich. The dual-process claim must rather be that there are ways in which prior experience can cue intuitions and behavior by associative and procedural learning that bypass working memory (type 1), which are separate from the retrieval and manipulation of explicit memories and beliefs through working memory (type 2). Not only must this be the only coherent claim, but the evidence increasingly supports this view. Fallacy 4 has arisen for the same historical reasons as fallacy 3: When a novel task requires attention to logical structure and hence decontextualization, in general type 2 processing will be necessary (but not sufficient) to achieve this.

Fallacy 5: Fast Processing Indicates Use of a Type 1 Rather Than Type 2 Process

It is widely agreed that type 1 processing is in general quicker than type 2 processing. The speeded-task method exploits this by giving participants a fixed short time limit for a decision or instructing them to respond quickly. In general, this manipulation does seem to shift people toward responses

theoretically assigned to type 1 processing (e.g., belief bias) and has similar effects to use of a concurrent working memory load. Nevertheless, it is a fallacy to assume that because a judgment is made quickly it is necessarily based on a type 1 process.

The term “intuitive judgment” is used rather loosely in the literature, and I suspect it has two different meanings. If intuition means based on feelings without access to explicit reasoning, then that sounds like a type 1 process. But in some applications it seems to mean *naïve* judgement, which could be based on explicit rules or heuristics that occur to an untrained judge, in which case they would be type 2. For example, are the “fast and frugal” heuristics proposed by Gigerenzer and colleagues based on type 1 or 2 processes? Despite the title *Gut Feelings*, Gigerenzer’s (2007) recent book on the topic describes heuristics as simple rules that could well be applied explicitly. (This was clearly the case in the famous application of heuristics in problem solving by Newell & Simon, 1972.) This ambiguity is discussed by Betsch (2008), who suggests a distinction between *intuitive judgment* based on feelings and *heuristic judgment* based on simple rules. The problem is that both may be quick, but in dual-process theory we would have to describe the former as type 1 and the latter as type 2.

Gigerenzer and colleagues frequently use the phrase “less is more” to convey the power of simple heuristics. This perspective is echoed in the popular work *Blink* by Malcolm Gladwell (2005). But consider two of the examples used by Gladwell to illustrate the less-is-more principle: (a) an art expert “knows” that a statue is a fake but cannot prove it by any explicit reasoning or knowledge, and (b) a hospital employs a short checklist to decide whether to treat patients with chest pain as suspected heart attack cases, with much better success than more complex procedures. Both are relatively quick ways of making a decision, but it is evident that judgment (a) has the implicit type 1 characteristics, whereas (b) type 2 is entirely explicit. However, there is an important difference between an intuitive (type 1) and heuristic (type 2) judgement. Both may be less in terms of time taken, but only the latter is less in terms of information considered. As explicit rules, heuristics are by definition quick and dirty, based on minimal cues and requiring little reflection to apply. Intuitive judgements on the other hand may take into account *more* information than could be handled by explicit, type 2 reasoning. This is why it may be harder to learn complex rules explicitly (Reber,

1993) and why expert decision making often relies on intuitive judgement (Klein, 1999; Reyna, 2004). Slow experiential learning may enable a person to take account of *more* cues in the environment, even though these are not consciously accessible.

In summary, type 2 processing is slow when a person reflects on a problem and engages in explicit reasoning or mental simulation to try to solve it. Intuitive (type 1) judgments will generally be quick, even though they may be based on a large amount of information if it is of the kind that can be encoded by associative learning. The problem is that there are also fast type 2 judgements that are made on the basis of simple rules and heuristics, with minimal reflection. This kind of type 2 processing will also make minimal demands on working memory and so is unlikely to reveal itself in a correlation with measures of cognitive ability or capacity. However, when people are given novel tasks—for which they are unlikely to have any available explicit heuristics—requiring them to respond quickly is still likely to shift the balance of power in favor of type 1 processing, as the research evidence suggests.

Conclusions

From around 1960 to 2000 the psychology of reasoning was strongly focused on the deduction paradigm, in which participants are assessed for their ability to judge the logical validity of arguments without any prior training or instruction. In the 1980s a major argument was developed about whether deductive competence was based on built-in inference rules (mental logic) or on the manipulation of mental models. However, experimental evidence has accumulated indicating that people were apparently poor at logical reasoning, highly influenced by irrelevant features of the content and subject to a number of other cognitive biases. As a result, the paradigm has shifted in the past 10–15 years, and while deduction is still studied, it is allied to a number of other methods. Theoretically, there is now also a lot more interest in human reasoning as a probabilistic and pragmatic, rather than deductive process (see Hahn & Oaksford, Chapter 15).

Dual-process theories are the focus of much contemporary research in cognitive and social psychology and have a number of (largely independent) origins. In this chapter, I have shown how dual-process accounts were developed from the 1970s onward within the study of deductive reasoning, primarily as an attempt to explain why cognitive

biases coexisted and competed with attempts at effortful logical reasoning on these tasks. In more recent times, reasoning researchers have examined individual differences in cognitive capacity, linked with type 2 (analytic) reasoning, and also introduced a range of experimental and neuroscientific methods to identify dual processes. However, I have also shown how a number of fallacies have arisen in the received view of dual-process theory, both within the psychology of reasoning and more generally. Five of the more important ones (Table 8.2) have been discussed in detail.

Future Directions

Research on dual-process theory remains a hot topic in cognitive psychology, and it is encouraging that linkage between such theories in reasoning, decision making, learning, and social cognition is now being recognized by contemporary authors. However, dual-process theory is also controversial and coming under increasing criticism from those unsympathetic to the approach. While I believe that the evidence for dual process is strong, there is also need for researchers to be a good deal more careful in formulating proposals and interpreting evidence in this field. The *received* view of the theory, which emerged around 2000 and is summarized in Table 8.1, is fraught with difficulties and has spawned a number of fallacies, which I have discussed here. Dual-process theories should not be (but often are) confused with accounts which simply propose two modes of processing that might be operated by a single cognitive mechanism, or two cognitive styles that may be culturally relative. Theories that genuinely posit two types of processing may also differ in cognitive architecture and in whether they subscribe to broader, two-system proposals.

To minimize the problems posed by the fallacies, I suggest the only firm foundation for two types of processing is that one can bypass working memory, whereas the other necessarily requires its use. However, the fallacies discussed here nevertheless reveal profound methodological difficulties for the study of dual processes in human reasoning. We cannot simply diagnose a type 2 process when we see a normatively correct answer, or a type 1 process when we see a bias. A process that is fast and fails to tax working memory sufficiently to correlate with cognitive ability may, nevertheless, be type 2 in some cases. Similarly, not all answers influenced or biased by belief are the result of type 1 processes.

The difficulties are so great that the reader may wonder why I continue to advocate a dual-process account at all. The earlier sections of this chapter make the case, however. First, the evidence for dual sources of variance in reasoning tasks is beyond dispute. It was the competing influence of nonlogical and task-irrelevant sources, resulting in matching and belief bias, which first pointed to the need for a dual-process account, and it still does. Recent mathematical modeling of these tasks confirms dual sources by several different methods. Problematic as they are in some respects, the standard methods involving working memory loads, correlation with cognitive capacity, and speeded tasks generate findings that are remarkably consistent with original dual-process claims when applied to these paradigms and others. There is strong behavioral and neuroscientific evidence that the brain has parallel implicit and explicit learning systems, and a clear evolutionary argument for the two-minds hypothesis (Evans, 2010; Stanovich, 2004). Crucially, perhaps, neuroimaging studies have confirmed that responding attributed to type 1 and 2 processes corresponds to activation of quite distinct regions in the brain, as well as monitoring both the detection and resolution of conflict.

Accordingly, my conclusion is that one-process theories cannot account for the massive amount of evidence now collected by dual-process researchers. Although the terms “System 1” and “System 2” now seem unhelpful, the case for a two-minds theory incorporating the distinction between type 1 and type 2 systems is a good deal more coherent. However, the case for dual-process theories is not helpfully advanced by researchers who implicitly or explicitly adopt any of the five fallacies that I have discussed in this chapter. Greater care needs to be taken in both the design of research studies and in the interpretation of their findings. Where possible, conclusions reached on the basis of one behavioral measure should be cross-validated with others and, if possible, by neuroimaging studies. This is a challenge to which I hope the psychology of reasoning will be able to rise in the years ahead.

Acknowledgments

I would like thank Keith Frankish and Shira Elqayam for their critical reading of an earlier draft of this chapter.

Note

1. Some philosophers have suggested that “System 2” might be an emergent property of the interactions of multiple modules or subsystems (Carruthers, 2006; Frankish, 2004), which sounds

a similar idea to ad hoc committees. However, my proposal differs first in regarding working memory as a real, not a virtual system, which is an essential component of all type 2 systems, and second by the proposal of unique recruitment of the particular resources required for the task at hand.

Inference with Mental Models

P. N. Johnson-Laird

Abstract

This chapter outlines the theory of mental models. The theory accounts for the deductive reasoning of individuals untrained in logic, and the chapter marshals corroboratory evidence. It goes on to describe how the theory applies to reasoning about probabilities based on the alternative possibilities in which an event occurs (“extensional” reasoning). It also outlines the theory’s application to inductions, including those that depend on the intuitive system of reasoning (System 1) and those that depend on deliberation (System 2). Inductions include the automatic use of knowledge to modulate the interpretation of assertions. Models appear to underlie both the detection of inconsistencies among propositions and abductions that create explanations, including those that resolve inconsistencies. The model theory is supposed to apply to all thinking about propositions, and the chapter concludes with some of the main gaps in its account.

Key Words: abduction, causation, deduction, induction, inconsistency, mental models, reasoning

Introduction

How do we think? One answer is that we rely on *mental models*. Perception yields models of the world that lies outside us. An understanding of discourse yields models of the world that the speaker describes to us. And thinking, which enables us to anticipate the world and to choose a course of action, relies on internal manipulations of these mental models. The present chapter is about this theory, which it refers to as the *model theory*, and about its experimental corroborations. The theory aims to explain all sorts of thinking about propositions, that is, thoughts capable of being true or false. There are other sorts of thinking—the thinking, for instance, of a musician who is improvising. In daily life, unlike the psychological laboratory, no clear demarcation exists between one sort of thinking and another. Here is a sequence of everyday thoughts that illustrates this point:

I had the book in the hotel’s restaurant, and now I’ve lost it. So either I left it in the restaurant, or it fell

out of my pocket on the way back to my room, or it’s somewhere here in my room. It couldn’t have fallen from my pocket—my pockets are deep and I walked slowly back to my room—and so it’s here or in the restaurant.

Embedded in this sequence is a logical deduction of this sort:

A or B or C.

Not B.

Therefore, A or C.

The conclusion is *valid*: It must be true given that the premises are true. But other sorts of thinking occur in the protocol, for example, the inference that the book couldn’t have fallen out of the protagonist’s pocket.

A simple way to categorize thinking about propositions is in terms of its effects on the possibilities consistent with the premises and with the conclusions (Johnson-Laird, 2006). The more possibilities

an assertion rules out, the greater the amount of semantic information it conveys (Bar-Hillel & Carnap, 1964). Any step in thought from current premises to a new conclusion therefore falls into one of five cases:

- The premises and the conclusion are consistent with the same possibilities.
- The premises hold in all the possibilities consistent with the conclusion, but it is consistent with additional possibilities in which the premises do not hold.
- The conclusion holds in all the possibilities consistent with the premises, but they hold in additional possibilities in which the conclusion does not hold.
- The premises and conclusion hold in overlapping possibilities.
- The premises and conclusion hold in completely disjoint possibilities.

The first two cases are valid deductions: The conclusion is true given the truth of premises (see Evans, Chapter 8). The third case includes the traditional instances of induction: The conclusion goes beyond the information given to exclude possibilities otherwise consistent with the premises (see the chapters in Part II of this volume). The fourth case occurs when the conclusion is consistent with the premises, but it does not follow from them. Such thinking occurs in an abduction that explains the premises at the cost of refuting one or more of them (see Lombrozo, Chapter 14). The fifth case occurs when the premises and conclusion are inconsistent.

The model theory aims to explain thinking based on propositions (see Markman, Chapter 4), and the present chapter illustrates its application to the five preceding categories. It begins with the history of the model theory. It then outlines the current theory and its account of deduction. It reviews the evidence for this account. It shows how the theory extends to probabilistic reasoning. It then turns to induction, including the unconscious inductions that affect the interpretation of assertions. It examines how individuals detect inconsistencies and how they make abductions, such as those that create explanations resolving inconsistencies. Finally, it assesses the current state of the model theory and the principal tasks for future research.

The History of Mental Models

In the fifth chapter of his book *The Nature of Explanation*, Kenneth Craik (1943) wrote:

If the organism carries a “small-scale model” of external reality and of its own possible actions within its head, it is able to try out various alternatives, conclude which is the best of them, react to future situations before they arise, utilize the knowledge of past events in dealing with the present and the future, and in every way to react in a much fuller, safer, and more competent manner to the emergencies which face it. (p. 61)

As Craik wrote, this same process of internal imitation of the external world is carried out in mechanical devices such as Kelvin's tidal predictor. Craik died in 1945 before he could develop his ideas, and he believed that reasoning depended on verbal rules rather than on models. Several earlier thinkers had, in fact, anticipated the idea of models (see Johnson-Laird, 2004). Nineteenth-century physicists, including Kelvin, Boltzmann, and Maxwell, stressed the role of models in thinking. In the 20th century, physicists downplayed these ideas with the advent of quantum theory (but cf. Deutsch, 1997).

One principle of the modern theory is that the parts of a mental model and their structural inter-relations correspond to those of the situation that it represents. This idea has many antecedents. It occurs in Maxwell's (1911) views on diagrams, in Wittgenstein's (1922) “picture” theory of meaning, and in Köhler's (1938) hypothesis of an isomorphism between brain fields and the world. However, the 19th-century grandfather of the model theory is Charles Sanders Peirce. He co-invented the main system of logic known as the *predicate calculus*, which governs sentences in a formal language containing idealized versions of negation, sentential connectives such as “and” and “or,” and quantifiers such as “all” and “some” (see Chater & Oaksford, Chapter 2). Peirce devised two diagrammatic systems of reasoning, not to improve reasoning, but to display its underlying mental steps (see Johnson-Laird, 2002). He wrote:

Deduction is that mode of reasoning which examines the state of things asserted in the premisses, forms a diagram of that state of things, perceives in the parts of the diagram relations not explicitly mentioned in the premisses, satisfies itself by mental experiments upon the diagram that these relations would always subsist, or at least would do so in a certain proportion of cases, and concludes their necessary, or probable, truth. (Peirce, 1.66; this standard notation refers to paragraph 66 of Volume 1 of Peirce, 1931–1958)

Diagrams can be *iconic*, that is, have the same structure as what they represent (Peirce, 4.447). It is the inspection of an iconic diagram that reveals truths other than those of the premises (2.279, 4.530). Hence, Peirce anticipates Maxwell, Wittgenstein, Köhler, and the model theory. Mental models are as iconic as possible (Johnson-Laird, 1983; see also Markman, Chapter 4).

A resurgence of mental models in cognitive science began in the 1970s. Theorists proposed that knowledge was represented in mental models, but they were not wedded to any particular structure for models. Hayes (1979) used the predicate calculus to describe the naive physics of liquids. Other theorists in artificial intelligence proposed accounts of how to envision models and to use them to simulate behavior (de Kleer, 1977). Psychologists similarly examined naive and expert models of various domains, such as mechanics (McCloskey, Caramazza, & Green, 1980) and electricity (Gentner & Gentner, 1983). They argued that vision yields a mental model of the three-dimensional structure of the world (Marr, 1982). They proposed that individuals use these models to simulate behavior (Hegarty, 1992; Schwartz & Black, 1996; see Hegarty & Stull, Chapter 31). They also studied how models develop (e.g., Halford, 1993; Vosniadou & Brewer, 1992), how they serve as analogies (e.g., Holland, Holyoak, Nisbett, & Thagard, 1986; see Holyoak, Chapter 13), and how they help in the diagnosis of faults (e.g., Rouse & Hunt, 1984). Artifacts, they argued, should be designed so that users easily acquire models of them (e.g., Ehrlich, 1996; Moray, 1990, 1999).

Discourse enables humans to experience the world by proxy, and so an early hypothesis was that comprehension yields models of the world (Johnson-Laird, 1970). Such models are iconic in these ways: They contain a token for each referent in the discourse, properties of these tokens correspond to the properties of the referents, and relations among the tokens correspond to the relations among the referents. Similar ideas occurred in psycholinguistics (e.g., Bransford, Barclay, & Franks, 1972), linguistics (Karttunen, 1976), artificial intelligence (Webber, 1978), and formal semantics (Kamp, 1981). Experimental evidence corroborated the hypothesis, showing that individuals rapidly forget surface and underlying syntax (Johnson-Laird & Stevenson, 1970), and even the meaning of individual sentences (Garnham, 1987). They retain models of only such matters as who did what to whom.

Psycholinguists showed that models are constructed from the meanings of sentences, general knowledge, and knowledge of human communication (e.g., Garnham, 2001; Garnham & Oakhill, 1996; Gernsbacher, 1990; Glenberg, Meyer, & Lindem, 1987). Another early discovery was that content affects deductive reasoning (Wason & Johnson-Laird, 1972), which was hard to reconcile with the then dominant view that reasoners depend on *formal* rules of inference (Braine, 1978; Johnson-Laird, 1975; Osherson, 1974–1976). Granted that models come from perception and discourse, they could be used to reason (Johnson-Laird, 1975): An inference is *valid* if its conclusion holds in all the models of the premises, because its conclusion must be true granted that its premises are true. The next section spells out this theory.

Models and Deduction

Mental models represent entities and persons, events and processes, and the operations of complex systems. But what is a mental model? The current theory is based on three principles that distinguish models from linguistic structures, semantic networks, and other proposed mental representations (cf. Markman, Chapter 4). The first principle (Johnson-Laird, 1983) is as follows:

- I. The principle of *iconicity*: A mental model has a structure that corresponds to the known structure of what it represents.

Visual images are iconic, but mental models underlie images (see Hegarty & Stull, Chapter 31). Even the rotation of mental images implies that individuals rotate three-dimensional models (Metzler & Shepard, 1982). Moreover, models of abstract entities cannot be visualized even though the models may be iconic. To illustrate this point, consider the three-dimensional representation of the world that congenitally blind individuals construct. As Landau, Spelke, and Gleitman (1984) showed, a blind child inferred new routes between objects as a result of walking between them. Her model of the world was iconic within a framework of spatial coordinates, but not visual. Similarly, an iconic model can represent that one set of entities overlaps with another set, and it can do so without any concomitant visual image. Indeed, evidence shows that when individuals reason from materials that do elicit visual images, their reasoning is slower than from other sorts of contents (Knauff, Fangmeier, Ruff, & Johnson-Laird, 2003; Knauff & Johnson-Laird, 2002).

One advantage of iconicity, as Peirce noted, is that models built from premises can yield new relations. For example, Schaeken, Johnson-Laird, and d'Ydewalle (1996) investigated problems of temporal reasoning concerning such propositions as:

John eats his breakfast before he listens to the radio.

Given a problem based on several premises of this sort:

- A before B.
- B before C.
- D while A.
- E while C.

Reasoners can build a mental model with the iconic structure:

A	B	C
D		E

where the left-to-right axis is time, and the vertical axis allows different events to be contemporaneous. Granted that each event takes roughly the same amount of time, reasoners can infer a new relation:

D before E.

Formal logic less readily yields the conclusion, because infinitely many conclusions follow validly from any set of premises, and logic does not tell you *which* conclusions are useful. From the aforementioned premises, for instance, this redundant conclusion follows:

A before B, *and* B before C.

Possibilities are crucial in human thinking, and the second principle of the theory assigns them a central role (Johnson-Laird & Byrne, 1991):

II. The principle of *possibilities*: Each mental model represents a distinct possibility, that is, it captures what is common to all the different ways in which the possibility might occur.

This principle is illustrated in *sentential* reasoning, which hinges on negation and such sentential connectives as "if" and "or." In logic, these connectives have idealized meanings: They are *truth-functional* in that the truth-values of sentences formed with them depend solely on the truth-values of the clauses that they connect. For example, a disjunction of the form: *A or else B but not both*, is true if *A* is true and *B* is false, and if *A* is false and *B* is true, but false in any

other case. This disjunction is known as "exclusive," because it excludes the truth of both *A* and *B*. Logicians capture these conditions in a truth table, as shown in Table 9.1. Each row in the table represents a different possibility; for example, the first row represents the possibility in which both *A* and *B* are true, and so in this case the disjunction is false.

Naive reasoners do not use truth tables (Osherson, 1974–1976). *Fully explicit* models of possibilities, however, are a step toward psychological plausibility. The fully explicit models of the exclusive disjunction, *There is a king or else there is an ace, but not both*, are shown here on two separate horizontal lines:

ace	not-king
not-ace	king

where "not" denotes negation. Table 9.2 presents the fully explicit models of assertions based on the main sentential connectives. Fully explicit models correspond exactly to the true rows in the truth table for each connective. As Table 9.2 shows, the conditional *If A then B* is treated in logic as though it can be paraphrased as *If A then B, and if not-A then B or not-B*. The paraphrase does not do justice to the varied meanings of everyday conditionals (Johnson-Laird & Byrne, 2002). In fact, as we will see, no connectives in natural language can be captured in truth tables.

Fully explicit models yield a more efficient reasoning procedure than truth tables. Each premise has a set of fully explicit models, for example, the premises:

1. There is a king or else there is an ace but not both.
2. There is not a king.

have the models:

Table 9.1. The Truth Table for an Exclusive Disjunction Between Two Propositions, A and B

A	B	A or else B, but not both
True	True	False
True	False	True
False	True	True
False	False	False

Table 9.2. The Fully Explicit Models and the Mental Models of the Possibilities Consistent With Assertions Based on the Principal Sentential Connectives

Sentences	Fully Explicit Models		Mental Models	
A and B:	A	B	A	B
Neither A nor B:	not-A	not-B	not-A	not-B
A or else B but not both:	A	not-B	A	B
	not-A	B		
A or B or both:	A	not-B	A	B
	not-A	B		
	A	B	A	B
If A, then B:	A	B	A	B
	not-A	B	...	
	not-A	not-B		
If, and only if A, then B:	A	B	A	B
	not-A	not-B	...	

Note. “Not” denotes the representation of negation, and “...” denotes an implicit model, that is, one with no explicit content.

(Premise 1)	(Premise 2)	
king	not-ace	not-king
not-king	ace	

Their conjunction depends on combining each model in one set with each model in the other set according to two rules:

- A contradiction between a pair of models yields the null model (akin to the empty set).
- Any other conjunction yields a model of each proposition in the two models.

The result of conjoining these two sets of models is therefore a single non-null model:

not-king ace

Since an inference is valid if its conclusion holds in all the models of the premises, the conclusion, *there is an ace*, follows validly from the premises. The two preceding rules can be used recursively to construct the models of compound premises containing multiple connectives.

Because infinitely many conclusions follow from any premises, computer programs for proving validity generally evaluate given conclusions. Human

reasoners, however, can draw conclusions for themselves. They normally abide by two constraints (Johnson-Laird & Byrne, 1991). First, they do not throw semantic information away by adding disjunctive alternatives to those to which the premises refer. For instance, given a single premise, *there is a king*, they never spontaneously conclude, *there is a king or there is an ace, or both*, even though the deduction is valid. Second, they draw novel conclusions that are parsimonious. For instance, they never draw a conclusion that merely forms a conjunction of all the premises, even though such a deduction is valid. Of course, human performance rapidly degrades with complex problems, but the goal of parsimony suggests that intelligent programs should draw conclusions that succinctly express all the information in the premises. The model theory yields an algorithm that draws such conclusions (Chapter 9, Johnson-Laird & Byrne, 1991).

Fully explicit models are simpler than truth tables, but they still place a heavy load on working memory. Mental models are still simpler, because they are limited by the third principle of the theory (Johnson-Laird, 2006):

- III. The principle of *truth*: Mental models represent only what is possible given the truth of assertions, not what is impossible, and each mental model represents

a clause in the premises only when the clause is true in the possibility that the model represents.

The simplest test of the principle is to ask naive individuals to list what is possible for a variety of assertions (Barrouillet & Lecas, 1999; Johnson-Laird & Savary, 1996). Given an exclusive disjunction, such as *There is a king in the hand or else there isn't an ace*, they list two possibilities corresponding to the mental models:

king	not-ace
------	---------

The first mental model does not represent that it is false that there isn't an ace in this possibility, that is, there *is* an ace; and the second mental model does not represent that it is false that there is a king in this possibility, that is, there *isn't* a king. Hence, people tend to neglect these cases. Readers might assume that the principle of truth is equivalent to the representation of the propositions *mentioned* in the premises. But this assumption yields the same models of clauses regardless of the connective relating them. A simple and approximate way to conceive the principle is therefore that it yields pared-down versions of fully explicit models, which in turn map into truth tables. As we will see, the principle of truth predicts a striking phenomenon in reasoning.

Individuals can make a mental footnote about what is false in a possibility, and these footnotes can be used to flesh out mental models into fully explicit models. But footnotes tend to be ephemeral. The most recent computer program implementing the model theory operates at two levels of expertise. At its more expert level, it uses *fully explicit* models, and so it makes no mistakes in reasoning. At its less expert level, it uses *mental* models without footnotes. Its representations for assertions based on the main sentential connectives are summarized in Table 9.2. The mental models of a conditional: *If there is a king, then there is an ace*, are as follows:

king	ace
...	

The ellipsis denotes an *implicit* model of the possibilities in which the if-clause of the conditional is false. In other words, there are alternatives to the possibility in which there is a king and an ace, but individuals tend not to think explicitly about what they are. If they retain the footnote about what is false, then they can flesh out the mental models into fully explicit models. The mental models of the biconditional: *If, and*

only if, there is a king, then there is an ace, as Table 9.2 shows, are identical to those for the conditional. What differs is that the footnote now conveys that *there is a king* and *there is an ace* are each false in the implicit model.

Inferences can be made with mental models using a procedure that builds a set of models for a premise and then updates them according to the other premises. From the premises:

There is a king or else there is an ace, but not both.
There is not a king.

the disjunction yields the mental models:

king	ace
------	-----

The categorical premise eliminates the first model, but it is compatible with the second model, yielding the valid conclusion: there is an ace. These procedures are summarized in Table 9.3.

The model theory was originally developed for so-called syllogisms, such as:

Some actuaries are businessmen.
All businessmen are conformists.
Therefore, some actuaries are conformists.

in which each assertion contains a quantifier, such as “all” or “some.” To account for the results, the theory was modified over the years (see, e.g., Johnson-Laird & Bara, 1984), but it became clear that in fact individuals develop different strategies for coping with syllogisms (Bucciarelli & Johnson-Laird, 1999). The model theory has also been extended to some sorts of inference from premises containing more than one quantifier (Johnson-Laird, Byrne, & Tabossi, 1989). Consider, for example, the following inference (from Cherubini & Johnson-Laird, 2004):

There are four persons: Ann, Bill, Cath, and Dave.
Everybody loves anyone who loves someone.
Ann loves Bill.
What follows?

Most people can envisage this model in which arrows denote the relation of *loving*:

Hence, they infer that everyone loves Ann. But if you ask them whether it follows that Cath loves Dave,

Table 9.3. The Procedures for Forming a Conjunction of a Pair of Models

1. For mental models only: The conjunction of a pair of models in which a proposition, B , in one model is not represented in the other model depends on the set of models of which this other model is a member. If B occurs in at least one of these models, then its absence in the current model is treated as negation, $\text{not-}B$. Otherwise, its absence is treated as its affirmation. The remaining mechanisms then apply.
2. For mental models only: The conjunction of an implicit model with a model representing propositions yields the null model by default (akin to the empty set), for example:

... and $B \wedge C$ yield nil.

But if none of the atomic propositions ($B \wedge C$) is represented in the set of models containing the implicit model, then the conjunction yields the model of the propositions, for example:

... and $B \wedge C$ yield $B \wedge C$.

Likewise:

... and ... yield ...

3. The conjunction of a pair of models containing respectively a proposition and its negation yield the null model, for example:

$A \wedge B$ and $\text{not-}A \wedge B$ yield nil

4. The conjunction of a null model with any model yields the null model, for example:

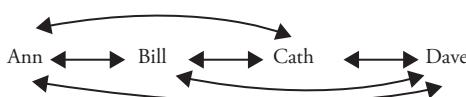

$A \wedge B$ and nil yield nil

5. The conjunction of a pair of fully explicit models free from contradiction update the second model with all the new propositions from the first model, for example:

$A \wedge B \wedge C$ and $A \wedge B$ yield $A \wedge B \wedge C$

Note. Each procedure is presented with an accompanying example. Only mental models can be implicit and therefore call for the first two procedures.

they tend to respond: “no.” They are mistaken, but the inference calls for using the quantified premise again. The result is this model (strictly speaking, all four persons love themselves, too):

It follows that Cath loves Dave, and people grasp its validity if it is demonstrated with such diagrams. No complete model theory exists for inferences based on quantifiers and connectives (cf. Bara, Bucciarelli, & Lombardo, 2001). But the main principles of the theory should apply: Mental models are iconic, they denote possibilities, and they represent only what is true.

Experimental Studies of Deductive Reasoning

Many experiments have corroborated the model theory, and the present section outlines the corroborations of five of its main predictions.

Prediction 1: The fewer the models needed for an inference, and the simpler they are, so the inference should take less time and be less prone to error. Fewer entities do improve inferences (e.g., Birney & Halford, 2002). Likewise, fewer models improve spatial and temporal reasoning (Byrne & Johnson-Laird, 1989; Carreiras & Santamaría, 1997; Schaeken, Johnson-Laird, & d'Ydewalle, 1996; Vandierendonck & De Vooght, 1997). Premises yielding one model of a spatial layout take less time to read than similar premises yielding multiple models, but the difference between two and three models is often so small that it is unlikely that reasoners construct all three models (Vandierendonck, De Vooght, Desimpelaere, & Dierckx, 1999). They may build a single model with one element represented as having two or more possible spatial locations.

Effects of number of models have been observed in comparing one sort of sentential connective with another and in examining batteries of such inferences

(Johnson-Laird & Byrne, 1991). As an illustration, consider a “double disjunction” (Bauer & Johnson-Laird, 1993):

Ann is in Alaska or else Beth is in Barbados, but not both.

Beth is in Barbados or else Cath is in Canada, but not both.

What follows?

Reasoners readily envisage the two possibilities compatible with the first premise, but it is harder to update them with those from the second premise. The solution yields the following two mental models, though real mental models represent spatial relations, not words or phrases:

Ann in Alaska

Cath in Canada

Beth in Barbados

These two models yield the conclusion: *Either Ann is in Alaska and Cath is in Canada, or else Beth is in Barbados*. An increase in number of models soon overloads working memory. The following inference defeats most people:

Ann is in Alaska or Beth is in Barbados, or both.

Beth is in Barbados or Cath is in Canada, or both.

What follows?

The premises yield five models, from which it follows: *Ann is in Alaska and Cath is in Canada, or Beth is in Barbados, or both*. When the order in which the premises are stated has the effect of reducing the number of models to be held in mind, reasoning improves (García-Madruga et al., 2001; Girotto, Mazzocco, & Tasso, 1997; Mackiewicz & Johnson-Laird, 2004).

Because one model is easier than many, an interaction occurs in *modal* reasoning, which concerns what is possible and what is necessary. It is easier to infer that a situation is possible (one model of the premises suffices as an example) than that it is *not* possible (all the models of the premises must be checked for a counterexample in which the situation occurs). In contrast, it is easier to infer that a situation is *not* necessary (one counterexample suffices) than that it is necessary (all the models of the premises must be checked as examples). The interaction occurs in both the accuracy and the speed of reasoning (Bell & Johnson-Laird, 1998).

Prediction 2: Reasoners should err as a result of overlooking models of premises. Given a double

disjunction (such as the ones mentioned earlier), the most frequent errors were conclusions consistent with just a single model of the premises (Bauer & Johnson-Laird, 1993). Likewise, many errors with syllogisms appear to arise because individuals consider only a single model of the premises (Bucciarelli & Johnson-Laird, 1999; Espino, Santamaría, & García-Madruga, 2000; Newstead & Griggs, 1999). Ormerod has proposed a “minimal completion” hypothesis according to which reasoners construct only the minimally necessary models (see Ormerod, Manktelow, & Jones, 1993; Richardson & Ormerod, 1997). Likewise, Sloutsky has postulated a process of “minimalization” in which reasoners tend to construct only single models for all connectives, thereby reducing them to conjunctions (Morris & Sloutsky, 2002; Sloutsky & Goldvarg, 1999). Certain assertions, however, do tend to elicit more than one model. As Byrne and her colleagues have shown (e.g., Byrne & McElaney, 2000; Byrne, 2002, 2005; Byrne & Tasso, 1999), counterfactual conditionals such as:

If the cable hadn't been faulty then the printer wouldn't have broken

tend to elicit models of both what is factually the case:

cable faulty printer broken

and what holds in a counterfactual possibility:

not cable faulty not printer broken

Prediction 3: Reasoners should be able to refute invalid inferences by envisaging counterexamples, that is, models of the premises that refute the putative conclusion. There is no guarantee that reasoners will find a counterexample, but, where they do succeed, they know that an inference is invalid (Barwise, 1993). The availability of a counterexample can suppress fallacious inferences from a conditional premise (Byrne, Espino, & Santamaría, 1999; Markovits, 1984; Vadeboncoeur & Markovits, 1999). Nevertheless, an alternative theory based on mental models has downplayed the role of counterexamples (Polk & Newell, 1995), and reasoners’ diagrams have sometimes failed to show their use (e.g., Newstead, Handley, & Buck, 1999). But when reasoners had to construct external models (Bucciarelli & Johnson-Laird, 1999), they used counterexamples (see also Neth & Johnson-Laird, 1999; Roberts, 2003).

There are two sorts of invalid conclusions. One sort is invalid because the conclusion is inconsistent with the premises, for example:

There is an apple or a banana on the table, or both.
There is a banana or else a cherry on the table, but not both.

Therefore, there isn't an apple on the table and there is a cherry on the table.

The premises have three fully explicit models:

apple	not-banana	cherry
not-apple	banana	not-cherry
apple	banana	not-cherry

The conclusion is inconsistent with the premises, because it conflicts with each of these models. Another sort of invalid conclusion, however, is consistent with the premises but does not follow from them. For instance, the conclusion *there is an apple on the table and there is a cherry*, holds in the first model, but it does not follow from the premises, because the other two models are counterexamples. Reasoners usually establish the invalidity of the first sort of conclusion by detecting its inconsistency with the premises, but they refute the second sort of conclusion with a counterexample (Johnson-Laird & Hasson, 2003). An experiment using functional magnetic resonance imaging examined reasoning based on numerical quantifiers, such as “at least five,” and mental arithmetic based on the same premises. Only a search for counterexamples in reasoning activated the right frontal pole, a region of the brain known to mediate inconsistencies (Kroger, Nystrom, Cohen, & Johnson-Laird, 2008).

Prediction 4: Reasoners should succumb to illusory inferences, which are compelling but invalid. They arise from the principle of truth, and its corollary that reasoners neglect what is false. Consider the problem:

Only one of the following assertions is true about a particular hand of cards:

There is a king in the hand or there is an ace, or both.

There is a queen in the hand or there is an ace, or both.

There is a jack in the hand or there is a ten, or both.

Is it possible that there is an ace in the hand?

Nearly everyone responds: “yes” (Goldvarg & Johnson-Laird, 2000). They grasp that the first assertion allows two possibilities in which an ace occurs. And so they infer that an ace is possible. In fact, it is impossible for an ace to be in the hand, because both of the first two assertions would then be true,

contrary to the rubric that only one of them is true. The inference is an illusion of possibility: Reasoners infer wrongly that a card is possible, because when they think about the truth of one assertion, they fail to think about the consequences of the falsity of other assertions. An analogous illusion of impossibility is created by replacing the two occurrences of *there is an ace* in the problem with *there is not an ace*. When the aforementioned premises were stated with the question:

Is it possible that there is a jack?

the participants nearly all responded, “yes.” They considered the third assertion, and its mental models showed that there could be a jack. But this time they were correct: The inference is valid. Hence, the focus on truth does not always lead to error, and experiments have compared illusions with similar control problems for which the neglect of falsity did not affect accuracy.

The computer program implementing the theory shows that illusory inferences should be sparse in the set of all possible inferences. But experiments have corroborated their occurrence in reasoning about possibilities in simple disjunctions (Khemlani & Johnson-Laird, 2009), probabilities, and causal and deontic relations (Buccicarelli & Johnson-Laird, 2005). Table 9.4 illustrates some typical illusions. Studies have used remedial procedures to reduce the illusions (e.g., Santamaría & Johnson-Laird, 2000). Yang taught participants to think explicitly about what is true and what is false. The difference between illusions and control problems vanished, but performance on the control problems fell from almost 100% correct to around 75% correct (Yang & Johnson-Laird, 2000). The principle of truth limits understanding, but it does so without participants realizing it. They were highly confident in their responses, usually no less so when they succumbed to an illusion than when they responded correctly to a control problem.

The rubric, “one of these assertions is true and one of them is false,” is equivalent to an exclusive disjunction between two assertions: *A or else B, but not both*. This usage leads to compelling illusions that seduce novices and experts alike, for example:

If there is a king then there is an ace or else if there isn't a king then there is an ace.

There is a king.

What follows?

Over 2,000 individuals have tackled this problem (see Johnson-Laird & Savary, 1999), and nearly

Table 9.4. Some Illusory Inferences in Abbreviated Form, With the Percentages of Illusory Responses

Premises Responses	Illusory Responses	Percentages of Illusory
1. If A then B or else B. A.	B.	100
2. Either A and B, or else C and D. A.	B.	87
3. If A then B or else if C then B. A and B.	Possibly both assertions are true.	98
4. A or else not both B and C. A and not B.	Possibly both assertions are true.	91
5. One true and one false: not-A or not-B, or neither. Not-C and not-B.	Possibly not-C and not-B.	85
6. Only one is true: At least some A are not B. No A are B.	Possibly No B are A.	95
7. If one is true so is the other: A or else not B. A.	A is more likely than B.	95
8. If one is true so is the other: A if and only if B. A.	A is equally likely as B.	90
9. Either A or else (B or else C).	A and B is not possible.	83
10. Either A, B, and C, or else C. A and not B.	The two assertions cannot both be true.	95

Notes. Each study examined other sorts of illusions and matched control problems. 1 is from Johnson-Laird & Savary (1999), 2 is from Walsh & Johnson-Laird (2004), 3 is from Johnson-Laird, Legrenzi, Girotto, & Legrenzi (2000), 4 is from Legrenzi, Girotto, & Johnson-Laird (2003), 5 is from Goldvarg & Johnson-Laird (2000), 6 is from Experiment 2, Yang & Johnson-Laird (2000), 7 and 8 are from Johnson-Laird & Savary (1996), 9 is from Khemlani & Johnson-Laird (2009), and 10 is from Byrne, Lotstein, & Johnson-Laird (in press).

everyone responded: *There is an ace*. The prediction of an illusion depends not on logic but on how other participants interpreted the relevant connectives in simple assertions. In particular, *or else* implies that one assertion that it connects can be true and the other assertion false; and if a conditional is false, then one possibility is that its if-clause is true and its then-clause is false. The illusion also occurs with the rubric *One of these assertions is true and one of them is false* applied to the two conditionals. The fact that the response is illusory is also borne out by the effect of various remedial procedures. Readers may suspect that the illusions arise from the artificiality of the problems, which never occur in real life, and which therefore confuse the participants. The problems may be artificial, though analogs do occur in real life (see Johnson-Laird & Savary, 1999), and artificiality fails to explain the correct responses to the controls or the high ratings of confidence in both illusory and control conclusions.

Prediction 5: Naive individuals should develop different reasoning strategies based on models. When they are tested in the laboratory, they start with only rough ideas of how to proceed. They can

reason, but not efficiently. With experience but no feedback about accuracy, they spontaneously develop various strategies (Schaeken, De Vooght, Vandierendonck, & d'Ydewalle, 1999). Deduction itself may be a master strategy (Evans, 2000), and people may resort to it more in Western cultures than in East Asian cultures (Peng & Nisbett, 1999). But deduction itself leads to different strategies (Van der Henst, Yang, & Johnson-Laird, 2002). Consider a problem in which each premise is *compound*, that is, contains a connective, and refers to different colored marbles that may be in a box:

There's a red if and only if there's a blue.
Either there's a blue or else there's a green, but not both.
There's a green if and only if there's a brown.
Does it follow that if there isn't red then there's a brown?

Some individuals develop a strategy based on suppositions. They say, for example:

Suppose there isn't a red. It follows from the first premise that isn't a blue. It follows from the second

premise that there's a green. The third premise then implies there's a brown. So, yes, the conclusion follows.

Some individuals construct a chain of conditionals leading from one clause in the conclusion to the other, for example: If there's a brown then there's a green, if there's a green then there isn't a blue, if there isn't a blue then there isn't a red. But most individuals develop a strategy in which they enumerate the different possibilities compatible with the premises. For example, they draw a horizontal line across the page and write down the two possibilities for the preceding premises:

red	blue
green	brown

When individuals are taught to use this strategy, as Victoria Bell showed in unpublished studies, their reasoning is both faster and more accurate. The nature of the premises and the conclusion can bias reasoners to adopt a predictable strategy, for example, conditional premises encourage the use of suppositions, whereas disjunctive premises encourage the enumeration of possibilities (Van der Henst et al., 2002).

Reasoners develop diverse strategies for relational reasoning (e.g., Goodwin & Johnson-Laird, 2005; Roberts, 2000), suppositional reasoning (e.g., Byrne & Handley, 1997), and reasoning with quantifiers (e.g., Buccirelli & Johnson-Laird, 1999). Granted the variety of strategies, there remains a robust effect: Inferences from one mental model are easier than those from multiple models (see also Espino, Santamaría, Meseguer, & Carreiras, 2000). Different strategies could reflect different mental representations (Stenning & Yule, 1997), but those so far discovered are all compatible with models. Individuals who have mastered logic could make a strategic use of formal rules. Given sufficient experience with a class of problems, individuals begin to notice some formal patterns.

Probabilistic Reasoning

Reasoning about probabilities is of two sorts. In *intensional* reasoning, individuals use heuristics to infer the probability of an event from some sort of evidence, such as the availability of information. In *extensional* reasoning, they infer the probability of an event from knowledge of the different ways in which it might occur. This distinction is due to Kahneman and Tversky, who together pioneered the investigation of heuristics in intensional reasoning (Kahneman, Slovic, & Tversky, 1982). Studies of

extensional reasoning focused at first on "Bayesian" reasoning in which participants try to infer a conditional probability of an event from various other probabilities. These studies offered no account of the mental processes of extensional reasoning, but the model theory filled the gap (Johnson-Laird, Legrenzi, Girotto, Legrenzi, & Caverni, 1999).

Mental models represent the extensions of assertions, that is, the possibilities to which they refer. The theory postulates the following:

The principle of *equiprobability*: Each mental model represents an equiprobable possibility unless there are reasons to the contrary.

The probability of an event accordingly depends on the proportion of models in which it occurs. The theory also allows that models can be tagged with numerals denoting probabilities or frequencies of occurrence, and that individuals can carry out primitive arithmetical operations on these numerals. Shimojo and Ichikawa (1989) and Falk (1992) proposed similar principles for Bayesian reasoning. The present account differs from theirs in that it assigns equiprobability, not to actual events but to mental models. And equiprobability applies only by default. Classical probability theory used an analogous principle of "indifference" (Hacking, 1975), but it is problematic because it applies to events per se rather than their mental representations.

Consider a simple problem from Johnson-Laird et al. (1999):

In the box, there is a green ball or a blue ball or both. What is the probability that both the green and the blue ball are there?

The premise elicits the mental models:

green	blue
green	blue

Naive reasoners follow the equiprobability principle, and infer the answer: 1/3. An experiment corroborated this and other predictions for the connectives in Table 9.2.

Conditional probabilities are on the borderline of naive competence. They are difficult because individuals need to consider several models. Here is a typical Bayesian problem:

The patient's PSA score is high. If he doesn't have prostate cancer, the chances of such a value is 1 in 1,000. Is he likely to have prostate cancer?

Many people respond: yes. But they are wrong. The model theory predicts the error: Individuals represent the conditional probability in the problem as one explicit model and one implicit model tagged with their respective chances:

not prostate cancer	high PSA	1
	...	999

The converse conditional probability has the same mental models, and so people are likely to assume that if the patient has a high PSA the chances are only 1 in 1,000 that he does not have prostate cancer, that is, given that the patient has a high PSA, the probability that he has prostate cancer is 999/1,000. To reason correctly, however, individuals must envisage the complete partition of possibilities and their chances. But the problem fails to provide enough information to do so. It yields only:

not prostate cancer	high PSA	1
not prostate cancer	not high PSA	999
prostate cancer	high PSA	?
prostate cancer	not high PSA	?

There are various ways to provide the missing information. One way is to give the base rate of prostate cancer, which can be used with Bayes' theorem in the probability calculus to infer the answer. But the theorem and its computations are beyond naive individuals (Kahneman & Tversky, 1973). The model theory postulates an alternative method:

The *subset principle*: Given a complete partition, individuals infer the conditional probability of *B* given *A* by computing the proportion corresponding to the subset of *B* that is *A*.
(Johnson-Laird et al., 1999)

If models are tagged with their absolute frequencies or chances, then this conditional probability is the value for *A and B* divided by the sum for all the models containing *B*. Suppose that the complete partition for the problem is as follows:

not prostate cancer	high PSA	1
not prostate cancer	not high PSA	999
prostate cancer	high PSA	2
prostate cancer	not high PSA	0

The probability of prostate cancer given a high PSA is the subset in which both occur (row 3) as a proportion of the cases of a high PSA (the sum of

rows 1 and 3), that is, 2/3. This probability is high but a long way from 999/1,000.

Evolutionary psychologists postulate that natural selection led to an innate “module” in the mind that makes Bayesian inferences from naturally occurring frequencies. It follows that naive reasoners should fail the patient problem because it is about a unique event (Cosmides & Tooby, 1996; Gigerenzer & Hoffrage, 1995). In contrast, as the model theory predicts, individuals cope with problems about unique (or repeated) events provided they can use the subset principle and the arithmetic is easy (Girotto & Gonzalez, 2001). Even infants are able to grasp the basics of probabilistic reasoning (Téglás, Girotto, Gonzalez, & Bonatti, 2007).

The model theory dispels some common misconceptions about probabilistic reasoning. It is *not* always inductive. Extensional reasoning can be deductively valid, and it need not depend on a tacit knowledge of the probability calculus. It is not always correct, because it can yield illusions (see items 7 and 8 in Table 9.4).

Induction and Models

Induction, Modulation, and Meaning

Induction is part of everyday thinking, but Popper (1972) argued that it is not part of scientific thinking. He claimed that science is based on explanatory conjectures, which observations serve potentially only to falsify. Some scientists agree (e.g., Deutsch, 1997, p. 159). But many astronomical, meteorological, and medical observations are not tests of hypotheses (see the chapters in Part VII). And everyone makes inductions in daily life. For instance, when the starter will not turn over the engine, your immediate thought is that the battery is dead. You are likely to be right, but there is no guarantee. Likewise, when the car ferry, *Herald of Free Enterprise*, sailed from Zeebrugge on March 6, 1987, its master made the plausible induction that the bow doors had been closed. They had always been closed in the past, and he had no evidence to the contrary. But they had not been closed, the vessel capsized and sank, and many people drowned. Induction is a common but risky business.

The textbook definition of *induction*—alas, all too common—is that it is an inference from the particular to the general. Such arguments are indeed inductions, but many other inductions such as the two earlier examples are inferences from the particular to the particular. That is why the Introduction to this chapter offered a more comprehensive definition: Induction

is a process that increases semantic information. As an example, consider again the inference:

The starter won't turn.
Therefore, the battery is dead.

Like all inductions, it depends on knowledge and in particular on the true conditional:

If the battery is dead, then the starter won't turn.

The conditional refers to three possibilities:

battery dead	not starter turn
not battery dead	not starter turn
not battery dead	starter turn

The premise of the induction eliminates the third possibility, but the conclusion goes beyond the given information because it eliminates the second possibility, too. The availability of the first model yields an intensional inference of a high probability, but the conclusion may be false. Inductions are risky because they increase semantic information.

Inductions depend on knowledge. As Kahneman and Tversky have shown, various heuristics constrain the use of knowledge in inductions. The present account presupposes these heuristics, but it examines the role of models in induction. The model theory gives a “dual-process” account of inferences: *Intuitive* reasoning has no access to working memory, and so it is incapable of recursion—loops of operations such as those in the earlier inference about Cath loving Dave—and incapable of representing alternative possibilities (Johnson-Laird, 1983, Chapter 9, 2006). Intuitive inductions are accordingly dependent on what is known as “System 1,” which is nonrecursive and therefore rapid. It is unconscious and therefore involuntary. And it yields only a single mental model of the situation. Other inductions are *explicit*: They are slow, voluntary, and conscious. Dual-process theories are long-standing (e.g., Evans & Over, 1996; Johnson-Laird & Wason, 1977, p. 341; Sloman, 1996; Stanovich, 1999; see Evans, Chapter 8; Stanovich, Chapter 22). What the model theory provides is a distinction in computational power: System 1 is computationally weak because it makes no use of working memory, whereas System 2 uses working memory and is therefore capable of recursion and the representation of alternative possibilities.

One sort of intuitive induction affects the interpretation of sentences and has subsequent effects on

reasoning. It is known as modulation (Johnson-Laird & Byrne, 2002):

The principle of *modulation*: the meanings of clauses, coreferential links between them, general knowledge, and knowledge of context, can modulate the core meanings of sentential connectives (which are shown in Table 9.2).

One effect is to block the construction of models of possibilities. Consider the conditional:

If it's a game, then it's not soccer.

It is compatible with only two possibilities:

game	not-soccer
not-game	not-soccer

The knowledge that soccer is a game blocks the construction of the possibility in which “it” refers to something that is not a game, but that is soccer. Hence, the conditional alone yields the valid inference: *It's not soccer*. Depending on the contents and the grammatical form of a conditional, modulation yields 10 distinct interpretations of conditionals depending solely on which possibilities it blocks (Johnson-Laird & Byrne, 2002). But, as we will see, still other interpretations of conditionals can occur. A corollary, however, is that no form of inference, such as: *if A then C; not C; therefore, not-A*, is guaranteed to yield a valid deduction regardless of its contents. The validity of inferences can be decided only on a case-by-case basis: Those inferences in which the conclusion must be true if the premises are true are valid. They are valid, not in virtue of their “logical form,” but in virtue of content. Hence, the model theory makes no use of logical form (Byrne & Johnson-Laird, 2009).

Experiments have shown that modulation occurs and affects the different sets of possibilities that participants list for assertions, which in turn predict the conclusions that participants in other experiments tend to draw (Quelhas, Johnson-Laird, & Juhos, 2010). Consider these two conditionals (translated from the Portuguese):

If the dish is kidney beans, then its basis is beans.
If the dish is made of meat, then it can be
Portuguese stew.

A subtle difference exists between their interpretations. When individuals evaluate possibilities in relation to the first sort of conditional (*If A then B*), they judge that it is possible that the dish isn't kidney

beans but its basis is beans (*not-A and B*), but that it is not possible that the dish is kidney beans and its basis isn't beans (*A and not-B*). But they make the opposite evaluations for the second conditional: It is impossible that the dish isn't made of meat and is Portuguese stew (*not-A and B*), but it is possible that that dish is made of meat and is not Portuguese stew (*A and not-B*). These interpretations, and those for other sorts of conditional, lead to quite different but predictable patterns of inference. For example, given an assertion of the if-clause in the conditional about the beans, *A*, reasoners infer that *B* follows; but given a denial of the if-clause, *not-A*, they refrain from inferring that *not-C* follows. They make the opposite pattern of inferences from the conditional about the stew.

Models can represent spatial and temporal information (Byrne & Johnson-Laird, 1989; Schaeken et al., 1996). And another effect of modulation is to add such information to models. For instance, the assertion, *If she put a book on the shelf, then it fell off*, elicits the temporal relation that the book was put on the shelf before it fell, and the spatial relation that the book ended up below the shelf (Johnson-Laird & Byrne, 2002). The effects of temporal modulation were borne out in a study in which individuals drew conclusions corroborating the predicted temporal relations, which in some cases were that the event in the if-clause occurred first, and in other cases were that the event in the then-clause occurred first (Quelhas et al., 2010). Modulation is rapid and automatic, and it affects comprehension and reasoning (Johnson-Laird & Byrne, 2002; Newstead, Ellis, Evans, & Dennis, 1997; Quelhas et al., 2010). In logic, connectives such as conditionals and disjunctions are *truth functional*, and so the truth-value of a sentence in which they occur can be determined solely from a knowledge of the truth-values of the clauses they interconnect (see Table 9.1). But in natural language connectives are not truth functional: The process of their interpretation has to check whether content and context modulate their meaning.

The Detection of Inconsistencies

When the premises and conclusion of an inference refer to disjoint possibilities, they are inconsistent with one another. But inconsistency is a more general phenomenon: A set of assertions can be inconsistent, even though any proper subset of them is consistent. For example, these three

assertions are inconsistent, that is, they cannot all be true at the same time:

If there is a square on the board, then there is a triangle.

If there is a triangle, then there is a circle.

There is a square on the board and there isn't a circle.

Yet any pair of them is consistent. This principle applies in general: A set of n propositions can be inconsistent even though any $n-1$ of them is consistent. In principle, 100 propositions, which can each be true or false, yield 2^{100} cases. To determine whether the propositions are consistent may call for an examination of all these cases to see whether there is one in which all the propositions are true. Even if you could examine each possibility in a millionth of a second, it would still take you much longer than the universe has existed to examine them all. In other words, the evaluation of a set of assertions as consistent or inconsistent is computationally intractable (Cook, 1971). As the number of possibilities increases, it soon ceases to be feasible to make an exhaustive check.

Some psychologists argue that logically untrained individuals are incapable of deductive reasoning, or reluctant to use it, and instead use various heuristics (e.g., Oaksford & Chater, 2007; Wetherick & Gilhooly, 1995). But if untrained individuals are able to detect inconsistencies, they are in effect making deductions. The two tasks seem different, but they are merely opposite sides of one another. This relation is exploited in one method of logic: to prove that a conclusion follows validly, you add its negation to the premises and show that the resulting set of propositions is inconsistent (see, e.g., Jeffrey, 1981). In fact, untrained individuals are deductively competent because they can detect inconsistencies. The evidence implies that they do so by searching for a model in which all the propositions hold. If they find such a model, they evaluate the propositions as consistent—they could all be true at the same time; otherwise, they evaluate the propositions as inconsistent.

The theory predicts that when the first model that individuals are likely to envisage satisfies a set of assertions, then the task should be easier than when it does not, and they have to search for an alternative model. Consider, for instance, these assertions about what is on top of a table:

If there isn't an apple, then there is a banana.

If there is a banana, then there is a cherry.

There isn't an apple and there is a cherry.

The explicit mental model of the first assertion (see Table 9.2) is one that satisfies its two clauses:

not-apple banana

The second assertion holds in this model and updates it:

not-apple banana cherry

The third assertion holds in this model, and so reasoners should respond that the assertions are consistent. A contrasting set of assertions is as follows:

There is an apple or there is a banana.

There isn't a banana or there is a cherry.

There isn't an apple and there is a cherry.

Individuals are likely to start with a model of the first clause of the first assertion:

apple

They may continue to update it only to discover that the third assertion is not consistent with it. They now have to start over with an alternative model of the first assertion:

banana

This model refutes the first clause of the second assertion, and so its second clause holds:

banana cherry

The third assertion holds in this possibility, and so individuals can now respond that the three assertions can all be true at the same time. This predicted difference in performance occurred in an experiment, which counterbalanced the two conditions over conditionals and disjunctions (Johnson-Laird, Legrenzi, Girotto, & Legrenzi, 2000).

Another line of evidence corroborating the use of models showed that individuals succumb to illusions of consistency and of inconsistency. Consider the exclusive disjunction:

If there's an apple then there's a banana, or else if there's a cherry then there's a banana.

Its mental models are as follows:

apple banana
 banana cherry

They imply that a second assertion:

There is an apple and a banana

is consistent with the first one. In contrast, the fully explicit models of the disjunction take into account that when one conditional is true, the other conditional is false. And individuals take the falsity of a conditional, such as *if there's an apple, then there's a banana* to mean that there can be an apple without a banana (e.g., Barres & Johnson-Laird, 2003). When the first conditional is true, the second conditional is false and so there is a cherry and not a banana, and this case can occur when there isn't an apple and isn't a banana according to the truth of the first conditional. Conversely, when the second conditional is true, the first conditional is false, and so the fully explicit models of the disjunction are as follows:

apple	not-banana	not-cherry
not-apple	not-banana	cherry

These models show that the correct response is that the previous two assertions cannot both be true: They are inconsistent with one another. Similar discrepancies yield illusions of inconsistency: Individuals infer that assertions are inconsistent when in fact they are consistent. Nevertheless, they respond correctly to control problems in which the neglect of falsity has no effect on accuracy. For example, they correctly evaluate these assertions as consistent:

If there's an apple then there's a banana, or else if there's a cherry then there's a banana.

There is an apple and not a cherry.

The second assertion holds in the mental models and the fully explicit models of the first assertion. Experiments have shown that individuals tend to err with illusions but to perform correctly with control problems (Johnson-Laird, et al., 2000; Legrenzi, Girotto, & Johnson-Laird, 2003).

Abduction, Causation, and the Creation of Explanations

Induction is the use of knowledge to increase semantic information: Possibilities are eliminated either by adding elements to a mental model or by eliminating a mental model altogether. Induction can yield general descriptions and scientific laws. For example, Kepler's first law describes the orbits of the planets as ellipses with the sun at one of the two foci, and it was an induction from Tycho Brahe's astronomical observations. Scientific theories explain such laws in terms of more fundamental considerations, for example, the general theory of

relativity explains planetary orbits as the result of the sun's mass curving space-time. Peirce (1955) called reasoning that leads to such explanations *abduction*. In terms of the five categories of the Introduction, abduction is creative when it overrides data or beliefs.

Consider this problem (from Lee & Johnson-Laird, 2006):

If a pilot falls from a plane without a parachute, the pilot dies. This pilot did not die, however. Why not?

Many people respond with putative explanations, such as: *The pilot fell into a deep snowdrift*. Others instead draw a logically valid conclusion: *The pilot did not fall from the plane without a parachute*. The human propensity to explain is extraordinary, and it goes far beyond what can currently be simulated in any computer program. Tony Anderson and the present author illustrated this point when they asked participants, in effect, to explain the inexplicable. The participants received pairs of sentences selected at random from separate stories, also selected at random, for example:

John made his way to a shop which sold TV sets.
Celia had recently had her ears pierced.

In another condition of the experiment, the sentences were edited to make them coreferential:

Celia made her way to a shop which sold TV sets.
She had recently had her ears pierced.

The participants' task was to explain what was going on. They readily went beyond the given information to account for what was happening. They proposed, for example, that Celia was getting reception in her earrings and wanted the TV shop to investigate, that she wanted to see some new earrings on closed circuit TV, that she had won a bet by having her ears pierced and was spending the money on a TV set. Only rarely were the participants stumped for an explanation, and they were almost as ingenious with the sentences that were not coreferential.

Abduction depends on knowledge, especially of causal relations, which according to the model theory refer to temporally ordered sets of possibilities (Goldvarg & Johnson-Laird, 2001; cf. Buehner & Cheng, Chapter 12). An assertion of the form *C causes E* refers to three possibilities:

C	E
not-C	E
not-C	not-E

with the temporal constraint that *E* cannot precede *C*. An "enabling" assertion of the form *C allows E* refers to the three possibilities with the same temporal constraint:

C	E
C	not-E
not-C	not-E

This account accordingly distinguishes between the meaning of causes and of enabling conditions (pace, e.g., Einhorn & Hogarth, 1986; Hart & Honoré, 1985; Mill, 1874). It also treats the meaning of causal assertions as deterministic rather than probabilistic (cf. Cheng, 1997; Suppes, 1970). Experiments support both these claims: Participants listed the possibilities mentioned earlier, and they rejected other cases as impossible, contrary to probabilistic accounts (Goldvarg & Johnson-Laird, 2001). However, when individuals *induce* a causal relation from a series of observations, they may be influenced by the relative frequencies of various sorts of observation (Perales & Shanks, 2008; but cf. Lagnado, Waldmann, Hagmayer, & Sloman, 2007). Yet the meaning of a causal relation seems to be deterministic, because individuals claim that a single counterexample suffices to refute a general claim, such as: *contact between these two sorts of substance causes an explosion to occur* (Frosch & Johnson-Laird, 2009).

Given the cause from a causal relation, there is only one possible effect, as the models show; but given the effect, there is more than one possible cause. Exceptions do occur (Cummins, Lubart, Alksnis, & Rist, 1991; Markovits, 1984), but the principle holds in general. It explains why inferences from causes to effects are more plausible than inferences from effects to causes. As Tversky and Kahneman (1982) showed, conditionals in which the if-clause is a cause, such as:

A girl has blue eyes if her mother has blue eyes,

are judged as more probable than conditionals in which the if-clause is an effect:

The mother has blue eyes if her daughter has blue eyes.

According to the model theory, when individuals discover inconsistencies, their immediate task is, not to revise their beliefs, but rather to construct a causal

model that resolves the inconsistency. Consider, for example, the scenario:

If the trigger is pulled, then the pistol will fire. The trigger is pulled, but the pistol does not fire. Why not?

Given 20 different scenarios of this form, most explanations were causal claims that repudiated the conditional (Johnson-Laird, Girotto, & Legrenzi, 2004). In a further experiment with the scenarios, the participants rated the statements of a cause and its effect as the most probable explanations, for example:

A prudent person had unloaded the pistol and there were no bullets in the chamber.

The cause alone was rated as less probable, but as more probable than the effect alone, which in turn was rated as more probable than an explanation that repudiated the categorical premise, for example:

The trigger wasn't really pulled.

The greater probability assigned to the conjunction of the cause and effect than to either of its clauses is an instance of the “conjunction” fallacy in which a conjunction is in error judged to be more probable than its constituents (Tversky & Kahneman, 1983), and it suggests that models of causes and their effects are a staple in long-term memory.

Abductions that resolve inconsistencies have been implemented in a computer program that uses a knowledge base to create causal explanations (Johnson-Laird et al., 2004). Given the preceding example, the program constructs the mental models of the conditional:

The conjunction of the categorical assertion yields:

The fact that the pistol did not fire is inconsistent with this model. The theory predicts that individuals should tend to abandon their belief in the conditional premise, because its one explicit mental model conflicts with the fact that the pistol did not fire (see Girotto, Johnson-Laird, Legrenzi, & Sonino, 2000, for corroborating evidence). Nevertheless, the conditional is a useful idealization, and so the

program uses it to construct a counterfactual set of possibilities:

trigger pulled	not pistol fires	[the model of the facts]
trigger pulled	pistol fires	[the models of counterfactual possibilities]

People know that a pistol without bullets does not fire, and so the program has in its knowledge base the fully explicit models:

not bullets in pistol	not pistol fires
bullets in pistol	not pistol fires
bullets in pistol	pistol fires

The model of the facts triggers the first possibility in this set, which modulates the model of the facts to create a possibility:

not bullets in trigger not pistol fires
pistol pulled [possibility]

The new proposition in this model triggers a causal antecedent from another set of models in the knowledge base, which completes the process:

person	not bullets	trigger	not
empties	in pistol	pulled	pistol fires
pistol			
not person	bullets in	trigger	pistol
empties	pistol	pulled	fires
pistol			

The first of the three models above denotes a possibility that explains the inconsistency: A person emptied the pistol and so it had no bullets. The remaining models denote counterfactual possibilities, which yield the counterfactual claim: If the person hadn't emptied the pistol, then it would have had bullets, and...it would have fired. The fact that the pistol did not fire has been used to reject the conditional premise, and available knowledge has been used to create an explanation and to modulate the conditional premise into a counterfactual. There are, of course, other possible explanations for the failure of the pistol to fire. And so the program has a set of alternatives from which it makes an arbitrary choice.

In sum, reasoners can resolve inconsistencies between incontrovertible evidence and the consequences of their beliefs. They use their available knowledge—in the form of explicit models—to try to create a causal scenario that makes sense of the facts. They may resolve the inconsistency, create an erroneous account, or fail to construct any explanation whatsoever.

Conclusions and Future Directions

The concept of a mental model has its antecedents in the 19th century. The present theory was developed in the 20th century. In its application to deduction, as Peirce anticipated, if a conclusion holds in all the models of the premises, it is necessary given the premises. If it holds in a proportion of the models, then, granted that they are equiprobable, its probability is equal to that proportion. If it holds in at least one model, then it is possible. The theory also applies to inductive reasoning—both the rapid implicit inferences of System 1 that underlie comprehension and the deliberate inferences of System 2 that yield generalizations. And it offers an account of the creation of explanations that resolve inconsistencies. But if mental models underlie all thinking with a propositional content, then the theory remains incomplete. It is currently under intensive development and intensive scrutiny. Indeed, there are distinguishable variants of the theory itself (see, e.g., Evans, 1993; Ormerod et al., 1993; Polk & Newell, 1995; Schroyens & Schaeken, 2003; Schroyens, Schaeken, & Dieussaert, 2008). The three most urgent questions to be answered in the 21st century are as follows:

1. What role do mental models play in problem solving?
2. In what ways, if any, do *intensional* estimates of probabilities depend on mental models?
3. Current programs simulate the operations of System 2 in deliberate reasoning, but what is the nature of the algorithm underlying the use of models in the intuitive thinking of System 1?

Acknowledgments

This chapter was made possible by a grant from the National Science Foundation (grant SES 0844851 to study deductive and probabilistic reasoning). The author is grateful to the editors, to the community of reasoning researchers, and to his colleagues, collaborators, and students—many of whose names are to be found in the References.

Abstract

Humans and other animals perceive and act on the basis of similarities among things because similarities are usually informative. Similar things usually behave similarly, and because we can grasp these similarities, we can organize and predict the things in our world. Four major classes of models have been proposed for how humans assess similarities. In geometric models, entities are represented by their positions in a multidimensional space, and similarity is based on the proximity of entities in this space. In featural models, entities are described by their features, and the similarity of entities is an increasing function of their shared features and/or a decreasing function of their unique features. In alignment-based models, the similarity between two structured entities is calculated by placing the elements of their structures into correspondence. In transformational models, the similarity between two entities is conceptualized as the number of transformations required to transform one entity into the other. We discuss issues related to the flexibility and constraints of similarity, and how similarity grounds other cognitive processes.

Key Words: similarity, multidimensional scaling, induction, categorization, contrast model, relations, alignment, structural representations, transformations, grounding

Introduction

Human assessments of similarity are fundamental to cognition because similarities in the world are revealing. The world is an orderly enough place that similar objects and events tend to behave similarly. This fact of the world is not just a fortunate coincidence. It is *because* objects are similar that they will tend to behave similarly in most respects. It is because crocodiles and alligators are similar in their external form, internal biology, behavior, diet, and customary environment that one can often successfully generalize from what one knows of one to the other. As Quine (1969) observed, "Similarity is fundamental for learning, knowledge and thought, for only our sense of similarity allows us to order things into kinds so that these can function as stimulus meanings. Reasonable expectation depends on the similarity of circumstances and on our tendency to

expect that similar causes will have similar effects (p. 114)." Similarity thus plays a crucial role in making predictions because similar things usually behave similarly.

From this perspective, psychological assessments of similarity are valuable to the extent that they provide grounds for predicting as many important aspects of our world as possible (Griffiths et al., Chapter 3; Holland, Holyoak, Nisbett, & Thagard, 1986; Dunbar & Klahr, Chapter 35). Appreciating the similarity between crocodiles and alligators is helpful because information learned about one is generally true of the other. If we learned an arbitrary fact about crocodiles, such as they are very sensitive to the cold, then we would probably be safe in inferring that this fact is also true of alligators. As the similarity between A and B increases, so does the probability of correctly inferring that B has X upon knowing

that A has X (Tenenbaum, 1999). This relation assumes that we have no special knowledge related to property X. Empirically, Heit and Rubinstein (1994) have shown that if we *do* know about the property, then this knowledge, rather than a one-size-fits-all similarity, is used to guide our inferences. For example, if people are asked to make an inference about an anatomical property, then anatomical similarities have more influence than behavioral similarities. Boars are anatomically but not behaviorally similar to pigs, and this difference successfully predicts that people are likely to make anatomical but not behavioral inferences from pigs to boars. The logical extreme of this line of reasoning (Goodman, 1972; Quine, 1977) is that if one has complete knowledge about the reasons why an object has a property, then general similarity is no longer relevant to generalizations. The knowledge itself completely guides whether the generalization is appropriate. Moonbeams and melons are not very similar generally speaking, but if one is told that the Moonbeams have the property that the word begins with Melanie's favorite letter, then one can generalize this property to melons with very high confidence.

By contrasting the cases of crocodiles, boars, and moonbeams, we can specify the benefits and limitations of similarity. We tend to rely on similarity to generate inferences and categorize objects into kinds when we do not know exactly what properties are relevant, we do not have explicit causal accounts for what makes something appear the way it does (Buehner & Cheng, Chapter 12), or when we cannot easily separate an object into separate properties. Similarity is an excellent example of a domain-general source of information. Even when we do not have specific knowledge about a domain, we can use similarity as a default method to reason about it. The contravening limitation of this domain generality is that when specific knowledge is available, then a generic assessment of similarity is no longer as relevant (Keil, 1989; Lombrozo, Chapter 14; Murphy, 2002; Murphy & Medin, 1985; Rips, 1989; Rips & Collins, 1993). Artificial laboratory experiments where subjects are asked to categorize unfamiliar stimuli into novel categories invented by the experimenter are situations where similarity is clearly important because subjects have little else to use (Estes, 1994; Nosofsky, 1984, 1986; see Rips et al., Chapter 11). However, similarity is also important in many real-world situations because our knowledge does not run as deep as we think it does (Rozenblit & Keil,

2002), and because a general sense of similarity often has an influence even when more specific knowledge ought to overrule it (Allen & Brooks, 1991; Smith & Sloman, 1994).

Another argument for the importance of similarity in cognition is simply that it plays a significant role in psychological accounts of problem solving, memory, prediction, and categorization. If a problem is similar to a previously solved problem, then the solution to the old problem may be applied to the new problem (Holyoak & Koh, 1987; Ross, 1987, 1989; see Holyoak, Chapter 13). If a cue is similar enough to a stored memory, the memory may be retrieved (Raaijmakers & Shiffrin, 1981). If an event is similar enough to a previously experienced event, the stored event's outcome may be offered as a candidate prediction for the current event (Sloman, 1993; Tenenbaum & Griffiths, 2001). If an unknown object is similar enough to a known object, then the known object's category label may be applied to the unknown object (Nosofsky, 1986). The act of comparing events, objects, and scenes, and establishing similarities between them is of critical importance for the cognitive processes we depend upon.

The utility of similarity for grounding our concepts has been rediscovered in all of the fields comprising cognitive science (see Medin & Rips, Chapter 2). Exemplar (Estes, 1994; Kruschke, 1992; Lamberts, 2000; Medin & Schaffer, 1978; Nosofsky, 1986), instance-based (Aha, 1992), view-based (Tarr & Gauthier, 1998), case-based (Schank, 1982), nearest neighbor (Ripley, 1996), configural cue (Gluck & Bower, 1990), and vector quantization (Kohonen, 1995) models all share the underlying strategy of giving responses learned from similar, previously presented patterns to novel patterns. Thus, a model can respond to repetitions of these patterns; it can also give responses to novel patterns that are likely to be correct by sampling responses to old patterns, weighted by their similarity to the novel pattern. Consistent with these models, psychological evidence suggests that people show good transfer to new stimuli in perceptual tasks to the extent that the new stimuli resemble previously learned stimuli (Kolers & Roediger, 1984; Palmeri, 1997). Another common feature of these approaches is that they represent patterns in a relatively raw, unprocessed form. This parallels the constraint described earlier on the applicability of similarity. Both raw representations and generic similarity assessments are most useful as a default strategy when one does not know

exactly what properties of a stimulus are important. One's best bet is to follow the principle of least commitment (Marr, 1982) and keep mental descriptions in a relatively raw form to preserve information that may be needed at a later point.

Another reason for studying similarity is that it provides an elegant diagnostic tool for examining the structure of our mental entities and the processes that operate on them. For example, one way to tell that a physicist has progressed beyond the novice stage is that he or she sees deep similarities between problems that require calculation of force even though the problems are superficially dissimilar (Chi, Feltovich, & Glaser, 1981; see Bassok & Novick, Chapter 21). Given that psychologists have no microscope with direct access to people's representations of their knowledge, appraisals of similarity provide a powerful, if indirect, lens onto representation/process assemblies (see also Markman, Chapter 4; Doumas & Hummel, Chapter 5).

A final reason to study similarity is that it occupies an important ground between perceptual constraints and the functions of higher level knowledge systems. Similarity is grounded by perceptual functions. A tone of 200 Hz and a tone of 202 Hz sound similar (Shepard, 1987), and the similarity is cognitively impenetrable (Pylyshyn, 1985) enough that there is little that can be done to alter this perceived similarity. On the other hand, similarity is also highly flexible and dependent on knowledge and purpose. By focusing on patterns of motion and relations, even electrons and planets can be made to seem similar (Gentner, 1983; Holyoak & Thagard, 1989; see Holyoak, Chapter 13). A complete account of similarity will make contact both with Fodor's (1983) isolated and modularized perceptual input devices and the "central system" where everything a person knows may be relevant.

A Survey of Major Approaches to Similarity

There have been a number of formal treatments that simultaneously provide theoretical accounts of similarity and describe how it can be empirically measured (Hahn, 2003). These models have had a profound practical impact in statistics, automatic pattern recognition by machines, data mining, and marketing (e.g., online stores can inform you that "people similar to you liked the following other items..."). Our brief survey is organized in terms of the following models: geometric, feature-based, alignment-based, and transformational.

Geometric Models and Multidimensional Scaling

Geometric models of similarity have been among the most influential approaches to analyzing similarity (Carroll & Wish, 1974; Torgerson, 1958, 1965). These approaches are exemplified by nonmetric multidimensional scaling (MDS) models (Shepard, 1962a, 1962b). MDS models represent similarity relations between entities in terms of a geometric model that consists of a set of points embedded in a dimensionally organized metric space. The input to MDS routines may be similarity judgments, dissimilarity judgments, confusion matrices, correlation coefficients, joint probabilities, or any other measure of pairwise proximity. The output of an MDS routine is a geometric model of the data, with each object of the data set represented as a point in an n -dimensional space. The similarity between a pair of objects is taken to be inversely related to the distance between two objects' points in the space. In MDS, the distance between points i and j is typically computed by:

$$distance(i, j) = \left[\sum_{k=1}^n |X_{ik} - X_{jk}|^r \right]^{\frac{1}{r}} \quad (\text{Eq. 1})$$

where n is the number of dimensions, X_{ik} is the value of dimension k for item i , and r is a parameter that allows different spatial metrics to be used. With $r = 2$, a standard Euclidean notion of distance is invoked, whereby the distance between two points is the length of the straight line connecting the points. If $r = 1$, then distance involves a city-block metric where the distance between two points is the sum of their distances on each dimension ("short-cut" diagonal paths are not allowed to directly connect points differing on more than one dimension). A Euclidean metric often provides a better fit to empirical data when the stimuli being compared are composed of integral, perceptually fused dimensions such as the brightness and saturation of a color. Conversely, a city-block metric is often appropriate for psychologically separated dimensions such as brightness and size (Attnave, 1950).

Richardson's (1938) fundamental insight, which is the basis of contemporary use of MDS, was to begin with subjects' judgments of pairwise object dissimilarity and work backward to determine the dimensions and dimension values that subjects used in making their judgments. MDS algorithms proceed by placing entities in an N -dimensional space such that the distances between the entities

accurately reflect the empirically observed similarities. For example, if we asked people to rate the similarities [on a scale from 1 (low similarity) to 10 (high similarity)] of Russia, Cuba, and Jamaica, we might find:

$$\begin{aligned}\text{Similarity (Russia, Cuba)} &= 7 \\ \text{Similarity (Russia, Jamaica)} &= 1 \\ \text{Similarity (Cuba, Jamaica)} &= 8\end{aligned}$$

An MDS algorithm would work to position the three countries in a space such that countries that are rated as being highly similar are very close to each other in the space. With nonmetric scaling techniques only ordinal similarity relations are preserved. The interpoint distances suggested by the similarity ratings may not be simultaneously satisfiable in a given dimensional space. If we limit ourselves to a single dimension (we place the countries on a “number line”), then we cannot simultaneously place Russia near Cuba (similarity = 7) and place Russia far away from Jamaica (similarity = 1). In MDS terms, the “stress” of the one-dimensional solution would be high. We could increase the dimensionality of our solution and position the points in two-dimensional space. A perfect reconstruction of any set of proximities among a set of N objects can be obtained if a high enough dimensionality (specifically, $N - 1$ dimensions) is used. However, increasing the number of dimensions always risks explaining noise in the data (“overfitting”) and tends to yield less interpretable solutions.

One of the main applications of MDS is to determine the underlying dimensions comprising the set of compared objects. Once the points are positioned in a way that faithfully mirrors the subjectively obtained similarities, it is often possible to give interpretations to the axes or to rotations of the axes. In the earlier example, dimensions may correspond to “political affiliation” and “climate.” Russia and Cuba would have similar values on the former dimension; Jamaica and Cuba would have similar values on the latter dimension. A study by Smith, Shoben, and Rips (1974) illustrates a classic use of MDS. They obtained similarity ratings from subjects on many pairs of birds. Submitting these pairwise similarity ratings to MDS analysis, they hypothesized underlying features that were used for representing the birds. Assigning subjective interpretations to the geometric model’s axes, the experimenters suggested that birds were represented in terms of their values on dimensions such as “ferocity” and “size.”

As another example of using MDS to create quantitative object and dimension interpretations, Figure 10.1 presents an MDS solution for 135 words representing animals. We started by obtaining subjective estimates of similarity by randomly selecting six anchor animal terms and asking subjects to determine to which of these terms each of the remaining 129 animals terms was most similar. We considered two terms as belonging to the same category if the same anchor term was judged most similar to both of them. After several passes through the 135 animals, choosing different random anchor terms each time, we calculated the similarity between any pair of animals as their probability of being placed in the same category. The resulting MDS solution based on this $(135 \times 135)/2$ (divided by 2 because we assume the similarity of A to B is equal to the similarity of B to A) matrix of similarities is shown in Figure 10.1. The first four dimensions can be imperfectly interpreted as mammalian versus nonmammalian (Dimension 1, with mammals on the left and nonmammals on the right), water-land-air (Dimension 2, with flying animals at the top and water animals at the bottom), mundane-mythical (Dimension 3, with mythical or extinct animals on the left), and unpleasant-pleasant (Dimension 4, with unpleasant animals at the bottom).

It is important to note that the proper psychological interpretation of a geometric representation of objects is not necessarily in terms of its Cartesian axes. In some domains, such as musical pitches, the best interpretation of objects may be in terms of their polar coordinates of angle and length (Shepard, 1982). Recent work has extended geometric representations still further, representing patterns of similarities by generalized, nonlinear manifolds (Tenenbaum, De Silva, & Lanford, 2000).

MDS is also used to create a compressed representation that conveys relational similarities among a set of items. A set of N items requires $N(N-1)/2$ numbers to express all pairwise distances among the items, assuming that any object has a distance of 0 to itself and distances are symmetric. However, if an MDS solution fits the distance data well, it can allow these same distances to be reconstructed using only ND numbers, where D is the number of dimensions of the MDS solution. This compression may be psychologically very useful. One of the main goals of psychological representation is to create efficient codes for representing a set of objects. Compressed representations can facilitate encoding, memory, and processing. Shimon Edelman (1999)

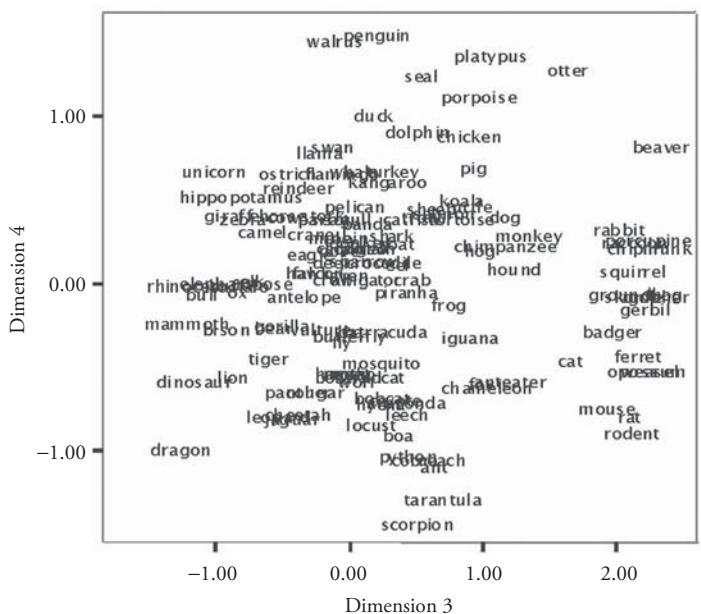

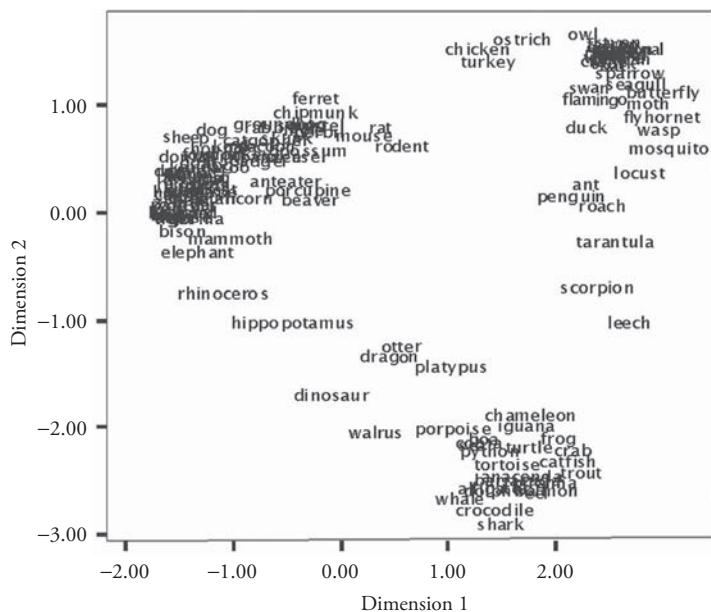

Fig. 10.1 A four-dimensional multidimensional scaling (MDS) solution for 135 animal terms. The four dimensions, in order, may be imperfectly interpreted as reflecting mammalian versus nonmammalian, water-land-air, mundane-mythical, and unpleasant-pleasant.

has proposed that both people and machines efficiently code their world by creating geometric spaces for objects with much lower dimensionality than the objects' physical description (see also Gardenfors, 2000).

A third use of MDS is to create quantitative representations that can be used in mathematical and computational models of cognitive processes. Numeric representations, namely coordinates in a psychological space, can be derived for stories, pictures, sounds, words, or any other stimuli for which

one can obtain subjective similarity data. Once constructed, these numeric representations can be used to predict people's categorization accuracy, memory performance, or learning speed. MDS models have been successful in expressing cognitive structures in stimulus domains as far removed as animals (Smith et al., 1974), Rorschach ink blots (Osterholm, Woods, & Le Unes, 1985), chess positions (Horgan, Millis, & Neimeyer, 1989), and air flight scenarios (Schvaneveldt, 1985). Many objects, situations, and concepts seem to be psychologically structured in

terms of dimensions, and a geometric interpretation of the dimensional organization captures a substantial amount of that structure.

Featural Models

In 1977, Amos Tversky brought into prominence what would become the main contender to geometric models of similarity in psychology. The reason given for proposing a feature-based model was that subjective assessments of similarity did not always satisfy the assumptions of geometric models of similarity.

PROBLEMS WITH THE STANDARD GEOMETRIC MODEL

Three assumptions of standard geometric models of similarity are as follows:

Minimality: $D(A,B) \geq D(A,A) = 0$

Symmetry: $D(A,B) = D(B,A)$

The Triangle Inequality: $D(A,B) + D(B,C) \geq D(A,C)$

where $D(A,B)$ is interpreted as the dissimilarity between items A and B.

According to the minimality assumption, all objects are equally (dis)similar to themselves. Some violations of this assumption are found (Nickerson, 1972) when confusion rates or RT measures of similarity are used. First, not all letters are equally similar to themselves. For example, Podgorny and Garner (1979) found that if the letter S is shown twice on a screen, subjects are faster to correctly say that the two tokens are similar (i.e., they come from the same similarity-defined cluster) than if the twice-shown letter is W. By this reaction time measure of similarity, the letter S is more similar to itself than the letter W is to itself. Even more troublesome for the minimality assumption, two different letters may be more similar to each other than a particular letter is to itself. For example, the letter C is more similar to the letter O than W is to itself, as measured by inter-letter confusions. Gilmore, Hersh, Caramazza, and Griffin (1979) found that the letter M is more often recognized as an H (probability = .391) than as an M (probability = .180). This finding is problematic for geometric representations because the distance between a point and itself should be zero.

According to the symmetry assumption, (dis)similarity should not be affected by the ordering of items because the distance from Point A to B is equal to the distance from B to A. Contrary to this presumed symmetry, similarity is asymmetric on occasion (Tversky, 1977). In one of Tversky's

examples, North Korea is judged to be more similar to Red China than Red China is to North Korea. Often, a nonprominent item is more similar to a prominent item than vice versa. This is consistent with the result that people judge their friends to be more similar to themselves than they themselves are to their friends (Holyoak & Gordon, 1983), under the assumption that a person is highly prominent to him/herself. Polk et al. (2002) found that when the frequency of colors was experimentally manipulated, rare colors are judged to be more similar to common colors than common colors are to rare colors.

According to the triangle inequality assumption, the distance/dissimilarity between two points A and B cannot be more than the distance between A and a third point C plus the distance between C and B. Geometrically speaking, a straight line connecting two points is the shortest path between the points. Tversky and Gati (1982) find violations of this assumption when it is combined with an assumption of segmental additivity ($D(A,B) + D(B,C) = D(A,C)$) if A, B, and C lie on a straight line). Consider three items in multidimensional space, A, B, and C, falling on a straight line such that B is between A and C. Also consider a fourth point, E, that forms a right triangle when combined with A and C. The triangle inequality assumption *cum* segmental additivity predicts that

$$D(A,E) \geq D(A,B) \text{ and } D(E,C) \geq D(B,C)$$

or

$$D(A,E) \geq D(B,C) \text{ and } D(E,C) \geq D(A,B)$$

Systematic violations of this prediction are found such that the path going through the corner point E is shorter than the path going through the center point B. For example, if the items represented by their coordinates in the size-color of Figure 10.2 are instantiated as follows:

A= White, three inches

B= Pink, four inches

C= Red, five inches

E= Red, three inches

then people's dissimilarity ratings have empirically demonstrated violations of the triangle inequality such that $D(A,E) < D(A,B)$ and $D(E,C) < D(B,C)$ (Tversky & Gati, 1982). Such an effect can be modeled by geometric models of similarity if r in Eq. 1 is given a value less than 1. However, if r is less than one, then dissimilarity does not satisfy a power metric, often times considered a minimal assumption

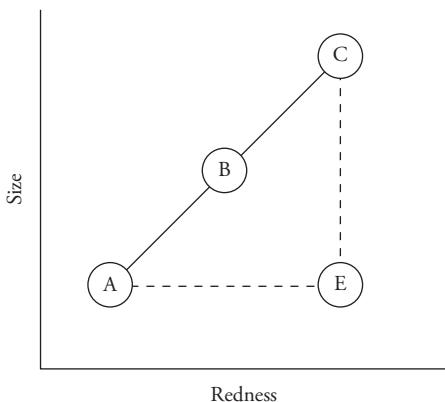

Fig. 10.2 The triangle inequality assumption requires the path from A to C going through B to be shorter than or equal to the path from A to C going through E.

for geometric solutions to be interpretable. The two assumptions of a power metric are (1) distances along straight lines are additive, and (2) the shortest path between points is a straight line.

Other potential problems with geometric models of similarity are (1) they strictly limit the number of nearest neighbors an item can have (Tversky & Hutchinson, 1986), (2) multidimensional scaling techniques have difficulty describing items that vary on a large number of features (Krumhansl, 1978), and (3) standard MDS techniques do not predict that adding common features to items increases their similarity (Tversky & Gati, 1982). On the first point: MDS models consisting of two dimensions cannot predict that item X is the closest item to 100 other items. There would be no way of placing those 100 items in two dimensions such that X is closer to all of them than any other item is. For human data, a superordinate term (e.g., fruit) is often the nearest neighbor of many of its exemplars (apples, bananas, etc.) as measured by similarity ratings. On the second point: Although there is no logical reason why geometric models cannot represent items of any number of dimensions (as long as the number of dimensions is less than number of items minus one), geometric models tend to yield the most satisfactory and interpretable solutions in low-dimensional space. MDS solutions involving more than six dimensions are rare. On the third point: The addition of the same feature to a pair of items increases their rated similarity (Gati & Tversky, 1984), but this is incompatible with simple MDS models. If adding a shared feature corresponds to adding a dimension in which the two items under consideration have the same value, then

there will be no change to the items' dissimilarity because the geometric distance between the points remains the same. MDS models that incorporate the dimensionality of the space could predict the influence of shared features on similarity, but such models would no longer relate similarity directly to an inverse function of interitem distance.

One research strategy has been to augment geometrical models of similarity in ways that solve these problems. One solution, suggested by Carol Krumhansl (1978), has been to model dissimilarity in terms of both interitem distance in a multidimensional space *and* spatial density in the neighborhoods of the compared items. The more items there are in the vicinity of an item, the greater is the spatial density of the item. Items are more dissimilar if they have many items surrounding them (their spatial density is high) than if they have few neighboring items. By including spatial density in an MDS analysis, violations of minimality, symmetry, and the triangle inequality can potentially be accounted for, as well as some of the influence of context on similarity. However, the empirical validity of the spatial density hypothesis is in some doubt (Corter, 1987, 1988; Krumhansl, 1988; Tversky & Gati, 1982).

Robert Nosofsky (1991) has suggested another potential way to save MDS models from some of the aforementioned criticisms. He introduces individual bias parameters in addition to the interitem relation term. Similarity is modeled in terms of interitem distance *and* in terms of biases toward particular items. Biases toward items may be due to attention, salience, knowledge, and frequency of items. This revision handles asymmetric similarity results and the result that a single item may be the most similar item to many other items, but it does not directly address several of the other objections.

THE CONTRAST MODEL

In light of the aforementioned potential problems for geometric representations, Tversky (1977) proposed to characterize similarity in terms of a feature-matching process based on weighting common and distinctive features. In this model, entities are represented as a collection of features and similarity is computed by

$$S(A,B) = \theta f(A \cap B) - \alpha f(A-B) - \beta f(B-A).$$

The similarity of A to B is expressed as a linear combination of the measure of the common and

distinctive features. The term $(A \cap B)$ represents the features that items A and B have in common. $(A - B)$ represents the features that A has but B does not. $(B - A)$ represents the features of B that are not in A. θ , α , and β are weights for the common and distinctive components. Common features, as compared to distinctive features, are given relatively more weight for verbal as opposed to pictorial stimuli (Gati & Tversky, 1984), for cohesive as opposed to noncohesive stimuli (Ritov, Gati, & Tversky, 1990), for similarity as opposed to difference judgments (Tversky, 1977), and for entities with a large number of distinctive as opposed to common features (Gati & Tversky, 1984). There are no restrictions on what may constitute a feature. A feature may be any property, characteristic, or aspect of a stimulus. Features may be concrete or abstract (i.e., "symmetric" or "beautiful").

The Contrast Model predicts asymmetric similarity because A is not constrained to equal B and $f(A - B)$ may not equal $f(B - A)$. North Korea is predicted to be more similar to Red China than vice versa if Red China has more salient distinctive features than North Korea, and A is greater than B. The Contrast Model can also account for nonmirroring between similarity and difference judgments. The common features term $(A \cap B)$ is hypothesized to receive more weight in similarity than difference judgments; the distinctive features terms receive relatively more weight in difference judgments. As

a result, certain pairs of stimuli may be perceived as simultaneously being more similar to and more different from each other, compared to other pairs (Tversky, 1977). Sixty-seven percent of a group of subjects selected West Germany and East Germany as more similar to each other than are Ceylon and Nepal. Seventy percent of subjects also selected West Germany and East Germany as more different from each other than are Ceylon and Nepal. According to Tversky, East and West Germany have more common and more distinctive features than Ceylon and Nepal. Medin, Goldstone, and Gentner (1993) present additional evidence for nonmirroring between similarity and difference, exemplified in Figure 10.3. When two scenes share a relatively large number of relational commonalities (e.g., Scenes T and B both have three objects that have the *same pattern*) but also a large number of differences on specific attributes (e.g., none of the patterns in Scene T match any of the patterns in B), then the scenes tend to be judged as simultaneously very similar and very different.

A number of models are similar to the Contrast model in basing similarity on features and in using some combination of the $(A \cap B)$, $(A - B)$, and $(B - A)$ components. Sjoberg (1972) proposes that similarity is defined as $f(A \cap B)/f(A \cup B)$. Eisler and Ekman (1959) claim that similarity is proportional to $f(A \cap B)/(f(A) + f(B))$. Bush and Mosteller (1951) defines similarity as $f(A \cap B)/f(A)$. These three models

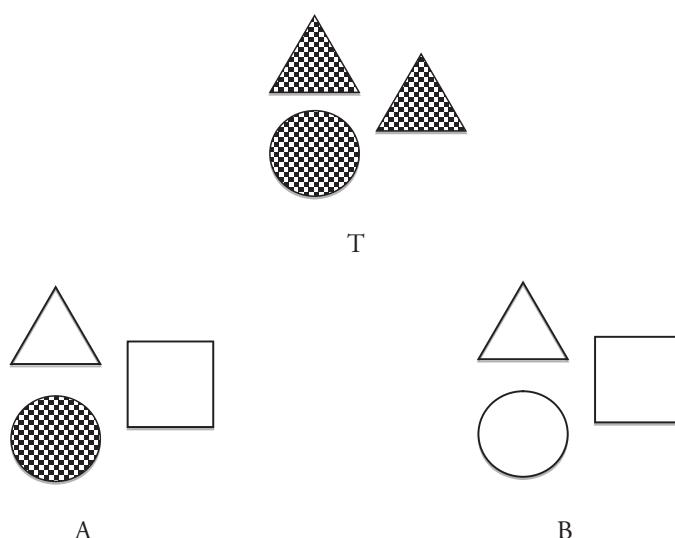

Fig. 10.3 The set of objects in B is selected as both more similar to, and more different from, the set of objects in T.

can all be considered specializations of the general equation $f(A \cap B) / [f(A \cap B) + \alpha f(A - B) + \beta f(B - A)]$. As such, they differ from the Contrast model by applying a ratio function as opposed to a linear contrast of common and distinctive features.

The fundamental premise of the Contrast Model, that entities can be described in terms of constituent features, is a powerful idea in cognitive psychology. Featural analyses have proliferated in domains of speech perception (Jakobson, Fant, & Halle, 1963), pattern recognition (Neisser, 1967; Treisman, 1986), perception physiology (Hubel & Wiesel, 1968), semantic content (Katz & Fodor, 1963), and categorization (Medin & Shaffer, 1978). Neural network representations are often based on features, with entities being broken down into a vector of ones and zeros, where each bit refers to a feature or “micro-feature.” Similarity plays a crucial role in many connectionist theories of generalization, concept formation, and learning. The notion of dissimilarity used in these systems is typically the fairly simple function “Hamming distance.” The Hamming distance between two strings is simply their city-block distance; that is, it is their $(A - B) + (B - A)$ term. “1 0 0 1 1” and “1 1 1 1 1” would have a Hamming distance of 2 because they differ on two bits. Occasionally, more sophisticated measures of similarity in neural networks normalize dissimilarities by string length. Normalized Hamming distance functions can be expressed by $[(A - B) + (B - A)] / [f(A \cap B)]$.

Considerable recent progress on featural models of similarity has involved the development of mathematical and computational efforts to automatically construct the features that, if posited, could account for the similarity relations observed between a large set of objects (Lee, 1998). For example, Bayesian methods have been proposed that can determine both the number of features (Navarro & Griffiths, 2008) or dimensions (Lee, 2001) underlying a set of objects, and their importance for determining similarity. One principle derived from Bayesian models of similarity (see Griffiths et al., Chapter 3) that has received empirical support is the “size principle,” according to which rare features, when shared by two objects, increase their similarity more than do common features (Navarro & Perfors, 2010).

SIMILARITIES BETWEEN GEOMETRIC AND FEATURE-BASED MODELS

While MDS and featural models are often analyzed in terms of their differences, they also share

a number of similarities. Recent progress has been made on combining both representations into a single model, using Bayesian statistics to determine whether a given source of variation is more efficiently represented as a feature or dimension (Navarro & Lee, 2003). Tversky and Gati (1982) described methods of translating continuous dimensions into featural representations. Dimensions that are sensibly described as being more or less (e.g., loud is more sound than soft, bright is more light than dim, and large is more size than small) can be represented by sequences of nested feature sets. That is, the features of B include a subset of A’s features whenever B is louder, brighter, or larger than A. Alternatively, for qualitative attributes like shape or hue (red is not subjectively “more” than blue), dimensions can be represented by chains of features such that if B is between A and C on the dimension, then $(A \cap B) \supset (A \cap C)$ and $(B \cap C) \supset (A \cap C)$. For example, if orange lies between red and yellow on the hue dimension, then this can be featurally represented if orange and red share features that orange and yellow do not share.

An important attribute of MDS models is that they create *postulated* representations, namely dimensions that explain the systematicities present in a set of similarity data. This is a classic use of abductive reasoning: Dimensional representations are hypothesized that, if they were to exist, would give rise to the obtained similarity data. Other computational techniques share with MDS the goal of discovering the underlying descriptions for items of interest but create featural rather than dimensional representations. Hierarchical cluster analysis, like MDS, takes pairwise proximity data as input. Rather than output a geometric space with objects as points, hierarchical cluster analysis outputs an inverted-tree diagram, with items at the root-level connected with branches. The smaller the branching distance between two items, the more similar they are. Just as the dimensional axes of MDS solutions are given subjective interpretations, the branches are also given interpretations. For example, in Shepard’s (1972) analysis of speech sounds, one branch is interpreted as voiced phonemes while another branch contains the unvoiced phonemes. In additive cluster analysis (Shepard & Arabie, 1979) similarity data is transformed into a set of overlapping item clusters. Items that are highly similar will tend to belong to the same clusters. Each cluster can be considered as a feature. Recent progress has been made on efficient and mathematically principled models that

find such featural representations for large databases (Lee, 2002a, 2002b; Tenenbaum, 1996).

One particularly useful application of abducing representations that can account for patterns of similarity has been the development of automated techniques for analyzing large corpora of text. A computational approach to word meaning that has received considerable recent attention has been to base word meanings solely on the patterns of co-occurrence between a large number of words in an extremely large text corpus (Burgess & Lund, 2000; Griffiths, Steyvers, & Tenenbaum, 2007; Landauer & Dumais, 1997). Mathematical techniques are used to create vector encodings of words that efficiently capture their co-occurrences. If two words, such as “cocoon” and “butterfly,” frequently co-occur in an encyclopedia or enter into similar patterns of co-occurrence with other words, then their vector representations will be highly similar. The meaning of a word, its vector in a high dimensional space, is completely based on the contextual similarity of words to other words. Within this high dimensional space, Landauer and Dumais (1997) conceive of similarity as the cosine of the angle between two words rather than their distance. With these new techniques, it is now possible to create geometric spaces or featural encodings with tens of thousands of words.

Another commonality between geometric and featural representations, one that motivates the next major class of similarity models that we consider, is that both use relatively unstructured representations. Entities are structured as sets of features or dimensions with no relations between these attributes. Entities such as stories, sentences, natural objects, words, scientific theories, landscapes, and faces are not simply a “grab bag” of attributes. Two

kinds of structure seem particularly important: propositional and hierarchical. A proposition is an assertion about the relation between informational entities (Palmer, 1975; see Markman, Chapter 4; Doumas & Hummel, Chapter 5). For example, relations in a visual domain might include *Above*, *Near*, *Right*, *Inside*, and *Larger-than* that take informational entities as arguments. The informational entities might include features such as square and values on dimensions such as 3 inches. Propositions are defined as the smallest unit of knowledge that can stand as a separate assertion and have a truth value. The order of the arguments in the predicate is critical. For example, *Above* (*Triangle*, *Circle*) does not represent the same fact as *Above* (*Circle*, *Triangle*). Hierarchical representations involve entities that are embedded in one another. Hierarchical representations are required to represent the fact that X is *part of* Y or that X is a *kind of* Y. For example, in Collins and Quillian’s (1969) propositional networks, labeled links (“Is-a” links) stand for the hierarchical relation between *Canary* and *Bird*.

Some quick fixes to geometric and featural accounts of similarity are possible, but they fall short of a truly general capacity to handle structured inputs. Hierarchical clustering does create trees of features, but there is no guarantee that there are relationships, such as Is-a or Part-of, between the subtrees. However, structure might exist in terms of features that represent conjunctions of properties. For example, using the materials in Figure 10.4, 20 undergraduates were shown triads consisting of A, B, and T, and were asked to say whether Scene A or B was more similar to T. The strong tendency to choose A over B in the first panel suggests that the feature “square” influences similarity. Other

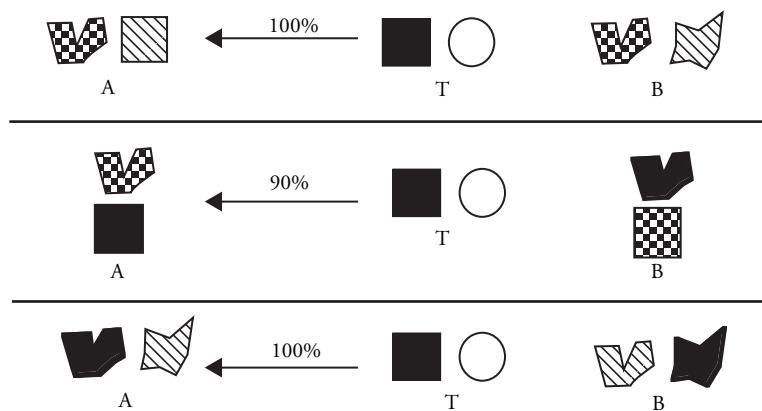

Fig. 10.4 The sets of objects T are typically judged to be more similar to the objects in the A sets than the B sets. These judgments show that people pay attention to more than just simple properties like “black” or “square” when comparing scenes.

choices indicated that subjects also based similarity judgments on the spatial locations and shadings of objects as well as their shapes.

However, it is not sufficient to represent the left-most object of T as {Left, Square, Black} and base similarity on the number of shared and distinctive features. In the second panel, A is again judged to be more similar to T than is B. Both A and B have the features “Black” and “Square.” The only difference is that for A and T, but not B, the “Black” and “Square” features belong to the same object. This judgment is only compatible with feature set representations if we include the possibility of *conjunctive features* in addition to *simple features* such as “Black” and “Square” (Gluck, 1991; Hayes-Roth & Hayes-Roth, 1977). By including the conjunctive feature “Black-Square,” possessed by both T and A, we can explain, using feature sets, why T is more similar to A than B. The third panel demonstrates the need for a “Black-Left” feature, and other data indicate a need for a “Square-Left” feature. Altogether, if we wish to explain the similarity judgments that people make, we need a feature set representation that includes six features (three simple and three complex) to represent the square of T.

However, there are two objects in T, bringing the total number of features required to at least two times the six features required for one object. The number of features required increases still further if we include feature-triplets such as “Left-Black-Square.” In general, if there are O objects in a scene, and each object has F features, then there will be OF simple features. There will be O conjunctive features that combine two simple features (i.e., *pairwise* conjunctive features). If we limit ourselves to simple and pairwise features to explain the pattern of similarity judgments in Figure 10.4, we still will require $OF(F+1)/2$ features per scene, or $OF(F+1)$ features for two scenes that are compared to one another.

Thus, featural approaches to similarity require a fairly large number of features to represent scenes that are organized into parts. Similar problems exist for dimensional accounts of similarity. The situation for these models becomes much worse when we consider that similarity is also influenced by relations between features, such as “Black to the left of white” and “square to the left of white.” Considering only binary relations, there are O^2F^2R -*OFF* relations within a scene that contains O objects, F features per object, and R different types of relations between features. Although more sophisticated objections have been raised about these approaches

by John Hummel and colleagues (Holyoak & Hummel, 2000; Hummel, 2000, 2001; Hummel & Biederman, 1992; Hummel & Holyoak, 1997, 2003; see Doumas & Hummel, Chapter 5), at the very least, geometric and featural models apparently require an implausibly large number of attributes to account for the similarity relations between structured, multipart scenes.

Alignment-Based Models

Partly in response to the difficulties that the previous models have in dealing with structured descriptions, a number of researchers have developed alignment-based models of similarity. In these models, comparison is not just matching features, but determining how elements correspond to, or align with, one another. Matching features are aligned to the extent that they play similar roles within their entities. For example, a car with a green wheel and a truck with a green hood both share the feature *green*, but this matching feature may not increase their similarity much because the car’s wheel does not correspond to the truck’s hood. Drawing inspiration from work on analogical reasoning (Gentner, 1983; Holyoak & Thagard, 1995; see also Holyoak, Chapter 13), in alignment-based models, matching features influence similarity more if they belong to parts that are placed in correspondence, and parts tend to be placed in correspondence if they have many features in common and are consistent with other emerging correspondences (Goldstone, 1994a; Markman & Gentner, 1993a). Alignment-based models make purely relational similarity possible (Falkenhainer, Forbus, & Gentner, 1989).

Initial evidence that similarity involves aligning scene descriptions was provided by Markman and Gentner (1993a), who found that when subjects are asked to determine corresponding objects, they tend to make more structurally sound choices when they have first judged the similarity of the scenes that contain the objects. For example, in Figure 10.5, subjects could be asked which object in the bottom set corresponds to the left-most object in the top set. Subjects who had rated the similarity of the sets were more likely to choose the right-most object, presumably because both objects were the smallest objects in their sets. Subjects who did not first assess similarity had a tendency to select the middle object, because its size exactly matched the target object’s size. These results are predicted if similarity judgments naturally entail aligning the elements of two scenes. Additional research has shown that relational choices

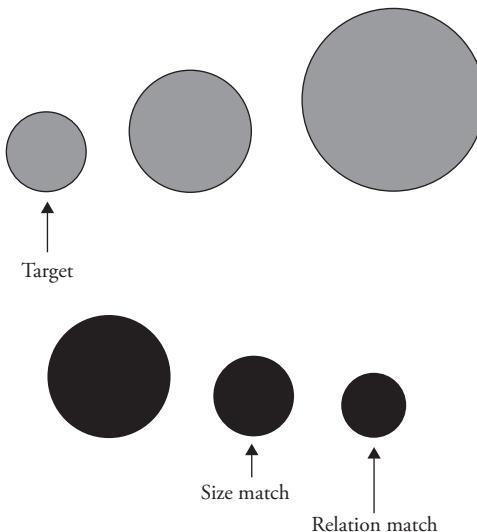

Fig. 10.5 The target from the gray circles could match either the middle black object because they are the same size or the right-most object because both objects are the smallest objects in their sets.

such as “smallest object in its set” tend to influence similarity judgments more than absolute attributes like “3 inches” when the overall amount of relational coherency across sets is high (Goldstone, Medin, & Gentner, 1991), the scenes are superficially sparse rather than rich (Gentner & Rattermann, 1991; Markman & Gentner, 1993a), subjects are given more time to make their judgments (Goldstone & Medin, 1994), the judges are adults rather than children (Gentner & Toupin, 1986), and abstract relations are initially correlated with concrete relations (Kotovsky & Gentner, 1996).

Formal models of alignment-based similarity have been developed to explain how feature matches that belong to well-aligned elements matter more for similarity than matches between poorly aligned elements (Goldstone, 1994a; Larkey & Love, 2003; Love, 2000). Inspired by work in analogical reasoning (Holyoak & Thagard, 1989), Goldstone’s (1994a) SIAM model is a neural network with nodes that represent hypotheses that elements across two scenes correspond to one another. SIAM works by first creating correspondences between the features of scenes. Once features begin to be placed into correspondence, SIAM begins to place objects into correspondence that are consistent with the feature correspondences. Once objects begin to be put into correspondence, activation is fed back down to the feature (mis)matches that are

consistent with the object alignments. In this way, object correspondences influence activation of feature correspondences at the same time that feature correspondences influence the activation of object correspondences. Activation between nodes spreads in SIAM by two principles: (1) nodes that are consistent send excitatory activation to each other and (2) nodes that are inconsistent inhibit each other (see also Holyoak, Chapter 13). Nodes are inconsistent if they create two-to-one alignments—if two elements from one scene would be placed into correspondence with one element of the other scene. Node activations affect similarity via the equation

$$\text{similarity} = \frac{\sum_{i=1}^n (\text{match value}_i * A_i)}{\sum_{i=1}^n A_i},$$

where n is the number of nodes in the system, A_i is the activation of node i , and the match value describes the physical similarity between the two features placed in correspondence according to the node i . By the equation, the influence of a particular matching or mismatching feature across two scenes is modulated by the degree to which the features have been placed in alignment. Consistent with SIAM, (1) aligned feature matches tend to increase similarity more than unaligned feature matches (Goldstone, 1994a), (2) the differential influence between aligned and unaligned feature matches increases as a function of processing time (Goldstone & Medin, 1994), (3) this same differential influences increases with the clarity of the alignments (Goldstone, 1994a), and (4) under some circumstances, adding a poorly aligned feature match can actually decrease similarity by interfering with the development of proper alignments (Goldstone, 1996). Direct tests of SIAM against other models of structural similarity have found advantages for SIAM in that it appropriately weights aligned feature matches more than unaligned feature matches, particularly if the unaligned feature matches are competing against aligned matches (Larkey & Markman, 2005).

Another empirically validated set of predictions stemming from an alignment-based approach to similarity concerns alignable and nonalignable differences (Markman & Gentner, 1993b). Nonalignable differences between two entities are attributes of one entity that have no corresponding attribute in the other entity. Alignable differences are differences

that require that the elements of the entities first be placed in correspondence. When comparing a police car to an ambulance, a nonalignable difference is that police cars have weapons in them, but ambulances do not. There is no clear equivalent of weapons in the ambulance. Alignable differences include the following: Police cars carry criminals to jails rather than carrying sick people to hospitals, a police car is a car while ambulances are vans, and police car drivers are policemen rather than emergency medical technicians. Consistent with the role of structural alignment in similarity comparisons, alignable differences influence similarity more than nonalignable differences do (Markman & Gentner, 1996), and they are more likely to be encoded into memory (Markman & Gentner, 1997). Alignable differences between objects also play a disproportionately large role in distinguishing between different basic-level categories (e.g., cats and dogs) that belong to the same superordinate category (e.g., animals) (Markman & Wisniewski, 1997). In short, knowing these correspondences affects not only how much a matching element increases similarity (Goldstone, 1994a) but also how much a mismatching element decreases similarity.

Thus far, much of the evidence for structural alignment in similarity has used somewhat artificial materials. Often times, the systems describe how “scenes” are compared, with the underlying implication that the elements comprising the scenes are not so tightly connected together as elements comprising objects. Still, if the structural alignment account proves to be fertile, it will be because it is applicable to naturally occurring materials. Toward this goal, researchers have considered structural accounts of similarity in language domains. The confusability of words depends on structural analyses to predict that “stop” is more confusable with “step” than “pest” (the “st” match is in the correct location with “step” but not “pest”), but more confusable with “pest” than “best” (the “p” match counts for something even when it is out of place). Substantial success has been made on the practical problem of determining the structural similarity of words (Bernstein, Demorest, & Eberhardt, 1994; Frisch, Broe, & Pierrehumbert, 1995). Structural alignment has also been implicated when comparing more complex language structures such as sentences (Bassok & Medin, 1997). Likewise, structural similarity has proven to be a useful notion in explaining consumer preferences of commercial products, explaining, for example, why new products are viewed more

favorably when they improve over existing products along alignable rather than unalignable differences (Zhang & Markman, 1998). Additional research has shown that alignment-based models of similarity provide a better account of category-based induction than feature-based models (Lassaline, 1996). Still other researchers have applied structural accounts of similarity to the legal domain (Hahn & Chater, 1998; Simon & Holyoak, 2002; see also Spellman & Schauer, Chapter 36). This area of application is promising because the U.S. legal system is based on cases and precedents, and cases are structurally rich and complex situations involving many interrelated parties. Retrieving a historical precedent, and assessing its relevance to a current case, almost certainly involves aligning representations that are more sophisticated than assumed by geometric or featural models.

Transformational Models

A final historic approach to similarity that has been recently resuscitated is that the comparison process proceeds by transforming one representation into the other. A critical step for these models is to specify what transformational operations are possible.

In an early incarnation of a transformational approach to cognition broadly construed, Garner (1974) stressed the notion of stimuli that are transformationally equivalent and are consequently possible alternatives for each other. In artificial intelligence, Shimon Ullman (1996) has argued that objects are recognized by being aligned with memorized pictorial descriptions. Once an unknown object has been aligned with all candidate models, the best match to the viewed object is selected. The alignment operations rotate, scale, translate, and topographically warp object descriptions. For rigid transformations, full alignment can be obtained by aligning three points on the object with three points on the model description. Unlike recognition strategies that require structural descriptions (e.g., Biederman, 1987; Hummel, 2000, 2001), Ullman’s alignment does not require an image to be decomposed into parts.

In transformational accounts that are explicitly designed to model similarity data, similarity is usually defined in terms of transformational distance. In Wiener-Ehrlich, Bart, and Millward’s (1980) generative representation system, subjects are assumed to possess an elementary set of transformations and to invoke these transformations when analyzing

stimuli. Their subjects saw linear pairs of stimuli such as {ABCD,DABC} or two-dimensional stimuli such as $\left\{ \begin{smallmatrix} AB, DA \\ CD, BC \end{smallmatrix} \right\}$. Subjects were required to rate the similarity of the pairs. The researchers determined transformations that accounted for each subject's ratings from the set {rotate 90 degrees, rotate 180, rotate 270, horizontal reflection, vertical reflection, positive diagonal reflection, negative diagonal reflection}. Similarity was assumed to decrease monotonically as the number of transformations required to make one sequence identical to the other increased.

Imai (1977) made a similar claim. The stimuli used were sequences such as XXOOXXXOXXXXOX where X's represent white ovals, and O's represent black ovals. The four basic transformations were mirror image (XXXXXOO->OOXXXX), phase shift (XXXXXOO->XXXXOOX), reversal (XXXXXOO->OOOOOXX), and wave length (XXOOXXOO->XOXOXOXO). The researcher found that sequences that are two transformations removed (e.g., XXXOXXXOXXXXO and OOXOOOXOOOXO require a phase shift and a reversal to be equated) are rated to be less similar than sequences that can be made identical with one transformation. In addition, sequences that can be made identical by more than one transformation (e.g., XOXOXOXO and OXOXOXOX can be made identical by either mirror image, phase shift, or reversal transformations) are more similar than sequences that have only one identity-producing transformation.

Recent work has followed up on Imai's research and has generalized it to stimulus materials, including arrangements of Lego bricks, geometric complexes, and sets of colored circles (Hahn, Chater, & Richardson, 2003). These researchers have argued that the similarity between two entities is a function of the complexity required to transform the representation of one into the representation of the other. The simpler the transformation, the more similar they are assumed to be. The complexity of a transformation is determined in accord with Kolmogorov complexity theory (Li & Vitanyi, 1997), according to which the complexity of a representation is the length of the shortest computer program that can generate that representation. For example, the conditional Kolmogorov complexity between the sequence 1 2 3 4 5 6 7 8 and 2 3 4 5 6 7 8 9 is small, because the simple instructions that add 1 to each digit (or subtract 1 from each digit) suffice to transform one into the other. Experiments by Hahn

et al. demonstrate that once reasonable vocabularies of transformations are postulated, transformational complexity does indeed predict subjective similarity ratings.

The transformational approach to similarity generally predicts that the similarity of A to B increases as operators become available that can efficiently transform A into B. One interesting empirical prediction from this prediction is that asymmetric similarity judgments may occur if transforming A into B is easier than transforming B into A. Specifically, when participants rated how similar a comparison object was to a reference object, their ratings were higher when the reference object came before, rather than after, the comparison object in a preceding morph sequence animation (Hahn, Close, & Graf, 2009). Transformational models can also account for the pattern of similarity ratings for scenes like that shown in Figure 10.4, if they are given transformational operators such as "delete object," "swap objects," and "move A's texture to B" (Hodgetts, Hahn, & Chater, 2009).

It is useful to compare and contrast alignment-based and transformational accounts of similarity, given that both can account for similarities involving structured scenes like those shown in Figure 10.4. Both approaches place scene elements into correspondence. Whereas the correspondences are explicitly stated in the structural alignment method, they are implicit in transformational alignment. The transformational account often *does* produce globally consistent correspondences, for example correspondences that obey the one-to-one mapping principle, but this consistency is a consequent of applying a pattern-wide transformation and is not enforced by interactions between emerging correspondences. It is revealing that transformational accounts have been applied almost exclusively to perceptual stimuli, whereas structural accounts are often most often applied to conceptual stimuli such as stories, proverbs, and scientific theories (there are also notable structural accounts in perception; e.g., Biederman, 1987; Hummel, 2000; Hummel & Biederman, 1992; Marr & Nishihara, 1978). Defining a set of constrained transformations is much easier for perceptual stimuli. The conceptual similarity between an atom and the solar system could possibly be discovered by transformations. As a start, a miniaturization transformation could be applied to the solar system. However, this single transformation is not nearly sufficient; a nucleus is not simply a small sun. The transformations that would turn the solar system

into an atom are not readily forthcoming. If we allow transformations such as an “earth-becomes-electron” transformation, then we are simply reexpressing the structural alignment approach and its part-by-part alignment of relations and objects.

Some similarity phenomena that are well explained by structural alignment are not easily handled by transformations. To account for the similarity of “BCDCB” and “ABCDCBA,” we could introduce the fairly abstract transformation “Add the left-most letter’s predecessor to both sides of string.” However, the pair “LMN” and “KLMNK” do not seem as similar as the earlier pair, even though the same transformation is applied. A transformation of the form “If the structure is symmetric, then add the preceding element in the series to both ends of the string” presupposes exactly the kind of analysis in defining “symmetric” and “preceding” that are the bread and butter of propositional representations and structural alignment. For this reason, one fertile research direction would be to combine the focus of alignment-based accounts on representing the internal structure within individual scenes with the constraints that transformational accounts provide for establishing psychologically plausible transformations (Hofstadter, 1997; Mitchell, 1993).

Conclusions

A meta-observation about the four models of similarity described earlier is that researchers tend to consider, or in many cases create, entities to be compared that are compatible with their proposed model. Researchers considering dimensional models of similarity tend to choose stimuli that are aptly described in terms of continuous, independent dimensions. Researchers proposing featural models often choose stimuli that have discrete features that either present or absent. Neither researcher tends to choose the richly structured stories or scenes that attract the alignment-based modeler. Researchers proposing transformational accounts often times select stimuli that have easily articulated transformations that can be applied to them. Cases in which a researcher proposing one model is able to accommodate the stimuli used by another modeling tradition are impressive but rare (Hodgetts et al., 2009). In fact, stimulus sets that are well accommodated by, for example, featural models such as additive clustering, are often times poorly accommodated by dimensional approaches such as multidimensional scaling, and vice versa.

Given this situation, ecumenical pluralism is a good strategy. The savvy researcher is well advised

to be proficient with a number of modeling techniques. While the search for a unified model of similarity is tempting and justified by Occam’s razor, it is likely that different kinds of entities are represented differently, and hence enter into similarity comparisons in different ways.

Future Directions

To provide a partial balance to our largely historical focus on similarity, we will conclude by raising some unanswered questions for the field. These questions are rooted in a desire to connect the study of similarity to cognition as a whole.

Is Similarity Flexible Enough to Provide Useful Explanations of Cognition?

The study of similarity is typically justified by the argument that so many theories in cognition depend upon similarity as a theoretical construct. An account of what makes problems, memories, objects, and words similar to one another often provides the backbone for our theories of problem solving, attention, perception, and cognition. As William James put it, “This sense of Sameness is the very keel and backbone of our thinking” (James, 1890/1950, p. 459).

However, others have argued that similarity is not flexible enough to provide a sufficient account, although it may be a necessary component. There have been many empirical demonstrations of apparent dissociations between similarity and other cognitive processes, most notably categorization. Researchers have argued that cognition is frequently based on theories (Murphy & Medin, 1985), rules (Sloman, 1996; Smith & Sloman, 1994), or strategies that go beyond “mere” similarity. To take an example from Murphy and Medin (1985), consider a man jumping into a swimming pool fully clothed. This man may be categorized as drunk because we have a theory of behavior and inebriation that explains the man’s action. Murphy and Medin argue that the categorization of the man’s behavior does not depend on matching the man’s features to the category *drunk*’s features. It is highly unlikely that the category *drunk* would have such a specific feature as “jumps into pools fully clothed.” It is not the similarity between the instance and the category that determines the instance’s classification; it is the fact that our category provides a theory that explains the behavior.

Developmental psychologists have argued that even young children have inchoate theories that allow them to go beyond superficial similarities

in creating categories (Carey, 1985; Gelman & Markman, 1986; Keil, 1989; see Gelman & Frazier, Chapter 26). For example, Carey (1985) observed that children choose a toy monkey over a worm as being more similar to a human; but that when they are told that humans have spleens, children are more likely to infer that the worm has a spleen than that the toy monkey does. Thus, the categorization of objects into “spleen” and “no spleen” groups does not appear to depend on the same knowledge that guides similarity judgments. Adults show similar dissociations between similarity and categorization. In an experiment by Rips (1989), an animal that is transformed (by toxic waste) from a bird into something that looks like an insect is judged by subjects to be more similar to an insect, but it is still judged to *be* a bird. Again, the category judgment seems to depend on biological, genetic, and historical knowledge, while the similarity judgments seem to depend more on gross visual appearance (see also Keil, 1989; Rips & Collins, 1993; Rips et al., Chapter 11).

Despite the growing body of evidence that similarity appraisals do not always track categorization decisions, there are still some reasons to be sanguine about the continued explanatory relevance of similarity. Categorization itself may not be completely flexible. People are influenced by similarity despite the subjects’ intentions and the experimenters’ instructions (Smith & Sloman, 1994). Allen and Brooks (1991) gave subjects an easy rule for categorizing cartoon animals into two groups. Subjects were then transferred to the animals that looked very similar to one of the training stimuli but belonged in a different category. These animals were categorized more slowly and less accurately than animals that were equally similar to an old animal but also belonged in the same category as the old animal. Likewise, Palmeri (1997) showed that even for the simple task of counting the number of dots, subjects’ performance is improved when a pattern of dots is similar to a previously seen pattern with the same numerosity and worse when the pattern is similar to a previously seen pattern with different numerosity. People seem to have difficulties ignoring similarities between old and new patterns, even when they know a straightforward and perfectly accurate categorization rule.

There may be a mandatory consideration of similarity in many categorization judgments (Goldstone, 1994b), adding constraints to categorization. At the same time, similarity may be more flexible and sophisticated than commonly acknowledged (Jones & Smith, 1993), bridging the gap between

similarity and high-level cognition. Krumhansl (1978) argued that similarity between objects decreases when they are surrounded by many close neighbors that were also presented on previous trials (also see Wedell, 1994). Tversky (1977) obtained evidence for an *extension effect*, according to which features influence similarity judgments more when they vary within an entire set of stimuli. Items presented within a particular trial also influence similarity judgments. Perhaps the most famous example of this is Tversky’s (1977) *Diagnosticity effect*, according to which features that are diagnostic for relevant classifications will have disproportionate influence on similarity judgments. More recently, Medin, Goldstone, and Gentner (1993) have argued that different comparison standards are created depending on the items that are present on a particular trial. Other research has documented intransitivities in similarity judgments, situations where A is judged to be more similar to T than is B, B is more similar to T than is C, and C is more similar to T than is A (Goldstone, Medin, & Halberstadt, 1997). This type of finding also suggests that the properties used to assess the similarity of objects are determined, in part, by the compared objects themselves.

Similarity judgments not only depend on the context established by recently exposed items, simultaneously presented items, and inferred contrast sets but also on the observer. Suzuki, Ohnishi, and Shigemasu (1992) have shown that similarity judgments depend on level of expertise and goals. Expert and novice subjects were asked to solve the Tower of Hanoi puzzle and judge the similarity between the goal and various states. Experts’ similarity ratings were based on the number of moves required to transform one position to the other. Less expert subjects tended to base their judgments on the number of shared superficial features. Similarly, Hardiman, Dufresne, and Mestre (1989) found that expert and novice physicists evaluate the similarity of physics problems differently, with experts basing similarity judgments more on general principles of physics than on superficial features (see Sjoberg, 1972 for other expert/novice differences in similarity ratings). The dependency of similarity on observer-, task-, and stimulus-defined contexts offers the promise that it is indeed flexible enough to subserve cognition.

Is Similarity Too Flexible to Provide Useful Explanations of Cognition?

As a response to the skeptic of similarity’s usefulness, the preceding two paragraphs could have the

exact opposite of their intended effect. The skeptic might now feel that similarity is much *too* flexible to be a stable ground for cognition. In fact, Nelson Goodman (1972) has put forth exactly this claim, maintaining that the notion of similarity is either vague or unnecessary. He argued that “when to the statement that two things are similar we add a specification of the property that they have in common...we render it [the similarity statement] superfluous” (p. 445). That is, all of the potential explanatory work is done by the “with respect to property Z” clause and not by the similarity statement. Instead of saying, “This object belongs to Category A because it is similar to A items with respect to the property ‘red,’ “ we can simplify matters by removing any notion of similarity with “This object belongs to Category A because it is red.”

There are reasons to resist Goodman’s conclusion that “Similarity tends under analysis either to vanish entirely or to require for its explanation just what it purports to explain” (p. 446). In most cases, similarity is useful precisely because we cannot flesh out the “respect to property Z” clause with just a single property. Evidence suggests that assessments of overall similarity are natural and perhaps even “primitive.” Evidence from children’s perception of similarity suggests that children are particularly likely to judge similarity on the basis of many integrated properties rather than analysis into dimensions. Even dimensions that are perceptually separable are treated as fused in similarity judgments (Smith & Kemler, 1978). Children under 5 years of age tend to classify on the basis of overall similarity and not on the basis of a single criterial attribute (Keil, 1989; Smith, 1989). Children often have great difficulty identifying the dimension along which two objects vary, even though they can easily identify that the objects are different in some way (Kemler, 1983). Smith (1989) argued that it is relatively difficult for young children to say whether two objects are identical on a particular property, but relatively easy for them to say whether they are similar across many dimensions.

There is also evidence that adults often have an overall impression of similarity without analysis into specific properties. Ward (1983) found that adult subjects who tended to group objects quickly also tended to group objects like children, by considering overall similarity across all dimensions instead of maximal similarity on one dimension. Likewise, Smith and Kemler (1984) found that adults who were given a distracting task produced more

judgments by overall similarity than subjects who were not. To the extent that similarity is determined by many properties, it is less subject to drastic context-driven changes. Furthermore, integrating multiple sources of information into a single assessment of similarity becomes particularly important. The four approaches to similarity described in the previous section all provide methods for integrating multiple properties into a single similarity judgment, and as such, they go significantly beyond simply determining a single “property Z” to attend to.

A final point to make about the potential overflexibility of similarity is that although impressions of similarity can change with context and experience, automatic and “generic” assessments of similarity typically change slowly and with considerable inertia. Similarities that were once effortful and strategic become second nature to the organism. Roughly speaking, this is the process of *perceiving* what was once a *conceptual* similarity. At first, the novice mycologist explicitly uses rules for perceiving the dissimilarity between the pleasing Agaricus Bisporus mushroom and the deadly Amanita Phalloides. With time, this dissimilarity ceases to be effortful and rule based, and becomes perceptual and phenomenologically direct. When this occurs, the similarity becomes generic and default, and it can be used as the ground for new strategic similarities. In this way, our cognitive abilities gradually attain sophistication, treating territory as level ground that once made for difficult mental climbing. A corollary of this contention is that our default impression of similarity does not typically mislead us; it is explicitly *designed* to lead us to see relations between things that often function similarly in our world. People, with good reason, expect their default similarity assessments to provide good clues about where to uncover directed, nonapparent similarities (Medin & Ortony, 1989).

Should “Similarity” Even Be a Field of Study Within Cognitive Science?

This survey has proceeded under the convenient fiction that it is possible to tell a general story for how people compare things. One reason to doubt this assumption is that the methods used for assessing similarity have large effects on the resulting similarity viewed. Similarity as measured by ratings is not equivalent to similarity as measured by perceptual discriminability. Although these measures correlate highly, systematic differences are found (Podgorny & Garner, 1979; Sergent & Takane, 1987). For

example, Beck (1966) found that an upright T is rated as more similar to a tilted T than an upright L, but that it is also more likely to be perceptually grouped with the upright L's. Previously reviewed experiments indicate the nonequivalence of assessments that use similarity versus dissimilarity ratings, categorization versus forced-choice similarity judgments, or speeded versus leisurely judgments. In everyday discourse we talk about the similarity of two things, forgetting that this assessment depends upon a particular task and circumstance.

Furthermore, it may turn out that the calculation of similarity is fundamentally different for different domains (see Medin, Lynch, & Solomon, 2000, for a thoughtful discussion of this issue). To know how to calculate the similarity of two faces, one would need to study faces specifically, and the eventual account need not inform researchers interested in the similarity of words, works of music, or trees. A possible conclusion is that similarity is not a coherent notion at all. The term *similarity*, like the terms *bug* or *family values*, may not pick out a consolidated or principled set of things.

Although we sympathize with the impulse toward domain-specific accounts of similarity, we also believe in the value of studying general principles of comparison that potentially underlie many domains. Although we do not know whether general principles exist, one justification for pursuing them is the large payoff that would result from discovering these principles if they *do* exist. A historically fruitful strategy, exemplified by Einstein's search for a law to unify gravitational and electromagnetic acceleration, and Darwin's search for a unified law to understand the origins of humans and other animals, has been to understand differences as parametric variations within a single model. Finding differences across tasks does not necessarily indicate the incoherency of similarity. An alternative perspective would use these task differences as an illuminating source of information in developing a unified account. The systematic nature of these task differences should stimulate accounts that include a formal description not only of stimulus components but also of task components. Future success in understanding the task of comparison may depend on comparing tasks.

Concepts and Categories: Memory, Meaning, and Metaphysics

Lance J. Rips, Edward E. Smith, and Douglas L. Medin

Abstract

The psychological study of concepts has two main goals: explaining how people's knowledge of categories such as tables or cats enables them to classify or recognize members of those categories, and explaining how knowledge of word meanings (e.g., the meaning of *table* and *cat*) enables people to make inferences and to compute the meanings of phrases and sentences. We review current theories and data relevant to these two functions of concepts, including recent insights from cognitive neuropsychology. Both kinds of theories have evolved in ways that suggest that people make use of mental representations at several levels of complexity, from sparse, atomic concepts to complex, knowledge-intensive ones. We examine the implications of this variety for issues including psychological essentialism and domain specificity.

Key Words: concepts, categories, semantics, prototypes, exemplars, generics, polysemy, essentialism, sortals, folk biology

Introduction

The concept of concepts is difficult to define, but no one doubts that concepts are fundamental to mental life and human communication. Cognitive scientists generally agree that a concept is a mental representation. Theories in psychology have concentrated on concepts that pick out certain sets of entities: categories. That is, concepts *refer*, and what they refer to are categories. It is also commonly assumed that category membership is not arbitrary but rather a principled matter. What goes into a category belongs there by virtue of some law-like regularities. But beyond these sparse facts, the concept CONCEPT is up for grabs. As an example, suppose you have the concept TRIANGLE represented as "a closed geometric form having three sides." In this case, the concept is a definition. But it is unclear what else might be in your triangle concept. Does it include the fact that geometry books discuss them (though some don't) or that they have 180 degrees (though in hyperbolic geometry none do)? It is also

unclear how many concepts have definitions or what substitutes for definitions in ones that don't.

Our goal in this chapter is to provide an overview of work on concepts and categories in the last half century. There has been such a consistent stream of research over this period that one critic of this literature, Gregory Murphy (2002), felt compelled to call his monograph, *The Big Book of Concepts*. Our task is eased by recent reviews, including Murphy's aptly named one (e.g., Medin, Lynch & Solomon, 2000; Murphy, 2002; Rips, 2001; Wisniewski, 2002). Their thoroughness gives us the luxury of doing a review focused on a single perspective—the relations among concepts, memory, and meaning.

The remainder of this chapter is organized as follows. In the rest of this section, we briefly describe some of the tasks or functions that cognitive scientists have expected concepts to perform. This will provide a roadmap to important lines of research on concepts and categories. Next, we return to developments in the late 1960s and early 1970s that raised

the exciting possibility that laboratory studies could provide deep insights into both concept representations and the organization of (semantic) memory. Then we describe the sudden collapse of this optimism and the ensuing lines of research that, however intriguing and important, ignored questions about semantic memory. Next we trace a number of relatively recent developments under the somewhat whimsical heading “Psychometaphysics.” This is the view that concepts are embedded in (perhaps domain-specific) theories. This will set the stage for returning to the question of whether research on concepts and categories is relevant to semantics and memory organization. We will use that question to speculate about future developments in the field. In this review, we will follow the usual conventions of using words in all caps to refer to concepts and quoted words to refer to linguistic expressions.

Functions of Concepts

For purposes of this review, we will collapse the many ways people can use concepts into two broad functions: categorization and communication. The conceptual function that most research has targeted is *categorization*, the process by which mental representations (concepts) determine whether some entity is a member of a category. Categorization enables a wide variety of subordinate functions because classifying something as a category member allows people to bring their knowledge of the category to bear on the new instance. Once people categorize some novel entity, they can use relevant knowledge for *understanding* and *prediction*. Recognizing a cylindrical object as a flashlight allows you to understand its parts, trace its functions, and predict its behavior. For example, you can confidently infer that the flashlight will have one or more batteries, will have some sort of switch, and will normally produce a beam of light when the switch is pressed.

Not only do people categorize in order to understand new entities, they also use the new entities to modify and update their concepts. In other words, categorization supports *learning*. Encountering a member of a category with a novel property—for example, a flashlight that has a siren for emergencies—can result in that novel property being incorporated into the conceptual representation. Relations between categories may also support inference and learning. For example, finding out that flashlights can contain sirens may lead you to entertain the idea that cell phones and fire extinguishers might also contain sirens. Hierarchical

conceptual relations support both inductive and deductive *reasoning*. If you know all trees contain xylem and hawthorns are trees, then you can deduce that hawthorns contain xylem. In addition, finding out that white oaks contain phloem provides some support for the inductive inference that other kinds of oaks contain phloem. People also use categories to instantiate goals in *planning* (Barsalou, 1983). For example, a person planning to do some night fishing might create an ad hoc concept, THINGS TO BRING ON A NIGHT FISHING TRIP, which would include a fishing rod, tackle box, mosquito repellent, and a flashlight.

Concepts are also centrally involved in *communication*. Many of our concepts correspond to lexical entries, such as the English word “flashlight.” In order for people to avoid misunderstandings, they must have comparable concepts in mind. If A’s concept of cell phone corresponds with B’s concept of flashlight, it won’t go well if A asks B to make a call. An important part of the function of concepts in communication is their ability to combine in order to create an unlimited number of new concepts. Nearly every sentence you encounter is new—one you’ve never heard or read before—and concepts (along with the sentence’s grammar) must support your ability to understand it. Concepts are also responsible for more creative uses of language. For example, from the base concepts of TROUT and FLASHLIGHT, you might create a new concept, TROUT FLASHLIGHT, which in the context of our current discussion would presumably be a flashlight used when trying to catch trout (and not a flashlight with a picture of a trout on it, though this may be the correct interpretation in some other context). A major research challenge is to understand the principles of *conceptual combination* and how they relate to communicative contexts (see Fodor, 1994, 1998; Gleitman & Papafragou, Chapter 28; Hampton, 1997; Partee, 1995; Rips, 1995; Wisniewski, 1997).

Overview

So far, we have introduced two roles for concepts: categorization (broadly construed) and communication. These functions and associated subfunctions are important to bear in mind because studying any one in isolation can lead to misleading conclusions about conceptual structure (see Solomon, Medin, & Lynch, 1999, for a review bearing on this point). At this juncture, however, we need to introduce one more plot element into the story we are telling. Presumably everything we have been talking about has implications for

human memory and memory organization. After all, concepts are mental representations, and people must store these representations somewhere in memory. However, the relation between concepts and memory may be more intimate. A key part of our story is what we call “the semantic memory marriage,” the idea that memory organization corresponds to meaningful relations between concepts. Mental pathways that lead from one concept to another—for example, from ELBOW to ARM—represent relations like IS A PART OF that link the same concepts. Moreover, these memory relations may supply the concepts with all or part of their meaning. By studying how people use concepts in categorizing and reasoning, researchers could simultaneously explore memory structure and the structure of the mental lexicon. In other words, the idea behind this move was to unify categorization, communication (in its semantic aspects), and memory organization. As we’ll see, this marriage was somewhat troubled, and there are many rumors about its breakup. But we are getting ahead of our story. The next section begins with the initial romance.

A Mini-History

Research on concepts in the middle of the last century reflected a gradual easing away from behaviorist and associative learning traditions. The focus, however, remained on learning. Most of this research was conducted in laboratories using artificial categories (a sample category might be any geometric figure that is both red and striped) and directed at one of two questions: (a) Are concepts learned by gradual increases in associative strength, or is learning all or none (Levine, 1971; Trabasso & Bower, 1968)? and (b) Which kinds of rules or concepts (e.g., disjunctive, such as RED OR STRIPED, versus conjunctive, such as RED AND STRIPED) are easiest to learn (Bruner, Goodnow, & Austin, 1956; Bourne, 1970; Restle, 1962)?

This early work tended either to ignore real-world concepts (Bruner et al., 1956, represent something of an exception here) or to assume implicitly that real-world concepts are structured according to the same kinds of rules that defined the artificial ones. According to this tradition, category learning is equivalent to identifying the definitions that determine category membership.

Early Theories of Semantic Memory

Although the work on rule learning set the stage for what was to follow, two developments associated

with the emergence of cognitive psychology dramatically changed how people thought about concepts.

TURNING POINT I: MODELS OF MEMORY ORGANIZATION

The idea of programming computers to do intelligent things (artificial intelligence or AI) had an important influence on the development of new approaches to concepts. Quillian (1967) proposed a hierarchical model for storing semantic information in a computer that was quickly evaluated as a candidate model for the structure of human memory (Collins & Quillian, 1969). Figure 11.1 provides an illustration of part of a memory hierarchy that is similar to what the Quillian model suggests.

First, note that the network follows a principle of cognitive economy. Properties true of all animals, like eating and breathing, are stored only with the animal concept. Similarly, properties that are generally true of birds are stored at the bird node, but properties distinctive to individual kinds (e.g., being yellow) are stored with the specific concept nodes they characterize (e.g., CANARY). A property does not have to be true of all subordinate concepts to be stored with a superordinate. This is illustrated in Figure 11.1, where CAN FLY is associated with the bird node; the few exceptions (e.g., flightlessness for ostriches) are stored with particular birds that do not fly. Second, note that category membership is defined in terms of positions in the hierarchical network. For example, the node for CANARY does not directly store the information that canaries are animals; instead, membership would be “computed” by moving from the canary node up to the bird node and then from the bird node to the animal node. It is as if the network presupposes a deductive argument of the form, “All canaries are birds and all birds are animals and therefore all canaries are animals.”

Although these assumptions about cognitive economy and traversing a hierarchical structure may seem speculative, they yield a number of testable predictions. Assuming that traversal takes time, one would predict that the time needed for people to verify properties of concepts should increase with the network distance between the concept and the property. For example, people should be faster to verify that a canary is yellow than to verify that a canary has feathers and faster to determine that a canary can fly than that a canary has skin. Collins and Quillian found general support for these predictions.

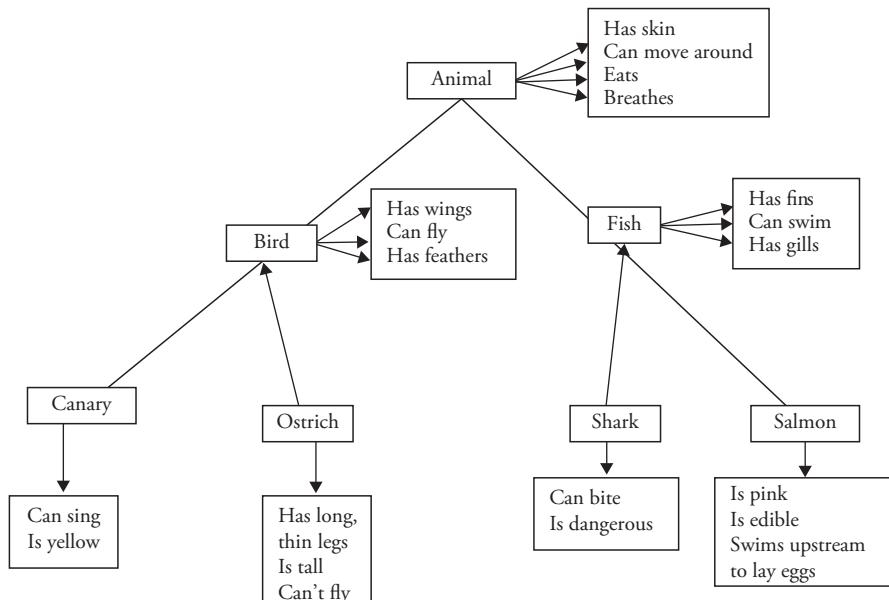

Fig. 11.1 A semantic network after Collins and Quillian (1969).

TURNING POINT 2: NATURAL CONCEPTS AND FAMILY RESEMBLANCE

The work on rule learning suggested that children (and adults) might learn concepts by trying out hypotheses until they hit on the correct definition. In the early 1970s, however, Eleanor Rosch and her associates (e.g., Rosch, 1973; Rosch & Mervis, 1975) argued that most everyday concepts are not organized in terms of the sorts of necessary and sufficient features that would form a (conjunctive) definition for a category. Instead, such concepts depend on properties that are generally true but need not hold for every member. Rosch's proposal was that concepts have a "family-resemblance" structure: What determines category membership is whether an example has enough characteristic properties (is enough like other members) to belong to the category.

One key idea associated with this view is that not all category members are equally "good" examples of a concept. If membership is based on characteristic properties and some members have more of these properties than others, then the ones with more characteristic properties should better exemplify the category. For example, canaries but not penguins have the characteristic bird properties of flying, singing, and building a nest; so one would predict that canaries would be more typical birds than penguins. Rosch and Mervis (1975) found that people do rate some examples of a category to be more typical than

others and that these judgments are highly correlated with the number of characteristic features an example possesses. They also created artificial categories conforming to family-resemblance structures and produced typicality effects on learning and on goodness-of-example judgments.

Rosch and her associates (Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976) also argued that the family-resemblance view had important implications for understanding concept hierarchies. Specifically, they suggested that the correlational structure of features (instances that share some features tend to share others) created natural "chunks" or clusters of instances that correspond to what they referred to as *basic-level categories*. For example, having feathers tends to correlate with nesting in trees (among other features) in the animal kingdom, and having gills with living in water. The first cluster tends to isolate birds, while the second picks out fish. The general idea is that these basic-level categories provide the best compromise between maximizing within-category similarity (birds tend to be quite similar to each other) and minimizing between-category similarity (birds tend to be dissimilar to fish). Rosch et al. showed that basic-level categories are preferred by adults in naming objects, are learned first by children, are associated with the fastest categorization reaction times, and have a number of other properties that indicate their special conceptual status.

Turning Points 1 and 2 are not unrelated. To be sure, the Collins and Quillian model, as initially presented, would not predict typicality effects (but see Collins & Loftus, 1975), and it wasn't obvious that it contained anything that would predict the importance of basic-level categories. Nonetheless, these conceptual breakthroughs led to an enormous amount of research premised on the notion that concepts are linked in memory by meaningful pathways, so that memory in effect groups concepts according to their similarity in meaning (see Anderson & Bower, 1973; and Norman & Rumelhart, 1975, for theories and research in this tradition, and Goldstone & Son, Chapter 10, for current theories of similarity).

Fragmentation of Semantics and Memory

Prior to about 1980, most researchers in this field saw themselves as investigating “semantic memory”—the way that long-term memory organizes meaningful information. Around 1980, the term itself became passé, at least for this same group of researchers, and the field regrouped under the banner of “Categories and Concepts” (the title of Smith & Medin’s 1981 synthesis of research in this area). At the time, these researchers may well have seen this change as a purely nominal one, but we suspect it reflected a retreat from the claim that semantic-memory research had much to say about either semantics or memory. How did this change come about?

MEMORY ORGANIZATION

Initial support for a Quillian-type memory organization came from Quillian's own collaboration with Allan Collins (Collins & Quillian, 1969), which we mentioned earlier. Related evidence also came from experiments on lexical priming: Retrieving the meaning of a word made it easier to retrieve the meaning of semantically related words (e.g., Meyer & Schvaneveldt, 1971). In these lexical decision tasks, participants viewed a single string of letters on each trial and decided, under reaction time instructions, whether the string was a word (e.g., “daisy”) or a nonword (“raisy”). The key result was that participants were faster to identify a string as a word if it followed a semantically related item than an unrelated one. For example, reaction time for “daisy” was faster if on the preceding trial the participant had seen “tulip” than if he or she had seen “steel.” This priming effect is consistent with the hypothesis that activation from one concept spreads through memory to semantically related ones.

Later findings suggested, however, that the relation between word meaning and memory organization was less straightforward. For example, the typicality findings (see *Turning Point 2*) suggested that time to verify sentences of the form *An X is a Y* (e.g., “A finch is a bird”) might be a function of the overlap in the information that participants knew about the meaning of *X* and *Y*, rather than the length of the pathway between these concepts. The greater the information overlap—for example, the greater the number of properties that the referents of *X* and *Y* shared—the faster the time to confirm a true sentence and the slower the time to disconfirm a false one. For example, if you know a lot of common information about finches and birds but only a little common information about ostriches and birds, you should be faster to confirm the sentence “A finch is a bird” than “An ostrich is a bird.” Investigators proposed several theories along these lines that made minimal commitments to the way memory organized its mental concepts (McCloskey & Glucksberg, 1979; Smith, Shoben, & Rips, 1974; Tversky, 1977). Rosch’s (1978) theory likewise studiously avoided a stand on memory structure.

Evidence from priming in lexical decision tasks also appeared ambiguous. Although priming occurs between associatively related words (e.g., “bread” and “butter”), it is not so clear that there is priming between semantically linked words in the absence of such associations. It is controversial whether, for example, there is any automatic activation between “glove” and “hat,” despite their joint membership in the clothing category (see Balota, 1994, for a discussion). If memory is organized on a specifically semantic basis—on the basis of word meanings—then there should be activation between semantically related words even in the absence of other sorts of associations. A meta-analysis by Lucas (2000) turned up a small effect of this type, but as Lucas notes, it is difficult to tell whether the semantically related pairs in these experiments are truly free of associations.

The idea that memory organization mimics semantic organization is an attractive one, and memory researchers attempted to modify the original Quillian approach to bring it into line with the results we have just reviewed (e.g., Collins & Loftus, 1975). The data from the sentence verification and lexical decision experiments, however, raised doubts about these theories. Later in this chapter we will consider whether newer techniques can give us a better handle on the structure of memory, but for

now let us turn to the other half of the memory = meaning equation.

SEMANTICS

Specifying the meaning of individual words is one of the goals of semantics, but only one. Semantics must also account for the meaning of phrases, sentences, and longer units of language. One problem in using a theory like Quillian's as a semantic theory is how to extend its core idea—that the meaning of a word is the coordinates of a node in memory structure—to explain how people understand meaningful phrases and sentences. Of course, Quillian's theory and its successors can tell us how we understand sentences that correspond to preexisting memory pathways. We have already seen how the model can explain our ability to confirm sentences like "A daisy is a flower." But what about sentences that do not correspond to preexisting connections, sentences like "Fred placed a daisy in a lunchbox"?

The standard approach to sentence meaning in linguistics is to think of the meaning of sentences as built from the meaning of the words that compose them, guided by the sentence's grammar (e.g., Chierchia & McConnell-Ginet, 1990). We can understand sentences that we have never heard or read before, and since there are an enormous number of such novel sentences, we cannot learn their meaning as single chunks. It therefore seems quite likely that we compute the meaning of these new sentences. But if word meaning is the position of a node in a network, it is hard to see how this position could combine with other positions to produce sentence meanings. What is the process that could take the relative network positions for FRED, PLACE, DAISY, IN, and LUNCHBOX and turn them into a meaning for "Fred placed a daisy in a lunchbox"?

If you like the notion of word meaning as relative position, then one possible solution to the problem of sentence meaning is to connect these positions with further pathways. Since we already have an array of memory nodes and pathways at our disposal, why not add a few more in order to encode the meaning of a new sentence? Perhaps the meaning of "Fred placed a daisy in the lunchbox" is given by a new set of pathways that interconnect the nodes for FRED, PLACE, DAISY, and so on, in a configuration corresponding to the sentence's structure. This is the route that Quillian and his successors took (e.g., Anderson & Bower, 1973; Norman & Rumelhart, 1975; Quillian, 1969), but it comes

at a high price. Adding new connections changes the overall network configuration and thereby alters the meaning of the constituent terms. (Remember: meaning is supposed to be *relative* position.) But it is far from obvious that encoding incidental facts alters word meaning. It seems unlikely, for example, that learning the sentence about Fred changes the meaning of "daisy." Moreover, because meaning is a function of the entire network, the same incidental sentences change the meaning of all words. Learning about Fred's daisy-placing shifts the meaning of seemingly unrelated words like "hippopotamus" if only a bit.

Related questions apply to other psychological theories of meaning in the semantic-memory tradition. To handle the typicality results mentioned earlier, some investigators proposed that the mental representation of a category like daisies consists of a prototype for that category—for example, a description of a good example of a daisy (e.g., Hampton, 1979; McCloskey & Glucksberg, 1979). The meaning of "daisy" in these prototype theories would thus include default characteristics, such as growing in gardens, that apply to most, but not all, daisies. We will discuss prototype theories in more detail soon, but the point for now is that prototype representations for individual words are difficult to combine to obtain a meaning for phrases that contain them. One potential way to combine prototypes—fuzzy set theory (Zadeh, 1965)—proved vulnerable to a range of counterexamples (Osherson & Smith, 1981, 1982). In general, the prototypes of constituent concepts can differ from the prototypes of their combinations in unpredictable ways (Fodor, 1994). The prototype of BIRDS THAT ARE PETS (perhaps a parakeet-like bird) may differ from the prototypes of both BIRDS and PETS (see Storms, de Boeck, van Mechelen, & Ruts, 1998, for related evidence). So if word meanings are prototypes, it is hard to see how the meaning of phrases could be a compositional function of the meaning of their parts.

Other early theories proposed that category representations consist of descriptions of exemplars of the category in question. For example, the mental representation of DAISY would include descriptions of specific daisies that an individual had encoded (e.g., Hintzman, 1986; Medin & Schaffer, 1978; Nosofsky, 1986). However, these theories have semantic difficulties of their own (see Rips, 1995). For example, if, by chance, the only Nebraskans you have met are chiropractors and the

only chiropractors you have met are Nebraskans, then exemplar models appear to mispredict that “Nebraskan” and “chiropractor” will be synonyms for you.

To recap briefly, we have found that experimental research on concepts and categories was largely unable to confirm that global memory organization (as in Quillian's semantic memory) conferred word meaning. In addition, neither the global theories that initiated this research nor the local prototype or exemplar theories that this research produced were able to provide insight into the basic semantic problem of how we understand the meaning of novel sentences. This left semantic-memory theory in the unenviable position of being unable to explain either semantics or memory.

Functions and Findings

Current research in this field still focuses on categorization and communication, but without the benefit of a framework that gives a unified explanation for the functions that concepts play in categorizing, reasoning, learning, language understanding, and memory organization. In this section, we survey the state of the art, and in the following one, we consider the possibility of reuniting some of these roles.

Category Learning and Inference

One nice aspect of Rosch and Mervis's (1975) studies of typicality is that they used both natural language categories and artificially created categories. Finding typicality effects with natural (real-world) categories shows that the phenomenon is of broad interest; finding these same effects with artificial categories provides systematic control for potentially confounding variables (e.g., exemplar frequency) in a way that cannot be done for lexical concepts. This general strategy linking the natural to the artificial has often been followed over the past few decades. Although researchers using artificial categories have sometimes been guilty of treating these categories as ends in themselves, there are enough parallels between results with artificial and natural categories that each area of research informs the other (see Medin & Coley, 1998, for a review).

PROTOTYPE VERSUS EXEMPLAR MODELS

One idea compatible with Rosch's family-resemblance hypothesis is the *prototype view*. It proposes that people learn the characteristic features (or central tendency) of categories and use them

to represent the category (e.g., Reed, 1972). This abstract prototype need not correspond to any experienced example. According to this theory, categorization depends on similarity to the prototypes. For example, to decide whether some animal is a bird or a mammal, a person would compare the (representation of) that animal to both the bird and the mammal prototypes and assign it to the category whose prototype it most resembled. The prototype view accounts for typicality effects in a straightforward manner. Good examples have many characteristic properties of their category and have few characteristics in common with the prototypes of contrasting categories.

Early research appeared to provide striking confirmation of the idea of prototype abstraction. Using random dot patterns as the prototypes, Posner and Keele (1968, 1970) produced a category from each prototype. The instances in a category were “distortions” of the prototype, generated by moving constituent dots varying distances from their original positions. Posner and Keele first trained participants to classify examples that they had created by distorting the prototypes. Then they gave a transfer test in which they presented both the old patterns and new low or high distortions that had not appeared during training. In addition, the prototypes, which the participants had never seen, were presented during transfer. Participants had to categorize these transfer patterns; but unlike the training procedure, the transfer test gave participants no feedback about the correctness of their responses. The tests either immediately followed training or appeared after a 1-week delay.

Posner and Keele (1970) found that correct classification of the new patterns decreased as distortion (distance from a category prototype) increased. This is the standard typicality effect. The most striking result was that a delay differentially affected categorization of prototypic versus old training patterns. Specifically, correct categorization of old patterns decreased over time to a reliably greater extent than performance on prototypes. In the immediate test, participants classified old patterns more accurately than prototypes; but in the delayed test, accuracy on old patterns and prototypes was about the same. This differential forgetting is compatible with the idea that training leaves participants with representations of both training examples and abstracted prototypes, but that memory for examples fades more rapidly than memory for prototypes. The Posner and Keele results were quickly replicated by

others and constituted fairly compelling evidence for the prototype view.

But this proved to be the beginning of the story rather than the end. Other researchers (e.g., Brooks, 1978; Medin & Schaeffer, 1978) put forth an *exemplar view* of categorization. Their idea was that memory for old exemplars by itself could account for transfer patterns without the need for positing memory for prototypes. On this view, new examples are classified by assessing their similarity to stored examples and assigning the new example to the category that has the most similar examples. For instance, some unfamiliar bird (e.g., a heron) might be correctly categorized as a bird not because it is similar to a bird prototype, but rather because it is similar to flamingos, storks, and other shore birds.

In general, similarity to prototypes and similarity to stored examples will tend to be highly correlated (Estes, 1986). Nonetheless, for some category structures and for some specific exemplar and prototype models, it is possible to develop differential predictions. Medin and Schaffer (1978), for example, pitted number of typical features against high similarity to particular training examples and found that categorization was more strongly influenced by the latter. A prototype model would make the opposite prediction.

Another contrast between exemplar and prototype models revolves around sensitivity to within-category correlations (Medin, Altom, Edelson, & Freko, 1982). A prototype representation captures what is on average true of a category but is insensitive to within-category feature distributions. For example, a bird prototype could not represent the impression that small birds are more likely to sing than large birds (unless one had separate prototypes for large and small birds). Medin et al. (1982) found that people are sensitive to within-category correlations (see also Malt & Smith, 1984, for corresponding results with natural object categories). Exemplar theorists were also able to show that exemplar models could readily predict other effects that originally appeared to support prototype theories—differential forgetting of prototypes versus training examples, and prototypes being categorized as accurately or more accurately than training examples. In short, early skirmishes strongly favored exemplar models over prototype models. Parsimony suggested no need to posit prototypes if stored instances could do the job. Since the early 1980s, there have been a number of trends and developments in research and theory with artificially constructed categories,

and we will be able to give only the briefest of summaries here.

NEW MODELS

There are now several contending models for categorizing artificial stimuli, and the early models have been extensively elaborated. For example, researchers have generalized the original Medin and Schaffer (1978) exemplar model to handle continuous dimensions (Nosofsky, 1986), to address the time course of categorization (Lamberts, 1995; Nosofsky & Palmeri, 1997a; Palmeri, 1997), to generate probability estimates in inference tasks (Juslin & Persson, 2002), and to embed it in a neural network (Kruschke, 1992).

Three new kinds of classification theories have been added to the discussion: rational approaches, decision-bound models, and neural network models. Anderson (1990, 1991) proposed that an effective approach to modeling cognition in general and categorization in particular is to analyze the information available to a person in the situation of interest and then to determine abstractly what an effective, if not optimal, strategy might be (see Chater & Oaksford, Chapter 2; Griffiths et al., Chapter 3). This approach has led to some new sorts of experimental evidence (e.g., Anderson & Fincham, 1996; Clapper & Bower, 2002) and pointed researchers more in the direction of the inference function of categories. Interestingly, the Medin and Schaffer exemplar model corresponds to a special case of the rational model, and Nosofsky (1991) has discussed the issue of whether the rational model adds significant explanatory power. However, there is also some evidence undermining the rational model's predictions concerning inference (e.g., Malt, Ross, & Murphy, 1995; Murphy & Ross, 1994; Palmeri, 1999; Ross & Murphy, 1996).

Decision-bound models (e.g. Ashby & Maddox, 1993; Maddox & Ashby, 1993) draw their inspiration from psychophysics and signal detection theory. Their primary claim is that category learning consists of developing decision bounds around the category that will allow people to categorize examples successfully. The closer an item is to the decision bound, the harder it should be to categorize. This framework offers a new perspective on categorization in that it may lead investigators to ask questions such as: How do the decision bounds that humans adopt compare with what is optimal? What kinds of decision functions are easy or hard to acquire? Researchers have also directed efforts

to distinguish decision-bound and exemplar models (e.g., Maddox & Ashby, 1998; Maddox, 1999; McKinley & Nosofsky, 1995; Nosofsky & Palmeri, 1997b; Nosofsky, 1998). One possible difficulty with decision-bound models is that they contain no obvious mechanism by which stimulus familiarity can affect performance, contrary to empirical evidence that it does (Verguts, Storms, & Tuerlinckx, 2003).

Neural network or connectionist models are the third type of new model on the scene (see Knapp & Anderson, 1984, and Kruschke, 1992, for examples; and Doumas & Hummel, Chapter 5, for further discussion of connectionism). It may be a mistake to think of connectionist models as comprising a single category, as they take many forms depending on assumptions about hidden units, attentional processes, recurrence, and the like. There is one sense in which neural network models with hidden units may represent a clear advance on prototype models: They can form prototypes in a bottom-up manner that reflects within-category structure (e.g., Love, Medin, & Gureckis, 2004). That is, if a category comprises two distinct clusters of examples, network models can create a separate hidden unit for each chunk (e.g., large birds versus small birds) and thereby show sensitivity to within-category correlations.

MIXED MODELS AND MULTIPLE CATEGORIZATION SYSTEMS

A common response to hearing about various models of categorization is to suggest that all the models may be capturing important aspects of categorization and that research should determine in which contexts one strategy versus another is likely to dominate. One challenge to this divide-and-conquer program is that the predictions of alternative models tend to be highly correlated and separating them is far from trivial. Nonetheless, there is both empirical research (e.g., Johansen & Palmeri, 2002; Nosofsky, Clark, & Shin, 1989; Reagher & Brooks, 1993) and theoretical modeling that support the idea that mixed models of categorization are useful and perhaps necessary. Current efforts combine rules and examples (e.g., Erickson & Kruschke, 1998; Nosofsky, Palmeri, & McKinley, 1994), as well as rules and decision bounds (Ashby, Alfonso-Reese, Turken, & Waldron, 1998). Some models also combine exemplars and prototypes (e.g., Homa, Sterling, & Trepel, 1981; Minda & Smith, 2001; Smith, Murray, & Minda, 1997; Smith & Minda,

1998, 2000), but it remains controversial whether the addition of prototypes is needed (e.g., Busemeyer, Dewey, & Medin, 1984; Nosofsky & Johansen, 2000; Nosofsky & Zaki, 2002; Stanton, Nosofsky, & Zaki, 2002).

The upsurge of cognitive neuroscience (see Morrison & Knowlton, Chapter 6) has reinforced the interest in multiple memory systems. One intriguing line of research by Knowlton, Squire, and associates (Knowlton, Mangels & Squire, 1996; Knowlton & Squire, 1993; Squire & Knowlton, 1995), favoring multiple categorization systems, involves a dissociation between categorization and recognition. Knowlton and Squire (1993) used the Posner and Keele dot pattern stimuli to test amnesic and matched control patients on either categorization learning and transfer or on a new-old recognition task (involving five previously studied patterns versus five new patterns). The amnesics performed very poorly on the recognition task but were not reliably different from control participants on the categorization task. Knowlton and Squire took this as evidence for a two-system model, one based on explicit memory for examples and one based on an implicit system (possibly prototype abstraction). Reed, Squire, Patalano, Smith, and Jonides (1999) used the same “prototype extraction” task to compare amnesic patients and controls, but instead of dot patterns Reed et al. employed a set of artificial animals that varied on 10 salient features. Unlike the dot patterns, which are quite abstract and difficult to describe, the features of the artificial animals were easy to verbalize. The results, however, were the same: The amnesics performed worse than controls on an explicit-memory test, but they were not reliably different from controls on the categorization task. So implicit category learning is not reserved for what cannot be articulated. On this view, amnesics have lost access to the explicit system but can perform the classification task using their intact implicit memory.

These results have provoked a number of counter-arguments to the hypothesis that categorization and recognition involve two different memory systems. First, investigators have raised questions about the details of the procedures in the prototype-extraction studies. Specifically, Palmeri and Flanery (1999) suggested that some learning may have occurred during the transfer tests (not during training), and this learning did not depend on the storage of exemplars. In support of the claim that learning during transfer occurs in the prototype extraction, Palmeri and Flanery showed that undergraduates who had never

been exposed to training exemplars (the students thought that they were being shown patterns subliminally) performed above chance on transfer tests. Bozoki, Grossman, and Smith (2006) did a similar study, but their subjects included amnesics in addition to normals, and they used artificial animals rather than dot patterns. Bozoki et al. again found that learning occurred even when no training exemplars occurred—for amnesics as well as controls!—but even more learning occurred when exemplars were presented. These results suggest that something is indeed being learned implicitly—namely, whatever it is that both amnesics and controls get from training exemplars. But the two studies under scrutiny differ in too many ways—kinds of materials and subjects—to draw firm conclusions.

Perhaps the most important argument against the Knowlton and Squire evidence for implicit category learning came from Nosofsky and Zaki (1998). They showed that a single-system (exemplar) model could account for both the categorization and recognition data from both the amnesics and controls, by assuming that: (1) the exemplar-based memory of amnesics was impaired but not absent; and (2) the categorization task was less cognitively demanding than the recognition task. A recent review of this literature (Smith, 2008) notes that the Nosofsky-Zaki analysis has never been refuted by patient data (and not for lack of trying).

But there is another kind of data that is relevant here, which turns out to have more diagnostic power—neuroimaging evidence from experiments in which normal subjects perform both prototype-extraction and recognition tasks. Reber, Stark, and Squire (1998a, b) had subjects perform these tasks while having their brains scanned by functional magnetic resonance imaging (fMRI). The recognition task resulted in increased activations in numerous brain areas, including the hippocampus, the very area that is damaged in the amnesiac patients that we have been discussing and that is routinely activated in neuroimaging studies of explicit memory (e.g., Wagner, Bunde, & Bader, 2004). However, none of these areas were activated in the categorization task. Even more striking, an area in visual cortex known to be involved in early visual processing was *activated* in recognition but *deactivated* in categorization. Reber, Gitelman, Parrish, and Mesulam (2003) have observed the same kind of dissociation in another neuroimaging experiment. These results argue quite strongly for a distinction between explicit and implicit category learning.

But what is the nature of the “category” acquired when learning is implicit? The neuroimaging findings suggest an answer. The deactivations observed in occipital cortex are similar to those reported in studies of visual priming (e.g., Buckner, 2000). The latter deactivations are attributed to increased efficiency in processing the perceptual features of the items. This same process could play a role in prototype extraction. The training items are highly similar to one another (else they would not form a category) and thus have numerous features in common. These common features occur frequently during the training phase—else the features would not be “common”—and consequently subjects become increasingly proficient in processing them. If we assume subjects experience a feeling of greater perceptual fluency with items that are processed efficiently, then subjects could use this feeling as a guide to categorization during the transfer phase—the greater the fluency, the more likely the item is a member of the category (Smith, 2008).

So fluency alone can support categorization, but are we really talking about “concepts” here? At the outset, we noted that one of the only things that cognitive scientists agree on concerning concepts is that they are mental representations. Feelings of fluency are not representations of categories (they are more like sensations), so what we have here is categorization without concepts. And perceptual fluency alone may not be able to support the functions that we attributed to concepts early on. Can perceptual fluency support inductive inferences? For example, if one learns a category of artificial animals via perceptual fluency and then learns that some of the instances have an additional feature, will one generalize this feature to other instances? And it seems clear that categories acquired by perceptual fluency will not be available for communication, as it is a hallmark of material learned implicitly that it cannot be verbalized.

The debate is far from resolved, and there are strong advocates both for and against the multiple systems view (e.g., Filoteo, Maddox, & Davis, 2001; Maddox, 2002; Nosofsky & Johansen, 2000; Palmeri & Flanery, 2002; Reber et al., 1998a, b). It is safe to predict that this issue will receive continuing attention.

INFERENCE LEARNING

Recently investigators have begun to worry about extending the scope of category learning by looking at inference. Often we categorize some entity in order to help us accomplish some function or goal.

Ross (1997, 1999, 2000) has shown that the category representations people develop in laboratory studies depend on use and that use affects later categorization. In other words, models of categorization ignore inference and use at their peril. Other work suggests that having a cohesive category structure is more important for inference learning than it is for classification (Yamauchi & Markman, 1998, 2000a, 2000b; Yamauchi, Love, & Markman, 2002; for modeling implications see Love, Markman, & Yamauchi, 2000; Love et al., 2004). More generally, this work raises the possibility that diagnostic rules based on superficial features, which appear so prominently in pure categorization tasks, may not be especially relevant for contexts involving multiple functions or more meaningful stimuli (e.g., Markman & Makin, 1998; Wisniewski & Medin, 1994).

FEATURE LEARNING

The final topic on our “must mention” list for work with artificial categories is feature learning. It is a common assumption in both models of object recognition and category learning that the basic units of analysis or features remain unchanged during learning. There is increasing evidence and supporting computational modeling indicating that this assumption is incorrect. Learning may increase or decrease the distinctiveness of features and may even create new features (see Goldstone, 1998, 2003; Goldstone & Steyvers, 2001; Goldstone, Lippa, & Shriffrin, 2001; Schyns & Rodet, 1997; Schyns, Goldstone, & Thibaut, 1998).

Feature learning has important implications for our understanding of the role of similarity in categorization. It is intuitively compelling to think of similarity as a causal factor supporting categorization—things belong to the same category because they are similar. But this may have things backward. Even standard models of categorization assume that learners selectively attend to features that are diagnostic, and the work on feature learning suggests that learners may create new features that help partition examples into categories. In that sense, similarity (in the sense of overlap in features) is the byproduct, not the cause, of category learning. We will take up this point in discussing the theory of categorization later in this review.

FEATURES OF NATURAL CATEGORIES AND COGNITIVE NEUROSCIENCE

In the research reviewed thus far, the features (1) have not been subdivided into types and (2) have

been assumed to be abstract symbols. Both of these assumptions have been challenged by the foray of cognitive neuroscience into the study of natural concepts, a movement that began in the mid-1980s but still remains somewhat separate from the mainstream of behavioral studies on categories and concepts. In what follows, we try to convey the gist of this research by focusing on studies dealing with Points (1) and (2) mentioned earlier. This work includes both neuropsychological studies of neurological patients with categorization deficits and neuroimaging studies of normals (typically college students) who answer questions about categories and their properties while having their brains scanned.

Neuropsychological Studies of Categorization

The seminal article in this line of research was a 1984 paper by Warrington and Shallice that analyzed the categorization abilities of patients with “visual agnosia,” an inability to categorize visual objects even though perceptual abilities remain intact. Such patients often have lesions in the bottom or ventral portion of temporal cortex. It had been known for some time that such patients may show greater deficits with some categories than others. Warrington and Shallice (1984) thoroughly documented such “category-specific” deficits in four patients, showing that patients could have normal levels of categorization accuracy on some categories while being drastically impaired on others. For example, in a task in which subjects simply had to match pictures to category-names, Patient JBR achieved 98% accuracy on categories of nonliving things (obviously normal), but only 67% on categories of animals (obviously impaired). Other patients showed a similar pattern. However, in some tasks there were exceptions to the living versus nonliving distinction, such as musical instruments, which clustered with living things, whereas body parts clustered with the nonliving categories.

To handle these exceptions, Warrington and Shallice (1984) shifted their analysis from the level of categories to that of features. They noted that the impaired categories tended to be those characterized by perceptual features, while the less impaired, or intact, categories tended to be characterized by functional features (where “functional” is used very broadly). This led to the “perceptual-functional” hypothesis of category deficits: Brain damage can selectively affect sensory/perceptual regions or regions more involved in the use of artifacts

(e.g., motor areas), and the first type of damage will hurt the categorization of living things while the second will mainly affect categories of nonliving things like tools. The hypothesis is extremely influential in neurological and neuroimaging studies, and it makes clear the importance of distinguishing features with regard to what they refer to—perceptual versus functional properties of objects.

If problems with perceptual features are what underlie patients' problems in dealing with animal categories, one would expect that, when asked about the features of a category (e.g., "Does a canary have a beak?") these patients should have more problems with questions about perceptual than nonperceptual features of the same category. This prediction has been confirmed numerous times (e.g., Thompson-Schill, D'Esposito, Aguirre, & Farah, 1997). The difference between perceptual and functional features seems to be a key distinction about the nature of concepts that has been relatively ignored in the mainstream literature on normal categorization.

This perceptual-functional distinction lies at the heart of a number of computational models of categorization that have been applied to the results of the neuropsychological studies. Farah and McClelland (1991) developed a model in which conceptual knowledge about objects is divided into perceptual and functional components, and the ratio of perceptual-to-functional features for living things is much greater than that for nonliving things. They then selectively degraded either perceptual or functional features and showed that this "lesioned" model provided a good account of patients' performance on simple categorization tasks. Subsequent models have become increasingly more sophisticated. Thus, in Rogers and McClelland's (2004) model, the features are not built into the model by the modeler, but rather are based on normal subjects' verbal descriptions and drawings of these objects. These empirically obtained features reveal not only the perceptual-functional distinction but also a further distinction based on whether color is a feature, which is critical in distinguishing animals from plants (fruits/vegetables), both of which are living things. When the different kinds of features are "lesioned," the model's performance on a variety of simple categorization tasks matches that of various patients to a striking degree.

Neuroimaging Studies

The first neuroimaging studies of natural concepts appeared in the mid-1990s. Martin, Haxby,

Lalonde, Wiggs, and Ungerleider (1995) imaged peoples' brains while they performed a simple property-verification task (e.g., "Is a banana yellow?"). Unsurprisingly they found increased activation in left-hemisphere language areas (located in the ventral part of the frontal cortex and the medial part of the temporal cortex). In addition, though, there was a notable increase in activation in the ventral region of temporal cortex, which is the region responsible for object recognition. Even though only semantic processing was called for, object-processing seemed to be involved as well. Even more striking, the activation at issue was close to the subregion that underlies the perception of the property. For example, when answering verbal questions about the color of an object, there was an activation in the area concerned with perceiving the color of objects.

Subsequent studies replicated the critical finding that perceptual questions activate perceptual areas—what has come to be called "modality specificity" (e.g., Chao & Martin, 1999; Kellenbach, Brett, & Patterson, 2001). Indeed, some studies showed activation in perceptual areas even when language areas were not activated (Kan, Barasalou, Solomon, Minor, & Thompson-Schill, 2003). The neuroimaging evidence for modality specificity gets even more detailed, as some property-verification studies have varied the kind of perceptual property queried—color versus size, for example—and shown that color questions activate color areas, whereas size questions activate areas in parietal cortex known to be involved in the perception of space. Interestingly, though the brain areas being activated are clearly perceptual ones, subjects in these experiments rarely if ever report experiencing visual imagery. The conclusion that has repeatedly been drawn from these studies is that knowledge about perceptual properties, which had been thought to be represented in a completely amodal fashion, is in fact partially represented in a modality-specific way (Thompson-Schill, 2003). Object concepts are claimed to be "perceptually embodied." Furthermore, since the different perceptual modalities are processed in different brain regions, "perceptual-conceptual knowledge" must be represented by a distributed network of brain regions. There is no Bird area in the brain.

Modality specificity cannot be the whole story, however. There are longstanding arguments against the idea that object concepts are purely perceptual (summarized in Miller & Johnson-Laird, 1976). For example, why do people who are congenitally blind seem to share the same concepts as the

sighted? It is even possible to question whether the modality-specific activations found in the aforementioned studies actually play an important role in categorization and property verification (e.g., Mahon & Caramazza, 2008). Specifically, the knowledge that is used to answer simple questions about object categories may be represented amodally (symbolically), as has routinely been assumed in the semantic-memory literature, but these representations may be closely linked to modality-specific ones, which may be used for purposes of recognizing objects and generating visual images. If so, activation of the relevant amodal representation may lead to the concurrent activation of the associated modality-specific representation. The apparent evidence for modality specificity is essentially a spread of activation from the amodal areas that do the real neural work. At this point, however, there is little independent evidence in favor of the spreading activation account, so modality specificity cannot be dismissed.

REASONING

As we noted earlier, one of the central functions of categorization is to support reasoning. Having categorized some entity as a bird, one may predict with reasonable confidence that it builds a nest, sings, and can fly, though none of these inferences is certain. In addition, between-category relations may guide reasoning. For example, from the knowledge that robins have some enzyme in their blood one is likely to be more confident that the enzyme is in sparrows than in raccoons. The basis for this confidence may be that robins are more similar to sparrows than to raccoons, or that robins and sparrows are more likely to share relevant biological mechanisms than robins and raccoons. We will not review this literature here, but see Heit (2000), Kemp and Tenenbaum (2009), and Rips (2001, 2011) for detailed treatments.

SUMMARY

Due to space limitations, we have glossed a lot of research and skipped numerous other relevant studies. The distinction between artificially created and natural categories is itself artificial, at least in the sense that it has no clear definition or marker. When we take up the idea that concepts may be organized in terms of theories, we will return to some laboratory studies that illustrate this fuzzy boundary. For the moment, however, we shift attention to the more language-like functions of concepts.

Language Functions

Most investigators in the concepts-and-categories area continue to assume that, in addition to their role in recognition and category learning, concepts also play a role in understanding language and in thinking discursively about things. In addition to determining, for example, which perceptual patterns signal the appearance of a daisy, the DAISY concept also contributes to the meaning of sentences like our earlier example, “Fred placed a daisy in a lunchbox.” We noted that early psychological research on concepts ran into problems in explaining the meaning of linguistic units larger than single words. Most early theories posited representations, such as networks, exemplars, or prototypes, that did not combine easily and thus complicated the problem of sentence meaning. Even if we reject the idea that sentence meanings are compositional functions of word meaning, we still need a theory of sentence meanings, and no obvious contenders are in sight. In this section, we return to the role that concepts play in language to see whether new experiments and theories have clarified this relationship.

CONCEPTS AS POSITIONS IN MEMORY STRUCTURES

One difficulty with the older semantic-memory view of word meaning is that memory seems to change with experience from one person to another, while meaning must be more or less constant. The sentences that you have encoded about daisies may differ drastically from those that we have encoded, because your conversation, reading habits, and other verbal give-and-take can diverge in important ways from ours. If meaning depends on memory for these sentences, then your meaning for “daisy” should likewise differ from ours. This observation raises the question of how you could possibly understand the sentences in this chapter in the way we intend or how you could meaningfully disagree with us about some common topic (see Fodor, 1994).

Two people—say, Calvin and Martha—might be able to maintain mutual intelligibility as long as their conceptual networks are not too different. It is partly an empirical question how much their networks can vary while still allowing Calvin’s concepts to map correctly into Martha’s. To investigate this issue, Goldstone and Rogosky (2002) carried out some simulations that try to recover such a mapping. The simulations modeled Calvin’s conceptual system as the distance between each pair of his concepts (e.g., the distance between DOG and

CAT in Calvin's system might be one unit, while the distance between DOG and DAISY might be six units). Martha's conceptual system was represented in the same way (i.e., by exactly the same interconcept distances), except for random noise that Goldstone and Rogosky added to each distance to simulate the effect of disparate beliefs. A constraint-satisfaction algorithm was then applied to Calvin's and Martha's systems that attempted to recover the original correspondence between the concepts—to map Calvin's DOG to Martha's DOG, Calvin's DAISY to Martha's DAISY, and so on. The results of the simulations show that with 15 concepts in each system (the maximum number considered and the case in which the model performed best) and with no noise added to Martha's system, the algorithm was always able to find the correct correspondence. When the simulation added to each dimension of the interconcept distance in Martha a small random increment (drawn from a normal distribution with mean 0 and standard deviation equal to .004 times the maximum distance), the algorithm recovered the correspondence about 63% of the time. When the standard deviation increased to .006 times the maximum distance, the algorithm succeeded about 15% of the time (Goldstone & Rogosky, 2002, Figure 2).

What should one make of the Goldstone and Rogosky results? Correspondences may be recovered for small amounts of noise, but performance dropped off dramatically for larger amounts of noise. Foes of the meaning-as-relative-position theory might claim that the poor performance under 0.6% noise proves their contention. Advocates would point to the successful part of the simulations and note that its ability to detect correct correspondences usually improved as the number of points increased (although there are some non-monotonocities in the simulation results that qualify this finding). Clearly, this is only the beginning of the empirical side of the debate. For example, the differences between Martha and Calvin are likely to be not only random but also systematic, as in the case where Martha grew up on a farm and Calvin was a city kid.

CONCEPT COMBINATION

Let us now consider attempts to tackle head-on the problem of how word-level concepts combine to produce the meanings of larger linguistic units. There is relatively little research in this tradition on entire sentences (see Conrad & Rips, 1986; Rips,

Smith, & Shoben, 1978), but there has been a fairly steady research stream devoted to noun phrases, including adjective-noun ("edible flowers"), noun-noun ("food flowers"), and noun-relative-clause combinations ("flowers that are foods"). We will call the noun or adjective parts of these phrases *components* and distinguish the main or *head noun* ("flowers" in each of our examples) from the adjective or noun *modifier* ("edible" or "food"). The aim of the research in question is to describe how people understand these phrases and, in particular, how the typicality of an instance in these combinations depends on the typicality of the same instance in the components. How does the typicality of a marigold in the category of edible flowers depend on the typicality of marigolds in the categories of edible things and flowers? As we have already noticed, this relationship is far from straightforward (parakeets are superbly typical as pet birds but less typical pets and even less typical birds). For reviews of work on this problem, see Hampton (1997), Murphy (2002), Rips (1995), and Wisniewski (1997).

Research on the typicality structure of combinations has turned up interesting phenomena. These same phenomena, however, pose some serious challenges to the idea that people can predict the typicality of a combination from the typicality of its components. This difficulty is instructive, in part because all psychological theories of concept combination posit complex, structured representations, and they depict concept combination either as rearranging (or augmenting) the structure of the head noun by means of the modifier (Franks, 1995; Murphy, 1988; Smith, Osherson, Rips, & Keane, 1988) or as fitting both head and modifier into a larger relational complex (Gagné & Shoben, 1997). Table 11.1 summarizes the assumptions of these theories. Earlier models (at the top of the table) differ from later ones mainly in terms of the complexity of the combination process. Smith et al. (1988), for example, aimed at explaining simple adjective-noun combinations (e.g., "white vegetable") that, roughly speaking, refer to the intersection of the sets denoted by modifier and head (white vegetables are approximately the intersection of white things and vegetables). In this theory, combination occurs when the modifier changes the value of an attribute in the head noun (changing the value of the color attribute in VEGETABLE to WHITE) and boosts the importance of this attribute in the overall representation. Later theories attempted to account for nonintersective combinations (e.g., "criminal

Table 11.1. Some Theories of Concept Combination

Model	Domain	Representation of Head Noun	Modification Process
Hampton (1987)	Noun-Noun and Noun-Relative-Clause NPs (conjunctive NPs, e.g., <i>sports that are also games</i>)	Schemas (attribute-value lists with attributes varying in importance)	Modifier and head contribute values to combination on the basis of importance and centrality
Smith, Osherson, Rips, & Keane (1988)	Simple Adjective-Noun NPs (e.g., <i>red apple</i>)	Schemas (attribute-value lists with distributions of values and weighted attributes)	Adjective shifts value on relevant attribute in head and increases weight on relevant dimension.
Murphy (1988)	Adj-Noun and Noun-Noun NPs (esp. non-predicating NPs, e.g., <i>corporate lawyer</i>)	Schemas (lists of slots and fillers)	Modifier fills relevant slot; then representation is “cleaned up” on the basis of world knowledge.
Franks (1995)	Adj-Noun and Noun-Noun NPs (esp. privatives, e.g., <i>fake gun</i>)	Schemas (attribute-value structures with default values for some attributes)	Attribute-values of modifier and head are summed, with modifier potentially overriding or negating head values.
Gagné & Shoben (1997)	Noun-Noun NPs	Lexical representations containing distributions of relations in which nouns figure	Nouns are bound as arguments to relations (e.g., <i>flu virus</i> = virus causing flu).
Wisniewski (1997)	Noun-Noun NPs	Schemas (lists of slots and fillers, including roles in relevant events)	<ol style="list-style-type: none"> 1. Modifier noun is bound to role in head noun (e.g., <i>truck soap</i> = soap for cleaning trucks). 2. Modifier value is reconstructed in head noun (e.g., <i>zebra clam</i> = clam with stripes). 3. Hybridization (e.g., <i>robin canary</i> = cross between robin and canary)

lawyers,” who are often not both criminals and lawyers). These combinations call for more complicated adjustments, for example, determining a relation that links the modifier and head (a criminal lawyer is a lawyer whose clients are in for criminal charges) or extracting a value from the modifier that can then be assigned to the head (e.g., a panther lawyer might be one who is especially vicious or tenacious).

One reason for difficulty in providing a theory for concept combination is that many of the combinations that investigators have studied are familiar or, at least, have familiar referents. Some people have experience with edible flowers, for example,

and know that they include nasturtiums, are sometimes used in salads, are often brightly colored, are peppery-tasting, and so on. We learn many of these properties by direct or indirect observation (by what Hampton, 1987, calls “extensional feedback”), and they are sometimes impossible to learn simply by knowing the meaning of “edible” and “flower.” Because these properties can affect the typicality of potential instances, the typicality of these familiar combinations won’t be a function of the typicality of their components. This means that if we are going to be able to predict typicality in a compositional way, we will have to factor out the contribution of these directly acquired properties. Rips (1995) refers

to this filtering as the “No Peeking Principle”—no peeking at the referents of the combination. Of course, you might be able to predict typicality if you already know the relevant real-world facts in addition to knowing the meaning of the component concepts. The issue about understanding phrases, however, is how we are able to interpret an unlimited number of new ones. For this purpose, people need some procedure for computing new meanings from old ones that is not restricted by the limited set of facts they happened to have learned (e.g., through idiosyncratic encounters with edible flowers).

Another reason why it is hard to explain concept combination is that some of the combinations used in this research may be compounds or lexicalized phrases (e.g., “White House” [accent on “White”] = the residence of the President) rather than modifier-head constructions (e.g., “white house” [accent on “house”] = a house whose color is white). Compounds are often idiomatic; their meaning is not an obvious function of their parts (see Gleitman & Gleitman’s, 1970, distinction between phrasal and compound constructions; and Partee, 1995).

There is a deeper reason, however, for the difficulty in predicting compound typicality from component typicality. Even if we adhere to the No Peeking Principle, and even if we stick to clear modifier-head constructions, the typicality of a combination can depend on “emergent” properties that are not part of the representation of either component (Hastie, Schroeder, & Weber, 1990; Kunda, Miller, & Claire, 1990; Medin & Shoben, 1988; Murphy, 1988). For example, you may never have encountered, or even thought about, a smoky apple (so extensional feedback does not inform your conception of the noun phrase), but nevertheless it is plausible to suppose that smoky apples are not good tasting. Having a bad taste, however, is not a usual property of (and is not likely to be stored as part of a concept for) either apples or smoky things; on the contrary, many apples and smoky things (e.g., smoked meats, cheeses, and fish) are quite good tasting. If you agree with our assessment that smoky apples are likely to be bad tasting, that is probably because you imagine a way in which apples could become smoky (being caught in a kitchen fire, perhaps) and you infer that under these circumstances the apple would not be good to eat. The upshot is that the properties of a combination can depend on complex inductive or explanatory inferences (Johnson & Keil, 2000; Kunda et al., 1990). If these properties affect the typicality of an instance with

respect to the combination, then models of this phenomenon will not be simple. No current theory provides an adequate and general account of these processes.

INFERENTIAL VERSUS ATOMISTIC CONCEPTS

Research on the typicality structure of noun phrases is of interest for what it can tell us about people’s inference and problem-solving skills. But because these processes can be quite complex—drawing on general knowledge and inductive reasoning to produce emergent information—we cannot predict noun phrase typicality in other than a limited range of cases. By themselves, emergent properties do not rule out the possibility of a model that explains how people derive the meaning of a noun phrase from the meaning of its components. Compositionality does not require that all aspects of the noun phrase’s meaning are literally parts of the components’ meanings. It is sufficient to find some computable function from the components to the composite that is simple enough to account for people’s understanding (see Partee, 1995, for a discussion of types of composition). The trouble is that if noun phrases’ meanings require theory construction and problem solving, such a process is unlikely to explain the ease and speed with which we usually understand them in ongoing speech.

We have only considered the role of networks or prototypes in concept combination, but many of the same difficulties with semantic composition affect other contemporary theories, such as latent semantic analysis (Landauer & Dumais, 1997), which take a global approach to meaning. Latent semantic analysis takes as input a table of the frequencies with which words appear in specific contexts. In one application, for example, the items comprise about 60,000 word types taken from 30,000 encyclopedia entries, and the table indicates the frequency with which each word appears in each entry. The analysis then applies a technique similar to factor analysis to derive an approximately 300-dimensional space in which each word appears as a point and in which words that tend to co-occur in context occupy neighboring regions in the space. Because this technique finds a best fit to a large corpus of data, it is sensitive to indirect connections between words that inform their meaning. However, the theory has no clear way to derive the meaning of novel sentences. Although latent semantic analysis could represent a sentence as the average position of its component words, this would not allow it to

capture the difference between, say, *The financier dazzled the movie star* versus *The movie star dazzled the financier*, which depend on sentence structure as well as word meaning. In addition, the theory uses the distance between two words in semantic space to represent the relation between them; so the theory has trouble with semantic relations that, unlike distances, are asymmetric. It is unclear, for example, how it could cope with the fact that *father* implies *parent* but *parent* does not imply *father*.

On the one hand, online sentence understanding is a rapid, reliable process. On the other, the meaning of even simple adjective-noun phrases seems to require heady inductive inferences. Perhaps we should distinguish, then, between the *interpretation* of a phrase or sentence and its *comprehension* (Burge, 1999). On this view, comprehension gives us a more or less immediate understanding of novel phrases, based primarily on the word meaning of the components and syntactic/semantic structure. Interpretation, by contrast, is a potentially open-ended process, relying on the result of comprehension plus inference and general knowledge. As we have just noticed, it is hard, if not impossible, to compute the typicality structure of composites. So if we want something readily computable in order to account for comprehension, we have to look to something simpler than typicality structures (and the networks, prototypes, schemas, or theories that underlie them). One possibility (Fodor, 1994, 1998) is to consider a representation in which word meanings are mental units not much different from the words themselves, and whose semantic values derive from (unrepresented) causal connections to their referents.

The comprehension/interpretation distinction that we just proposed may be more of a continuum than a dichotomy. Background knowledge about the component concepts may come in gradually as part of sentence interpretation, with more atomistic components becoming available early in the process, simple typicality information arriving later, and inference-intensive information still later. Researchers usually study sentence understanding, classification, and inference with different methodologies. Reaction time, for example, is often a dependent measure for sentence understanding and classification, but rarely for interpretation tasks, which employ off-line choice and think-aloud methods (more on interpretation tasks in upcoming sections). Different methodologies make it hard to generalize about the way in which knowledge

informs sentence understanding. However, some evidence exists that typicality information, in particular, can impact simple language generation tasks. In early work, Rosch (1975) asked one group of subjects to produce sentences containing names of categories like “bird” and “weapon.” The result was often items like “Twenty or so birds often perch on the telephone wires outside my window and twitter in the morning.” Rosch substituted for the category name in these sentences either the name of a typical member of the category (“sparrow”) or an atypical member (“turkey”). An independent group of subjects then judged how natural or peculiar the resulting sentences were, and they gave higher naturalness ratings to the sentences with typical instances (“Twenty or so robins often perch on the telephone wires...”) than sentences with atypical instances (“Twenty or so turkeys often perch on the telephone wires...”). Typicality therefore seems to inform simple sentence production.

Returning to concept combination, we might be able to salvage some of the models in Table 11.1 if we view the models as describing a particular stage of the comprehension process. Theories like Smith et al.’s (1988) Selective Modification Model, for example, might give the right account of concept combination for a stage that is not too early (so some typicality information can enter the picture) and not too late (so higher level inferences do not have time to override typicality).

GENERIC NOUN PHRASES

Even if we abandon typicality structures as accounts of comprehension, however, it does not follow that these structures are useless in explaining all linguistic phenomena. Recent research on two fronts seems to us to hold promise for interactions between psychological and linguistic theories. First, there are special constructions in English that, roughly speaking, describe default characteristics of members of a category. For example, “Lions have manes” means (approximately) that having a mane is a characteristic property of lions. Bare plural noun phrases (i.e., plurals with no preceding determiners) are one way to convey such a meaning as we have just seen, but indefinite singular sentences (“A lion has a mane”) and definite singular sentences (“The lion—*Panthera leo*—has a mane”) can also convey the same idea in some of their senses. These generic sentences seem to have normative content. Unlike “Most lions have manes,” generic sentences seem to hold despite the existence of numerous exceptions;

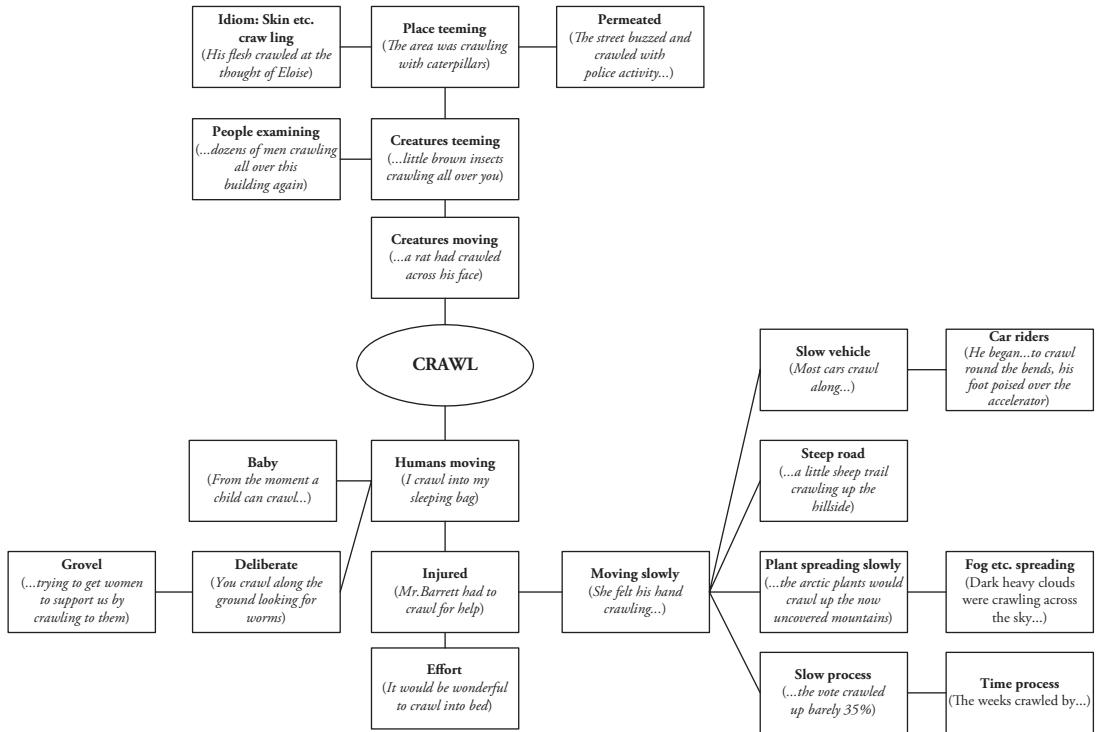

Fig. 11.2 The meaning of crawl: Why it is difficult to distinguish different related meanings (polysemy) from different uses of the same meaning (contextual variation) and from different unrelated meanings (homonymy). Adapted from Fillmore & Alking (2000) by permission of Oxford University Press.

“Lions have manes” seems to be true despite the fact that most lions (e.g., female and immature lions) do not have manes (see Krifka et al., 1995, for an introduction to generic sentences, and Leslie, 2008, for one recent account). There is an obvious relation between the truth or acceptability of generic sentences and the typicality structure of categories, since the typical properties of a category are those that appear in true generic sentences. Of course, as Krifka et al. note, this may simply be substituting one puzzle (the truth conditions of generic sentences) for another (the nature of typical properties), but this may be one place where linguistic and cognitive theories might provide mutual insight. Research by Susan Gelman and her colleagues (see Gelman, 2003, for a thorough review) suggests that generic sentences are a frequent way for caregivers to convey category information to children. Four-year-olds differentiate sentences with bare plurals (“Lions have manes”) from those explicitly quantified by “all” or “some” in comprehension, production, and inference tasks (Gelman, Star, & Flukes, 2002; Hollander, Gelman, & Star, 2002). It would be of interest to know, however, exactly

what meaning children and adults attach to generic sentences.

POLYSEMY

A second place to look for linguistic-cognitive synergy is in an account of the meanings of polysemous words. Linguists (e.g., Lyons, 1977) traditionally distinguish homonyms like “mold,” which have multiple unrelated meanings (e.g., a form into which liquids are poured vs. a fungus) from polysemous terms like “line” that have multiple related meanings (e.g., a geometric line vs. a fishing line vs. a line of people, etc.). What makes polysemous terms interesting to psychologists in this area is that the relations among their meanings often possess a kind of typicality structure of their own. This is the typicality of the senses of the expression rather than the typicality of the referents of the expression, making it a kind of higher level typicality phenomenon. Figure 11.2 illustrates such a structure for the polysemous verb “crawl,” as analyzed by Fillmore and Atkins (2000). A rectangle in the figure represents each sense or use and includes both a brief label indicating its distinctive property and an example

from British corporuses. According to Fillmore and Atkins, the central meanings for *crawl* have to do with people or creatures moving close to the ground (these uses appear in rectangles with darker outlines in the figure). But there are many peripheral uses, for example, time moving slowly ("The hours seemed to crawl by") and creatures teeming about ("The picnic supplies crawled with ants"). The central meanings are presumably the original ones, with the peripheral meanings derived from these by a historical chaining process. Malt, Sloman, Gennari, Shi, and Wang (1999) have observed similar instances of chaining in people's naming of artifacts, such as bottles and bowls, and it is possible that the gerrymandered naming patterns reflect the polysemy of the terms (e.g., "bottle") rather than different uses of the same meaning. As Figure 11.2 shows, it is far from easy to distinguish different related meanings (polysemy) from different uses of the same meaning (contextual variation) and from different unrelated meanings (homonymy).

Some research has attacked the issue of whether people store each of the separate senses of a polysemous term (Klein & Murphy, 2002) or store only the core meaning, deriving the remaining senses as needed for comprehension (Caramazza & Grober, 1976; Franks, 1995). Conflicting evidence in this respect may be due to the fact that some relations between senses seem relatively productive and derivable (*regular* polysemy), such as the relationship between terms for animals and their food products, e.g., the animal meaning of "lamb" and its menu meaning), while other senses seem ad hoc (e.g., the relation between "crawl" = *moving close to the ground* and "crawl" = *teeming with people* in Fig. 11.2). Multiple mechanisms are likely to be at work here.

SUMMARY

We do not mean to suggest that the only linguistic applications of psychologists' "concepts" are in dealing with interpretation, generic phrases, and polysemy. Far from it. There are many areas, especially in developmental psycholinguistics, that hold the promise of fruitful interactions but that we cannot review here. Nor are we suggesting that investigators in this area give up the attempt to study the use of concepts in immediate comprehension. But concepts for comprehension seem to have different properties from the concepts that figure in the other functions we have discussed, and researchers need to direct more attention to the interface between them.

Theories, Modules, and Psychometaphysics

We have seen, so far, some downward pressure on cognitive theories to portray human concepts as mental entities that are as simple and streamlined as possible. This pressure comes not only from the usual goal of parsimony but also from the role that concepts play in immediate language comprehension. But there is also a great deal of upward pressure, pressure to include general knowledge about a category as part of its representation. For example, the presence of emergent properties in concept combinations suggests that people use background knowledge in interpreting these phrases. Similarly, people may bring background knowledge and theories to bear in classifying things, even when they know a decision rule for the category. Consider psychodiagnostic classification. Although *DSM-IV* (the official diagnostic manual of the American Psychological Association) is atheoretical and organized in terms of rules, there is clear evidence that clinicians develop theories of disorders and, contra *DSM-IV*, weight causally central symptoms more than causally peripheral symptoms (e.g., Kim & Ahn, 2002a). The same holds for laypeople (e.g. Furnham, 1995; Kim & Ahn, 2002b).

In this section we examine the consequences of expanding the notion of a concept to include theoretical information about a category. In the case of the natural categories, this information is likely to be causal (see Buehner & Cheng, Chapter 12), since people probably view physical causes as shaping and maintaining these categories. For artifacts, the relevant information may be the intentions of the person creating the object (e.g., Bloom, 1996). The issues we raise here concern the content and packaging of these causal beliefs.

The first of these issues focuses on people's beliefs about the locus of these causal forces—what we called "psychometaphysics." At one extreme, people may believe that each natural category is associated with a single source, concentrated within a category instance, that controls the nature of that instance. The source could determine, among other things, the instance's typical properties, its category membership, and perhaps even the conditions under which it comes into and goes out of existence. Alternatively, people may believe that the relevant causal forces are more like a swarm—not necessarily internal to an instance, nor necessarily emanating from a unitary spot—but shaping the category in aggregate fashion.

The second issue has to do with the cognitive divisions that separate beliefs about different sorts

of categories. People surely think that the causes that help shape daisies differ in type from those that shape teapots. Lay theories about flowers and other living things include at least crude information about specifically biological properties, whereas lay theories of teapots and other artifacts touch instead on intended and actual functions. But how deep do these divisions go? On the one hand, beliefs about these domains could be modular (relatively clustered, relatively isolated), innate, universal, and local to specific brain regions. On the other, they may be free-floating, learned, culturally specific, and distributed across cortical space. This issue is important to us because it ultimately affects whether we can patch up the “semantic memory” marriage.

Essentialism and Sortalism

PSYCHOLOGICAL ESSENTIALISM

What is the nature of people’s beliefs about the causes of natural kinds? One hypothesis is that people think there is something internal to each member of the kind—an essence—that is responsible for its existence, category membership, typical properties, and other important characteristics (e.g., Atran, 1998; Gelman & Hirschfeld, 1999; Medin & Ortony, 1989). Of course, it is unlikely that people think that all categories of natural objects have a corresponding essence. There is probably no essence of pets, for example, that determines an animal’s pet status. But for basic-level categories, such as dogs or gold or daisies, it is tempting to think that something in the instance determines crucial aspects of its identity. Investigators who have accepted this hypothesis are quick to point out that the theory applies to people’s beliefs and not to the natural kinds themselves. Many biologists and philosophers of science agree that essentialism will not account for the properties and variations that real species display, in part because the very notion of species is not coherent (e.g., Ghiselin, 1981; Hull, 1999). Chemical kinds (e.g., gold) may conform much more closely to essentialist doctrine (see Sober, 1980). Nevertheless, expert opinion is no bar to laypersons’ essentialist views on this topic. In addition, psychological essentialists have argued that people probably do not have a fully fleshed out explanation of what the essence is. What they have, on this hypothesis, is an IOU for a theory: a belief that there must be *something* that plays the role of essence, even though they cannot supply a description of it (Medin & Ortony, 1989).

Belief in a hypothetical, minimally described essence may not seem like the sort of thing that could do important cognitive work, but psychological essentialists have pointed out a number of advantages that essences might afford, especially to children. The principle advantage may be induction potential. Medin (1989) suggested that essentialism is poor metaphysics but good epistemology in that it may lead people to expect that members of a kind will share numerous, unknown properties—an assumption that is sometimes correct. In short, essences have a motivational role to play in getting people to investigate kinds’ deeper characteristics. Essences also explain why category instances seem to run true to type—for example, why the offspring of pigs grow up to be pigs rather than cows. They also explain the normative character of kinds (e.g., their ability to support inductive arguments and their ability to withstand exceptions and superficial changes), as well as people’s tendency to view terms for kinds as well defined.

Evidence for essentialism tends to be indirect. There are results that show that children and adults do in fact hold the sorts of beliefs that essences can explain. By the time they reach first or second grade, children know that animals whose insides have been removed are no longer animals, that baby pigs raised by cows grow up to be pigs rather than cows (Gelman & Wellman, 1991), and that cosmetic surgery does not alter basic-level category membership (Keil, 1989). Research on adults also shows that “deeper” causes—those that themselves have few causes but many effects—tend to be more important in classifying than shallower causes (Ahn, 1998; Sloman, Love, & Ahn, 1998; but see Rehder, 2009).

However, results like these are evidence for essence only if there are no better explanations for the same results, and it seems at least conceivable that children and adults make room for multiple types and sources of causes that are not yoked to an essence. According to Strevens (2000), for example, although people’s reasoning and classifying suggest that causal laws govern natural kinds, it may be these laws alone, rather than a unifying essence, that are responsible for the findings. According to essentialists, people think there is something (an essence) that is directly or indirectly responsible for the typical properties of a natural kind. According to Strevens’ minimalist alternative, people think that for each typical property there is something that causes it, and that something may vary for different properties.

Essentialists counter that both children and adults assume a causal structure consistent with essence (see Gelman & Frazier, Chapter 26; also see Braisby, Franks, & Hampton, 1996; Diesendruck & Gelman, 1999; Kalish, 1995, 2002, for debate on this issue). One strong piece of evidence for essentialism is that participants who have successfully learned artificial, family-resemblance categories (i.e., those in which category members have no single feature in common) nevertheless believe that each category contained a common, defining property (Brooks & Wood, as cited by Ahn et al., 2001). Other studies with artificial “natural” kinds have directly compared essentialist and nonessentialist structures but have yielded mixed results (e.g., Rehder & Hastie, 2001). It is possible that explicit training overrides people’s natural tendency to think in terms of a common cause.

In the absence of more direct evidence for essence, the essentialist-minimalist debate is likely to continue (see Ahn et al., 2001; Sloman & Malt, 2003; and Strevens, 2001, for the latest salvos in this dispute). Indeed, the authors of this chapter are not in full agreement. Medin finds minimalism too unconstrained, whereas Rips opines that essentialism suffers from the opposite problem. Adding a predisposition toward parsimony to the minimalist view seems like a constructive move, but such a move would shift minimalism considerably closer to essentialism. Ultimately the issue boils down to determining to what extent causal understandings are biased toward the assumption of a unique, central cause for a category’s usual properties.

SORTALISM

According to some versions of essentialism, an object’s essence determines not only which category it belongs to but also the object’s very identity. According to this view, it is by virtue of knowing that Fido is a dog that you know (in principle) how to identify Fido over time, how to distinguish Fido from other surrounding objects, and how to determine when Fido came into existence and when he will go out of it. In particular, if Fido happens to lose his dog essence, then Fido not only ceases to be a dog, he ceases to exist entirely. As we noted in discussing essentialism, not all categories provide these identity conditions. Being a pet, for example, does not lend identity to Fido, since he may continue to survive in the wild as a non-pet. According to one influential view (Wiggins, 1980), the critical identity-lending category is the one that answers the

question *What is it?* for an object; and since basic-level categories are sometimes defined in just this way, basic-level categories are the presumed source of the principles of identity. (Theories of this type usually assume that identity conditions are associated with just one category for each object, since multiple identity conditions lead to contradictions; see Wiggins, 1980). Contemporary British philosophy tends to refer to such categories as *sortals*, and we will adopt this terminology here.

Sortalism plays an important role in current developmental psychology because developmentalists have used children’s mastery of principles of identity to decide whether these children possess the associated concept. Xu and Carey (1996) staged for infants a scene in which (e.g.) a toy duck appears from one side of an opaque screen and then returns behind it. A toy truck next emerges from the other side of the screen and then returns to its hidden position. Infants habituate after a number of encores of this performance, at which time the screen is removed to reveal both the duck and truck (the scene that adults expect) or just one of the objects (duck or truck). Xu and Carey reported that younger infants (e.g., 10-month-olds) exhibit no more surprise at seeing one object than at seeing two, while older infants (and adults) show more surprise at the one-object tableau. Xu and Carey also showed in control experiments that younger and older infants perform identically if they see a preview of the two starring objects together before the start of the performance. The investigators infer that the younger infants lack the concepts DUCK and TRUCK, since they are unable to use a principle of identity for these concepts to discern that a duck cannot turn into a truck while behind the screen. Xu and Carey’s experiments have sparked a controversy about whether the experimental conditions are simple enough to allow babies to demonstrate their grip on object identity (see Wilcox & Baillargeon, 1998; Xu, 2003), but for present purposes what is important is the assumption that infants’ inability to reidentify objects over temporal gaps implies lack of the relevant concepts.

Sortal theories impose strong constraints on some versions of essentialism. We noted that one of essentialism’s strong points is its ability to explain some of the normative properties of concepts, for example, the role concepts play in inductive inferences. However, sortalism places some restrictions on this ability. Members of sortal categories cannot lose their essence without losing their existence, even in

counterfactual circumstances. This means that if we are faced with a premise like *Suppose dogs can bite through wire...*, we cannot reason about this supposition by assuming that the essence of dogs has changed in such a way as to make dogs stronger. A dog with changed essence is not a superdog, according to sortalism, but rather has ceased to exist (see Rips, 2001). For the same reason, it is impossible to believe without contradiction both that basic-level categories are sortals and that objects can shift from one basic-level category to another.

These consequences of sortalism may be reasonable ones, but it is worth considering the possibility that sortalism—however well it fares as a metaphysical outlook—incorrectly describes people's views about object identity. Although objects typically do not survive a leap from one basic-level category to another, it may not be impossible for them to do so. Blok, Newman, and Rips (2005) and Liitschwager (1995) gave participants scenarios that described novel transformations that sometimes altered the basic-level category. In both studies, participants were more likely to agree that the transformed object was identical to the original if the transformational distance was small. But these judgments could not always be predicted by basic-level membership.

Results from these sci-fi scenarios should be treated cautiously, but they suggest that people think individual objects have an integrity that does not necessarily depend on their basic-level category. Although this idea may be flawed metaphysics, it is not unreasonable as psychometaphysics. People may think that individuals exist as the result of local causal forces, forces that are only loosely tethered to basic-level kinds. As long as these forces continue to support the individual's coherence, that individual can exist even if it finds itself in a new basic-level category. Of course, not all essentialists buy into this link between sortalism and essentialism. For example, people might believe that individuals have both a category essence *and* a set of historical and other characteristics that make it unique. Gutheil and Rosengren (1996) hypothesize that objects have two difference essences, one for membership and another for identity. Just how individual identity and kind identity play out under these scenarios could then be highly variable.

Domain Specificity

The notion of domain specificity has served to organize a great deal of research on conceptual development. For example, much of the work on

essentialism has been conducted in the context of exploring children's naïve biology (see also Au, 1994; Carey, 1995; Gopnik & Wellman, 1994; Spelke, Phillips, & Woodward, 1995). Learning in a given domain may be guided by certain skeletal principles, constraints, and (possibly innate) assumptions about the world (see Gelman & Coley, 1990; Gelman, 2003; Keil, 1981; Kellman & Spelke, 1983; Markman, 1990; Spelke, 1990). Susan Carey's influential (1985) book presented a view of knowledge acquisition as built on framework theories that entail ontological commitments in the service of a causal understanding of real-world phenomena. Two domains can be distinguished from one another if they represent ontologically distinct entities and sets of phenomena and are embedded within different causal explanatory frameworks. These ontological commitments serve to organize knowledge into domains such as naïve physics (or mechanics), naïve psychology, or naïve biology (e.g., see Au, 1994; Carey, 1995; Gelman & Koenig, 2001; Gopnik & Wellman, 1994; Hatano & Inagaki, 1994; Keil, 1994; Spelke et al., 1995; Wellman & Gelman, 1992). In the following we will focus on one candidate domain, naïve biology.

FOLK BIOLOGY AND UNIVERSALS

There is fairly strong evidence that all cultures partition local biodiversity into taxonomies whose basic level is that of the “generic species” (Atran, 1990; Berlin, Breedlove, & Raven, 1973). Generic species often correspond to scientific species (e.g., elm, wolf, and robin); however, for the large majority of perceptually salient organisms (see Hunn, 1999), such as vertebrates and flowering plants, a scientific genus frequently has only one locally occurring species (e.g., bear, oak). In addition to the spontaneous division of local flora and fauna into generic species, cultures seem to structure biological kinds into hierarchically organized groups, such as white oak/oak/tree. Folk-biological ranks vary little across cultures as a function of theories or belief systems (see Malt, 1994, for a review). For example, in studies with Native American and various U.S. and Lowland Maya groups, correlations between folk taxonomies and classical evolutionary taxonomies of the local fauna and flora average $r = .75$ at the generic-species level and about 0.5 with higher levels included (Atran, 1999; Bailenson et al., 2002; Medin et al., 2002). Much of the remaining variance owes to obvious perceptual biases (Itza' Maya group bats with birds in the same life form) and local

ecological concerns. Contrary to received notions about the history and cross-cultural basis for folk-biological classification, utility does *not* appear to drive folk taxonomies (cf. Berlin et al., 1973).

These folk taxonomies also appear to guide and constrain reasoning. For example, Coley, Medin, and Atran (1997) found that both Itza' Maya and U.S. undergraduates privilege the generic-species level in inductive reasoning. That is, an inference from Swamp White Oak to all White Oaks is little if any stronger than an inference from Swamp White Oak to all Oaks. Above the level of Oak, however, inductive confidence takes a sharp drop. In other words, people in both cultures treat the generic level (e.g., Oak) as maximizing induction potential. The results for undergraduates are surprising, since the original Rosch et al. (1976) basic-level studies had suggested that a more abstract level (e.g., TREE) acted as basic for undergraduates and should have been privileged in induction. That is, there is a discrepancy between results with undergraduates on basicness in naming, perceptual classification, and feature listing, on the one hand, and inductive inference, on the other. Coley et al. suggest that the reasoning task relies on expectations rather than knowledge, and that undergraduates may know very little about biological kinds (see also Wolff, Medin, & Pankratz, 1999). Medin and Atran (2004) caution against generalizing results on biological thought from undergraduates, since most have relatively little firsthand experience with nature.

INTERDOMAIN DIFFERENCES

Carey (1985) argued that children initially understand biological concepts like ANIMAL in terms of folk psychology, treating animals as similar to people in having beliefs and desires. Others (e.g., Keil, 1989) argue that young children do have biologically specific theories, albeit more impoverished than those of adults. For example, Springer and Keil (1989) show that preschoolers think biological properties are more likely to be passed from parent to child than are social or psychological properties. They argue that this implies that the children have a biology-like inheritance theory.

The evidence concerning this issue is complex. (see, e.g., Au & Romo, 1996, 1999; Carey, 1991; Coley, 1995; Gelman, 2003; Hatano & Inagaki, 1996; Inagaki, 1997; Inagaki & Hatano, 1993, 1996, 2002; Johnson & Carey, 1998; Keil, 1995; Keil, Levin, Richman, & Gutheil, 1999; Rosengren,

Gelman, Kalish, & McCormick, 1991; Springer & Keil, 1989, 1991). On one hand, Solomon, Johnson, Zaitchik, and Carey (1996) claim that preschoolers do not have a biological concept of inheritance, because they do not have an adult's understanding of the biological causal mechanism involved. On the other hand, there is growing cross-cultural evidence that 4- to 5-year-old children believe (like adults) that the identity of animals and plants follows that of their progenitors, regardless of the environment in which the progeny matures (e.g., progeny of cows raised with pigs, acorns planted with apple trees) (Atran et al., 2001; Gelman & Wellman, 1991; Sousa et al., 2002). Furthermore, it appears that Carey's (1985) results on psychology versus biology may only hold for urban children who have little intimate contact with nature (Atran et al., 2001; Ross et al., 2003). Altogether, the evidence suggests that 4- to 5-year-old children do have a distinct biology, though perhaps one without a detailed model of causal mechanisms (see Rozenblit & Keil, 2002, for evidence that adults also have only a superficial understanding of mechanisms).

DOMAINS AND BRAIN REGIONS

While some cognitive scientists have argued strongly for the idea that different biological categories, such as animals, are represented in different regions of the brain, we saw earlier that the current evidence favors the hypothesis that these categories are represented in terms of their constituent features (the perceptual-functional hypothesis). There is, however, some evidence for different categories being represented in different brain regions, but the categories involved are not the familiar animals and tools, but rather faces and places.

Consider faces. Why should the category of faces get special treatment in the brain? Because faces are special in a number of ways. First, unlike most categories, faces do not seem to be perceived in terms of their constituent features; rather, the visual perception of a face involves configurational processes, not featural ones (e.g., Tanaka & Farah, 1993; Tanaka & Sengco, 1997). Second, the recognition of a face is substantially disrupted by inverting it, more so than with any other category of objects (Yin, 1969). And lastly, recognition of faces may be more critical to an infant's survival than recognition of just about any other class of objects—the first thing that an infant needs to know is who are its conspecifics, as they are the ones who will take care of the infant.

The neural basis of face recognition and face categorization again are located in the general region responsible for object recognition, the ventral temporal cortex. Within this broad region, faces activate a subregion called the fusiform face area, or FFA (so called because the subregion lies on the fusiform gyrus). The precise location of the FFA varies somewhat from person to person, but it is always in the fusiform gyrus of the temporal cortex (Kanwisher, McDermott, & Chun, 1997). Most important, viewing human faces will activate this subregion more than does viewing any other object, including body parts (e.g., Kanwisher, 2000). Indeed, some studies show that the FFA activates to virtually every presentation of a face, but not at all to many other objects, such as letter strings, animal torsos, and the backs of human heads. Furthermore, activation in the FFA is less when viewing inverted than upright faces, which fits perfectly with the fact that inversion disrupts face recognition. That is, if increased activation in the FFA mediates successful face recognition, then unsuccessful face recognition should go with less activation in the FFA.

Some have argued that the special status of faces—the fact that this domain gets its own specialized chunk of brain—is really due to the fact that we spend so much time recognizing faces that we become experts at it, and it is really the expertise that is responsible for the brain specialization (e.g., Gauthier, Tarr, Anderson, Skudlarski, & Gore, 1999). There is something to this point, as researchers have shown that the FFA is increasingly activated by a novel domain of objects as the subject becomes increasingly expert at discriminating among novel objects with a face-like structure (Gauthier, Anderson, Tarr, Skudlarski, & Gore, 1997). Still, neither such highly practiced objects nor even other kinds of faces, like the faces of dogs, will activate the FFA as much as human faces do (Kanwisher, 2000).

There is also evidence that another subregion of ventral temporal cortex is specialized for the domain of places: landscapes and layouts of buildings. The region is referred to as the “parahippocampal place area,” or PPA (as it is located on the parahippocampal gyrus). Viewing scenes of landscapes or buildings will activate the PPA more than will any other class of objects (Epstein, Harris, Stanley, & Kanwisher, 1999). Faces do not activate the PPA just as places do not activate the FFA. And activation of the place area seems sufficient for one to be able to categorize it as a place.

Will other domain-specific areas be found in the brain? There is suggestive evidence of a “word area” located in the occipital cortex of literate people (distinct from the face and place areas) (e.g., Polk & Farah, 2002). What is interesting about this domain-specific area is that it must be acquired through experience with reading. Like the face and place areas, the word area has been studied more in the context of object recognition than object categorization. So at this point in time, there may a limit to what these domain-specific categories can tell us about the implementation of concepts in the human brain.

DOMAINS AND MEMORY

The issue of domain specificity returns us to one of our earlier themes: Does memory organization depend on meaning? We have seen that early research on semantic memory was problematic in this respect, since many of the findings that investigators used to support meaning-based organization had alternative explanations. General-purpose decision processes could produce the same pattern of results, even if the information they operated on was haphazardly organized. Of course, in those olden days, semantic memory was supposed to be a hierarchically organized network like that in Figure 11.1; the network clustered concepts through shared superordinates and properties but was otherwise undifferentiated. Modularity and domain specificity offer a new interpretation of semantic-based memory structure—a partition of memory space into distinct theoretical domains. Can large-scale theories like these support memory organization in a more adequate fashion than homogeneous networks?

One difficulty in merging domain specificity with memory structure is that domain theories do not taxonomize categories; they taxonomize assumptions. What differentiates domains is the set of assumptions or warrants they make available for thinking and reasoning (see Toulmin, 1958, for one such theory), and this means that a particular category of objects usually falls in more than one domain. To put it another way, domain-specific theories are “stances” (Dennett, 1971) or “construals” (Keil, 1995) that overlap in their instances. Take the case of people. The naive psychology domain treats people as having beliefs and goals that lend themselves to predictions about actions (e.g., Leslie, 1987; Wellman, 1990). The naive physics domain treats people as having properties like mass and velocity that warrant predictions about support and

motion (e.g., Clement, 1983; McCloskey, 1983). The naive law-school domain treats people as having properties, such as social rights and responsibilities, that lead to predictions about obedience or deviance (e.g., Fiddick, Cosmides, & Tooby, 2000). The naive biology domain (at least in the Western adult version) treats people as having properties like growth and self-animation that lead to expectations about behavior and development. In short, each ordinary category may belong to many domains.

If domains organize memory, then long-term memory will have to store a concept in each of the domains to which it is related. Such an approach makes some of the difficulties of the old semantic-memory theories yet more perplexing. Recall the issue of identifying the same concept across individuals, which we discussed earlier (see section on “Concepts as Positions in Memory Structure”). Memory modules have the same problem, but they add to it the dilemma of identifying concepts *within* individuals. How do you know that PEOPLE in your psychology module is the same concept as PEOPLE in your physics module and PEOPLE in your law-school module? Similarity is out (since the modules won’t organize them in the same way), spelling is out (both concepts might be tied to the word “people” in an internal dictionary, but then fungi and metal forms are both tied to the word “mold”), and interconnections are out (since they would defeat the idea that memory is organized by domain). We cannot treat the multiple PEOPLE concepts as independent either, since it is important to get back and forth between them. For example, the rights-and-responsibilities information about people in your law-school module has to get together with the goals-and-desires information about people in your psychology module in case you have to decide, together with your fellow jury members, whether the killing was a hate crime or was committed with malice aforethought.

It is reasonable to think that background theories provide premises or grounds for inferences about different topics, and it is also reasonable to think that these theories have their “proprietary concepts.” But if we take domain-specific modules as the basis for memory structure—as a new semantic memory—we have to worry about nonproprietary concepts, too. We have argued that there must be such concepts, since we can reason about the same thing with different theories. Multiple storage is a possibility, if you are willing to forego memory economy and parsimony, and if you can solve the

identifiability problem that we discussed in the previous paragraph. Otherwise, these domain-independent concepts have to inhabit a memory space of their own, and modules cannot be the whole story.

SUMMARY

We seem to be arriving at a skeptical position with respect to the question of whether memory is semantically organized, but we need to be clear about what is and what is not in doubt. What we doubt is that there is compelling evidence that long-term memory is structured in a way that mirrors lexical structure, as in the original semantic-memory models. We do not doubt that memory reflects meaningful relations among concepts, and it is extremely plausible that these relations depend to some extent on word meanings. For example, there may well be a relation in memory that links the concept TRUCKER with the concept BEER, and the existence of this link is probably due in part to the meaning of “trucker” and “beer.” What is not so clear is whether memory structure directly reflects the sort of relations that, in linguistic theory, organizes the meaning of words (where, e.g., “trucker” and “beer” are probably not closely connected). We note, too, that we have not touched (and we do not take sides on) two related issues, which are themselves subjects of controversy.

One of these residual issues is whether there is a split in memory between (a) general knowledge and (b) personally experienced information that is local to time and place. *Semantic memory* (Tulving, 1972) or *generic memory* (Hintzman, 1978) is sometimes used as a synonym for general knowledge in this sense, and it is possible that memory is partitioned along the lines of this semantic/episodic difference, even though the semantic side is not organized by lexical content. The controversy in this case is how such a dual organization can handle learning of “semantic” information from “episodic” encounters (see Tulving, 1984, and his critics in the same issue of *Behavioral and Brain Sciences* for the ins and outs of this debate).

The second issue that we are shirking is whether distributed brands of connectionist models can provide a basis for meaning-based memory. One reason for shirking is that distributed organization means that concepts like DAISY and CUP are *not* stored according to their lexical content. Instead, parts of the content of each concept are smeared across memory in overlapping fashion. It is possible, however, that at a subconcept level—at the level of

features or hidden units—memory has a semantic dimension, and we must leave this question open.

Conclusions and Future Directions

Part of our charge was to make some projections about the future of research on concepts. We do not recommend a solemn attitude toward our predictions. But there are several trends that we have identified and, barring unforeseen circumstances (never a safe assumption), these trends should continue. One property our nominations share is that they uniformly broaden the scope of research on concepts. Here is our shortlist.

Sensitivity to Multiple Functions

The prototypical categorization experiment involves training undergraduates for about an hour and then giving transfer tests to assess what they have learned. This practice is becoming increasingly atypical, even among researchers studying artificially constructed categories in the lab. Recently researchers have studied functions other than categorization, as well as interactions across functions (see also Solomon et al., 1999).

Broader Applications of Empirical Generalizations and Computational Models

As a wider range of conceptual functions come under scrutiny, new generalizations emerge and computational models face new challenges (e.g., Yamauchi et al., 2002). Both developments set the stage for better bridging to other contexts and applications. This is perhaps most evident in the area of cognitive neuroscience where computational models have enriched studies of multiple categorization and memory systems (and vice versa). Norman, Brooks, Coblenz, and Babcock (1992) provide a nice example of extensions from laboratory studies to medical diagnosis in the domain of dermatology.

Greater Interactions Between Work on Concepts and Psycholinguistic Research

We have pressed the point that research on concepts has diverged from psycholinguistics because two different concepts of concepts seem to be in play in these fields. But it cannot be true that the concepts we use in online sentence understanding are unrelated to the concepts we employ in reasoning and categorizing. There is an opportunity for theorists and experimenters here to provide an account of the interface between these functions. To our knowledge, no one has tried to build a model

that would integrate concept combination over its different stages, but it might be a worthwhile goal to do so. One possibility, for example, is to use sentence comprehension techniques to track the way that the lexical content of a word in speech or text is transformed in deeper processing (see Piñango, Zurif, & Jackendoff, 1999, for one effort in this direction). Another type of effort at integration is Wolff and Song's (2003) work on causal verbs and people's perception of cause, which contrasts predictions derived from cognitive linguistics with those from cognitive psychology.

Greater Diversity of Participant Populations

Although research with undergraduates at major Western universities will probably never go out of style (precedent and convenience are two powerful staying forces), we expect the recent increase to continue in the use of other populations. Work by Nisbett and his associates (e.g., Nisbett, Peng, Choi, & Norenzayan, 2001; Nisbett & Norenzayan, 2002) has called into question the idea that basic cognitive processes are universal, and categories and conceptual functions are basic cognitive functions. In much of the work by Atran, Medin, and their associates, undergraduates are the “odd group out” in the sense that their results deviate from those of other groups. In addition, cross-linguistic studies are often an effective research tool for addressing questions about the relationship between linguistic and conceptual development (e.g., Waxman, 1999).

More Psychometaphysics

An early critique of the “theory theory” is that it suffered from vagueness and imprecision. As we have seen in this review, however, this framework has led to more specific claims (e.g., Ahn’s causal status hypothesis) and the positions are clear enough to generate theoretical controversies (e.g., contrast Smith, Jones, & Landau, 1996, with Gelman, 2000; Booth & Waxman, 2002, 2003, with Smith, Jones, Yoshida, & Colunga, 2003; and Ahn, 1998, with Rehder & Kim, 2006 and Rehder, 2009). It is safe to predict even greater future interest in these questions.

All of the Above in Combination

Concepts and categories are shared by all the cognitive sciences, so there is very little room for researchers to stake out a single paradigm or sub-topic and work in blissful isolation. Although the

idea of a semantic memory uniting memory structure, lexical organization, and categorization may have been illusory, this does not mean that progress will be fostered by ignoring the insights on concepts that these perspectives (and others) provide. We may see further fragmentation in the concepts of concepts, but it will still be necessary to explore the relations among them. Our only firm prediction is that the work we will find most exciting will be research that draws on multiple points of view.

Causal Learning

Patricia W. Cheng *and* Marc J. Buehner

Abstract

This chapter is an introduction to the psychology of causal inference using a computational perspective, with the focus on causal discovery. It explains the nature of the problem of causal discovery and illustrates the goal of the process with everyday and hypothetical examples. It reviews psychological research under two approaches to causal discovery, an associative approach and a causal approach that incorporates causal assumptions in the inference process. The latter approach provides a framework within which to answer different questions regarding causal inference coherently. The chapter ends with a consideration of causality as unfolding over time. We conclude with a sketch of future directions for the field.

Key Words: causal learning, rationality, associative models, causal models, causal Bayes nets, Bayesian causal models, temporal contiguity, causal invariance, intervention, empirical knowledge

Why Causality?

The central question of this chapter is: “How can any intelligent system put on Planet Earth, if given cognitive resources and types of information similar to those available to us, discover how the world works so that it can best achieve its goals?” Before we attempt to answer this question, let us imagine that our cognition were different in various respects. First, suppose we were unable to learn associations between events (i.e., detect statistical regularity in the occurrence of events). We would be unable to predict any events, causal or otherwise. For example, we would be unable to predict that if the traffic light turns red, we should stop or an accident is likely to happen, or that if we hear a knock on our door, someone will be on the other side when we open the door. Nor would we be able to predict the weather, even imperfectly. We would be unable to learn the sequences of sound in language or music, or the meaning of words. We would behave as if we had prosopagnosia, unable to relate our parents’

faces, or the face of the person we have been dating for the past month, to their past history. A nonassociative world would be grim.

Now, imagine a world where we were able to learn associations but unable to reason about causes and effects. What would it be like? In that world, for a child growing up on a farm who has always experienced sunrise after the rooster crows, if the rooster is sick one morning and does not crow, she would predict that the sun would not rise until the rooster crows. Similarly, if the rooster has been deceived into crowing, say, by artificial lighting in the middle of the night, the child would predict that the sun would rise soon after. Notice that under normal conditions noncausal associations do enable one to reliably predict a subsequent event from an observation (e.g., sunrise from a rooster’s crowing, a storm soon to come from a drop in the barometric reading, or from ants migrating uphill). They do not, however, support predictions about the event (e.g., sunrise) when the observation (crowding or no

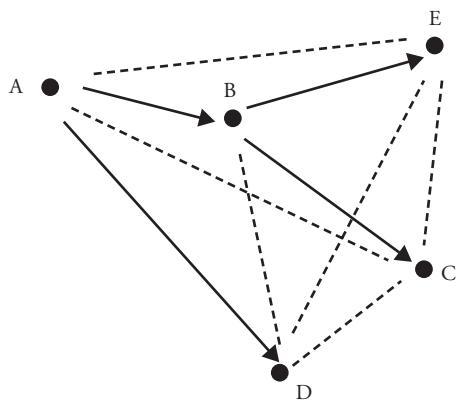

Fig. 12.1 A causal tree and the implied associative links. Nodes represent variables, labeled by letters. Arrows represent direct causal links. Dotted lines represent implied associations, which include indirect causal links as well as associations between direct and indirect effects of a common cause.

crowning) is produced by an action or an extraneous cause (respectively, artificial light and the rooster's sickness). An associative world without causation would be exasperating.

Consider how often we would be wrong, and how inefficient we would be, were we to store all associations, both causal and noncausal. We illustrate the problem with the causal tree in Figure 12.1. In the figure, each node represents a variable, and each arrow represents a causal relation. There are four causal links, but six additional associations (the dotted lines).¹ These additional associations can be inferred from the causal links, and thus are redundant. In an associative world, if information on any of the six extra associations is salient (e.g., as information on a rooster's crowing and sunrise might be), they would be indistinguishable from the causal links. Thus, not only would the extra associations be inefficient to store, many would yield erroneous predictions based on actions. For example, node D in the figure is linked by a single arrow, but by three additional associations, to nodes B, C, and E; manipulating any of these variables would not lead to D, the “desired” outcome predicted by these three associations.

Finally, not only would we be unable to achieve our goals, but we would be unable to structure an otherwise chaotic flux of events into meaningful episodes. We explain events by causation. Returning to our storm example, whereas we might explain that a car skidded and rolled down the mountain-side because of the rainstorm, it would be odd to explain that the car skidded because of the low

barometric reading. Causal explanations are universal, as anthropologists who study everyday narratives across cultures have observed; they serve to imbue life events with an orderliness, to demystify unexpected events, and establish coherence (Ochs & Capps, 2001).

Predicting the Consequences of Actions to Achieve Goals: A Framework for Causal Learning, Category Formation, and Hypothesis Revision

For the just mentioned reasons, it is easy to see why it is important to distinguish between causation and mere association. A less obvious reason, one that has implications for the formulation of the problem to be solved, is that whereas associations are observable, causal relations are inherently unobservable and can only be inferred. For example, one can observe the number of lung cancer patients among cigarette smokers and among nonsmokers and see the association between cigarette smoking and lung cancer, but the association can be causal or noncausal. It may, for example, be due to confounding by the higher incidence of radon in the smokers' dwellings, and the exposure to radon is what caused the smokers' lung cancer. The challenge is how to encapsulate causal relations, even though they are unobservable, so that the causal knowledge can be applied to best achieve desired outcomes.

We have so far implicitly assumed that cause-and-effect variables, such as “sunrise,” “drop in barometric reading,” and “storm,” are predefined, given to the causal learner, and only the relations between them are to be discovered. A more realistic description of the situation is: In order for our causal knowledge to be generalizable from the learning context (e.g., prior experience, whether one's own or that of others, shows that icy roads cause skidding) to the application context (I don't want my car to skid, so I will wait until the ice has melted before I drive), we construct a representation of the world in which cause-and-effect variables are so defined that they enable ideally invariant causal relations to be constructed. As the philosopher C. I. Lewis (1929) observed, “Categories are what obey laws.” Defining the objects, events, and categories linked by causal relations is part of the problem of causal discovery. Fortunately for cognitive psychologists studying human causal discovery, some of the work defining variables is already taken care of by evolution, prewired into our perceptual system and emotions. For example, we see a rooster as figure

against the ground of the farm landscape. Strong gusts of wind alarm us, and getting wet in the rain is unpleasant. But there is definitely remaining work; for example, what determines that “ants migrating uphill” should be defined as a variable?

Whenever we apply causal knowledge to achieve a goal, we are assuming that the causal relations in question remain invariant from the learning context to the application context. Because of our limited causal knowledge, however, a causal relation that we assume to be invariant would no doubt in fact often change (e.g., a scientist might hypothesize “vitamin E has antioxidant effects” but find instead that whereas natural foods rich in vitamin E have antioxidant effects, vitamin E pills do not). The assumption of causal invariance in our everyday application of causal knowledge might seem too strong. Although simplistic as a static hypothesis, however, this assumption is rational as a defeasible default within the dynamic process of hypothesis testing and hypothesis revision. Given our limited access to information at any particular moment, the criterion of causal invariance serves as a compass aimed at formulating the simplest explanation of a phenomenon that allows invariance to obtain (e.g., the scientist might search for other substances in natural foods that in conjunction with vitamin E consistently produce the effects). Observed deviation from the default indicates a need for hypothesis revision, a change in direction aimed at capturing causal invariance (Carroll & Cheng, 2010).

Cheng (2000) showed that an alternative assumption that would also justify generalization of a causal relation regarding an outcome to a new context is that enabling conditions (causal factors in the contextual background interacting with the hypothesized cause) and preventive causes that occur in the background (all of which are often unobserved) occur just as frequently in the generalization context as in the learning context. She also showed that with respect to the accuracy of generalization to new contexts, the two assumptions are equivalent. In the rest of our chapter, we use causal invariance (which we term “independent causal influence” when we define it mathematically) because it is the simpler of the two equivalent conceptions.

Now that we have considered some goals and constraints of causal inference, let us rephrase the question of causal learning with respect to those goals and constraints: How can any intelligent agent given the information and resources available to humans discover ideally invariant causal relations

that support generalization from the learning context to an application context? In particular, would it suffice to have a powerful statistical process that detects regularities among events but lacks any a priori assumptions about how the world works? Because humans have limited access to information, an accompanying question is, What hypothesis testing and revision process would allow the ideally invariant causal relations to be constructed?

By posing our question in terms of discovery, we by no means rule out the possibility that there exist some innate domain-specific biases. Classic studies by Garcia, McGowan, Ervin, and Koelling (1968) demonstrated two such biases. In each of four groups of rats, one of two cues, either a novel size or a novel flavor of food pellets, was conditionally paired with either gastrointestinal malaise induced by X-ray or with pain induced by electrical shock. The combination of flavor and illness produced a conditioned decrement in the amount consumed but that of the size of the pellet and illness did not. Conversely, the combination of size and pain produced hesitation before eating, but flavor and pain did not. Apparently, the novelty had to be of the right kind for effective causal learning regarding the malaise and shock to occur.

Most of what we do know about the world, however, must have been acquired due to experience. How else could we have come to know that exposure to the sun causes tanning in skin but causes bleaching in fabrics? Or come to know that billiard ball A in motion hitting billiard ball B at rest would not jump over B, rebound leaving B still, or explode (Hume, 1739/1888)? Notice that it is not necessary for the causal learner to know *how* sunlight causes tanning in skin or bleaching in fabrics to discover that it does. Neither was it necessary, for that matter, for the rats to know *how* the X-ray or electricity caused their respective effects for their learning to occur. We will return to the issue of adding intervening nodes in a causal network to explain how an outcome is achieved via a causal mechanism.

Proposed Solutions: Two Dominant Approaches

We have only gone so far as posing the problem to be solved. Hopefully, posing the problem clearly will mean much of the work has been done. In the rest of this chapter, we review proposed solutions according to two dominant approaches: the associative approach, including its statistical variants, and the causal approach. We follow each of these

accounts with a review of main empirical tests of the approach. (For a discussion of how the perceptual view [Michotte, 1946/1963], the mechanism view [Ahn, Kalish, Medin, & Gelman, 1995], and the coherence view [Thagard, 2000] relate to these approaches, see Buehner and Cheng [2005].) We then broaden our scope to consider the role of temporal information in causal learning. We end the chapter with a sketch of future research directions.

The Associative Approach

An intuitive approach that has dominated psychological research on learning is the associative approach (e.g., Allan & Jenkins, 1980; Jenkins & Ward, 1965; Rescorla & Wagner, 1972), which traces its roots to the philosopher David Hume (1739/1888). Hume made a distinction between analytic and empirical knowledge, and argued that causal knowledge is empirical. Only experience tells us what effect a cause has. The strong conviction of causality linking two constituent events is but a mental construct. The problem of causal learning posed by Hume radically shaped subsequent research on the topic and set the agenda for the study of causal learning from a cognitive science perspective. Both the associative and causal approaches are predicated on his posing of the problem.

To Hume, the relevant observed aspects of experience that give rise to the mentally constructed causal relations were the repeated association between the observed states of a cause and its effect, their temporal order and contiguity, and spatial proximity. Our examples have illustrated that one can predict a future event from a *covariation*—the concerted variation among events—provided that causes of that event remain unperturbed. Predictions of this kind are clearly useful; we appreciate weather reports, for example. To early associative theorists, causality is nothing more than a fictional epiphenomenon floating unnecessarily on the surface of indisputable facts.² After all, causal relations are unobservable. In fact, Karl Pearson, one of the fathers of modern statistics, subscribed to a positivist view and concluded that calculating correlations is the ultimate and only meaningful transformation of evidence at our disposal: “Beyond such discarded fundamentals as ‘matter’ and ‘force’ lies still another fetish amidst the inscrutable arcana of modern science, namely, the category of cause and effect” (Pearson, 1911, p. iv).

But, as we saw earlier, mere associations are inadequate for predicting the consequences of actions

and would also be inefficient to store. Thus, in addition to dissecting the traditional associative view to understand its shortcomings, we will also consider a more viable augmented variant of the associative view, one similar to how scientists infer causation. The augmented view assumes that rational causal learning requires not only a sophisticated detector of covariations among events but also the use of actions as a causality marker: When the observed states of events are obtained by an action, by oneself or others, intervening in the normal course of events, the observed associations are causal; otherwise, they are noncausal. After all, one can observe that actions are what they are; there is therefore no deviation from Hume’s constraint that causal discovery begins with observable events as input. In entertaining this variant, we are taking the perspective of the design of an intelligent causal learner on our planet, rather than adhering to how the associative view has been traditionally interpreted. This more viable variant of the associative view implicitly underlies the use of associative statistics in typical tests of causal hypotheses in medicine, business, and other fields. It retains the strong appeal of the associative approach, namely, its objectivity. Other things being equal, positing unobservable events, as the causal view does, seems objectionable.

A growing body of research is dedicated to the role of intervention in causal learning, discovery, and reasoning (e.g., Blaisdell, Sawa, Leising, & Waldmann, 2006; Gopnik et al., 2004; Lagnado & Sloman, 2004; Steyvers, Tenenbaum, Wagenmakers, & Blum, 2003). Indeed, the general pattern reported is that observations based on intervention allow causal inferences that are not possible based on mere observations.

A STATISTICAL MODEL

For situations involving only one varying candidate cause, an influential decision rule for more than four decades has been the ΔP rule:

$$\Delta P = P(e^+|c^+) - P(e^+|c^-) \quad (1)$$

according to which the strength of the relation between binary causes c and effects e is determined by their *contingency* or *probabilistic contrast*—the difference between the probabilities of e in the presence and absence of c (see, e.g., Allan & Jenkins, 1980; Jenkins & Ward, 1965). ΔP is estimated by relative frequencies. In our equations, we denote the

		Effect <i>e</i>	
		present	absent
Candidate cause <i>c</i>	present	A	B
	absent	C	D

Fig. 12.2 A standard 2×2 contingency table; *a* through *d* are labels for event types resulting from factorial combination of the presence and absence of cause *c* and effect *e*.

“presence” value of a binary variable by a “+” superscript and the “absence” value by a “−” superscript (e.g., $c+$ denotes the presence of *c*). Figure 12.2 displays a standard *contingency table* where cells *A* and *B* respectively represent the frequencies of the occurrence, and nonoccurrence, of *e* in the presence of *c*; cells *C* and *D* represent, respectively, the frequencies of the occurrence, and of nonoccurrence, of *e* in the absence of *c*.

If ΔP is noticeably positive, then *c* is thought to produce *e*; if it is noticeably negative, then *c* is thought to prevent *e*; and if ΔP is not noticeably different from zero, then *c* and *e* are thought not to be causally related to each other. Several modifications of the ΔP rule to include various parameters have been proposed (e.g., Anderson & Sheu, 1995; Perales & Shanks, 2007; Schustack & Sternberg, 1981; White, 2002). By allowing extra degrees of freedom, these modified models fit certain aspects of human judgment data better than the original rule. Another type of modification is to compute the ΔP value of a candidate cause conditioned on constant values of alternative causes (Cheng & Holyoak, 1995). This modification allows the model to better account for the influence of alternative causes (as illustrated later). Like all other psychological models of causal learning, all variants of the ΔP model assume that the candidate causes are perceived to occur before the effect in question.

AN ASSOCIATIONIST MODEL

In the domain of animal learning, an organism’s capacity to track contingencies in its environment has long been of central interest, and apparent parallels between conditioning and causal

learning have led many researchers (see Shanks & Dickinson, 1987; for a review see De Houwer & Beckers, 2002) to search for explanations of human causal learning in neural-network models that specify the algorithm of learning. The most influential associationist theory, the Rescorla-Wagner (RW) model (Rescorla & Wagner, 1972), and all its later variants, is based on an algorithm of error correction driven by a discrepancy between the expected and actual outcomes. For each learning trial where a cue was presented the model specifies

$$\Delta V_{CS} = \alpha_{CS} \beta_{US} (\lambda - \Sigma V) \quad (2)$$

where ΔV is the change in the strength of a given CS-US association on a given trial (CS stands for conditioned stimulus, e.g., a tone; US stands for unconditioned stimulus, e.g., a foot-shock), α and β represent learning rate parameters reflecting the saliences of the CS and US, respectively, λ stands for the actual outcome of each trial (usually 1.0 if it is present and 0 if it is absent), and ΣV is the expected outcome defined as the sum of all associative strengths of all CSs present on that trial.

For situations involving only one varying cue, its mean weight at equilibrium according to the RW algorithm has been shown to equal ΔP if the value of β remains the same when the US is present and when it is absent for the λ values just mentioned (Chapman & Robins, 1990; Danks, 2003). In other words, this simple and intuitive algorithm elegantly explains why causal learning is a function of contingency. It also explains a range of results for designs involving multiple cues, such as *blocking* (see section on “Blocking” to follow), *conditioned inhibition*, *overshadowing*, and *cue validity* (Miller, Barnet, & Grahame, 1995).

Blocking: Illustrating an Associationist Explanation

“Blocking” (Kamin, 1969) occurs after a cue (*A*) is established as a perfect predictor (*A+*, with “+” representing the occurrence of the outcome), followed by exposure to a compound consisting of *A* and a new, redundant, cue *B*. If *AB* is also always followed by the outcome (*AB+*), cue *B* receives very little conditioning; its conditioning is *blocked* by cue *A*. According to RW, *A* initially acquires the maximum associative strength supported by the stimulus. Because the association between *A* and the outcome

is already at asymptote when B is introduced, there is no error left for B to explain, hence the lack of conditioning to B. What RW computes is the ΔP for B conditioned on the constant presence of A. Shanks (1985) replicated the same finding in a causal reasoning experiment with human participants, although the human responses seemed to reflect uncertainty of the causal status of cue B rather than certainty that it is noncausal (e.g., Waldmann & Holyoak, 1992).

Failure of the RW Algorithm to Track Covariation When a Cue Is Absent

However, Shanks' (1985) results also revealed evidence for *backward blocking*; in fact, there is evidence for backward blocking even in young children (Gopnik et al., 2004). In this procedure, the order of learning phases is simply reversed; participants first learn about the perfect relation between AB and the outcome (AB+), and subsequently learn that A by itself is also a perfect predictor (A+). Conceptually, forward and backward blocking are identical, at least from a causal perspective. A causal explanation might go: If one knows that A and B together always produce an effect, and one also knows that A by itself also always produces the effect, one can infer that A is a strong cause. B, however, might be a cause, even a strong one, or noncausal; its causal status is unclear. Typically, participants express such uncertainty with low to medium ratings relative to ratings for control cues that have been paired with the effect an equal number of times (see Lu, Yuille, Liljeholm, Cheng, & Holyoak, 2008, for a review).

Beyond increasing susceptibility to attention and memory biases (primacy and recency; see, e.g., Dennis & Ahn, 2001), there is no reason why the temporal order in which knowledge about AB and A is acquired should play a role from a rational standpoint. This is not so for the RW model, however. The model assumes that the strength of a cue can only be updated when that cue is present. In the backward blocking paradigm, however, participants *retrospectively* alter their estimate of B on the A+ trials in phase 2. In other words, the ΔP of B, conditioned on the presence of A, decreases over a course of trials in which B is actually absent, and the algorithm therefore fails to track its covariation.

Several modifications of RW have been proposed to allow the strengths of absent cues to be changed, for instance, by setting the learning parameter α negative on trials where the cue is absent: Van Hamme and Wasserman's (1994) modified RW model, Dickinson and Burke's modified sometimes-opponent-process

model (1996), and the comparator hypothesis (Denniston, Savastano, & Miller, 2001; Miller & Matzel, 1988; Stout & Miller, 2007). Such modifications can explain backward blocking and some other findings showing retrospective revaluation (for an extensive review of modifications to associative learning models applicable to human learning see De Houwer & Beckers, 2002). But these modifications also oddly predict that one will have difficulty learning that there are multiple sufficient causes of an effect. For example, if one drinks tea by itself and finds it quenching, but one sometimes drinks both tea and lemonade, then learning subsequently that lemonade alone can quench thirst will cause one to unlearn that tea can quench thirst. Carroll, Cheng, and Lu (2010) found that in such situations human subjects do not revise causal relations for which they have unambiguous evidence (e.g., that tea is quenching).

Causal Inference: Empirical Findings on Humans and Rats

Association does not equal causation, as we illustrated earlier and as every introductory statistics text warns. We now review how humans and rats reason causally rather than merely associatively.

THE DIRECTION OF CAUSALITY

The concept of causality is fundamentally directional (Reichenbach, 1956) in that causes produce effects, but effects cannot produce causes. Thus, whereas we might say that, given the angle of the sun at a certain time of the day, the height of a flagpole explains the length of its shadow on the ground, it would be odd to say the reverse.³ A straightforward demonstration that humans make use of the direction of the causal arrow was provided by Waldmann and Holyoak (1992), who reasoned that only causes, but not effects, should "compete" for explanatory power. If P is a perfect cause of an outcome A, and R, a redundant cue, is only presented preceding A in conjunction with P, one has no basis of knowing to what extent, if at all, R actually produces A. Consequently, the predictiveness of R should be depressed relative to P in a predictive situation. But if P is instead a consistent effect of A, there is no reason why R cannot also be an equally consistent effect of A. Alternative causes need to be kept constant to allow causal inference, but alternative effects do not. Consequently, the predictiveness of R should not be depressed in a diagnostic situation.

This asymmetry prediction was tested with the blocking design, using scenarios to manipulate whether a variable is interpreted as a candidate

cause or as an effect. Participants in Waldmann and Holyoak's (1992) Experiment 3 had to learn the relation between several light buttons and the state of an alarm system. The instructions introduced the buttons as causes for the alarm in the *predictive* condition, but as potential consequences of the state of the alarm system in the *diagnostic* condition.

Waldmann and Holyoak found exactly the pattern of results they predicted: There was blocking in the predictive condition, but not the diagnostic condition. These results reveal that humans make use of the direction of the causal arrow. Follow-up work from Waldmann's lab (Waldmann & Holyoak, 1997; Waldmann, 2000, 2001) as well as others (Booth & Buehner, 2007; López, Cobos, & Caño, 2005) has demonstrated that the asymmetry in cue competition is indeed a robust finding.

CEILING EFFECTS

One might think that augmenting statistical models with intervention would solve the problem of the directionality of causation. But although intervention generally allows causal inference, it does not guarantee it. Consider a food allergy test that introduces samples of food into the body by needle punctures on the skin. The patient may react with hives on all punctured spots, and yet one may not know whether the patient is allergic to any of the foods. Suppose her skin is allergic to needle punctures, so that hives appear also on punctured spots without food. In this example, there is an intervention, but no causal inference regarding food allergy seems warranted (Cheng, 1997). More generally, interventions are subject to the problem of the well-known *placebo effect*, in which the intended intervention is accompanied by a concurrent intervention (as adding allergens into the bloodstream is accompanied by the puncturing the skin), resulting in confounding. Our example illustrates that intervention does not guarantee causal inference. Not only is intervention insufficient for differentiating causation from association, it is also unnecessary. Mariners since ancient times have known that the position and phase of the moon is associated with the rising and falling of the tides (Salmon, 1989). Notably, they did not consider the association causal, and they had no explanation for the ebb and flow of the tides, until Newton proposed his law of universal gravitation. No intervention on the moon and the tides is possible, but there was nonetheless a dramatic change in causal assessment.

A revealing case of the distinction between covariation and causation that does not involve confounding has to do with what is known in experimental design as a *ceiling effect*. We illustrate this effect with the preventive version of it (a principle never covered in courses on experimental design); the underlying intuition is so powerful it needs no instruction. Imagine that a scientist conducts an experiment to find out whether a new allergy drug relieves migraine as a side effect. She follows the usual procedure and administers the medicine to an experimental group of patients, while an equivalent control group receives a placebo. At the end of the study, the scientist discovers that none of the patients in the experimental group but also none of the patients in the control group suffered from migraine. The effect never occurred, regardless of the intervention. If we enter this information into the ΔP rule, we see that $P(e^*|c^*) = 0$ and $P(e^*|c) = 0$, yielding $\Delta P = 0$. According to the ΔP rule and RW, this would indicate that there is no causal relation, that is, the drug does not relieve migraine. Would the scientist really conclude that? No, the scientist would instead recognize that she has conducted a poor experiment and hence withhold judgment on whether the drug relieve migraine. If the effect never occurs in the first place, how can a preventive intervention be expected to prove its effectiveness?

Even rats seem to appreciate this argument (Zimmer-Hart & Rescorla, 1974). For associative models, however, when an inhibitory cue (i.e., one with negative associative strength) is repeatedly presented without the outcome, so that the actual outcome is 0 whereas the expected outcome is negative, the prediction is that the cue reduces its strength toward 0. That is, in a noncausal world, we would unlearn our preventive causes whenever they are not accompanied by a generative cause. For example, if we inoculate child after child with polio vaccine in a country, and there is no occurrence of polio in that country, we would come to believe that the polio vaccine does not function anymore, rather than merely that it is not needed. To the contrary, even for rats, the inhibitory cue retains its negative strength (Zimmer-Hart & Rescorla, 1974). In other words, when an outcome in question never occurs, either when a conditioned inhibitory cue is present or when it is not, rats apparently treat the zero ΔP value as uninformative, retaining the inhibitory status of the cue. In this case, in spite of a discrepancy between the expected and actual outcomes, there is no revision of causal strength.

Table 12.1. Relative Frequencies of Headache and Model Values for Each Hypothetical Study and Each Condition in Liljeholm and Cheng (2007, Experiment 2)

	Study 1		Study 2		Study 3	
	e no A	e A	e no A	e A	e no A	e A
Varying-base rate	16/24	22/24	8/24	20/24	0/24	18/24
Constant base rate	0/24	6/24	0/24	12/24	0/24	18/24

Notice that given the aforementioned hypothetical migraine-relief experiment, from the same exact data, showing that migraine never occurs one can conclude that the drug *does not cause* migraine rather than withhold judgment. Thus, given the exact same covariation, the causal learner can simultaneously have two conclusions depending on the direction of influence under evaluation (generative vs. preventive). Wu and Cheng (1999) conducted an experiment that showed that beginning college students, just like experienced scientists, do and do not refrain from making causal inferences in the generative and preventive ceiling effects situations depending (in opposite ways) on the direction of influence to be evaluated. We are not aware of any convincing modification of associationist models that can accommodate the finding.

DEFINITION OF CAUSAL INVARIANCE: BEYOND AUGMENTATION OF ASSOCIATIONS WITH INTERVENTION AND OTHER PRINCIPLES OF EXPERIMENTAL DESIGN

The same problem that leads to the ceiling effect—namely, the lack of representation of causal relations—manifests itself even when *all* the principles of experimental design are obeyed. Even in that case, the associative view makes anomalous predictions. Liljeholm and Cheng (2007, Experiment 2) presented college students with a scenario involving three studies of a single specific cue A (Medicine A, an allergy medicine) as a potential cause of an outcome (headache as a potential side-effect of the allergy medicine). In the scenario, allergy patients in the studies were randomly assigned to an experimental group that received Medicine A and a control group that received a placebo. In the three studies, the probability of the outcome was higher by, respectively, $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{3}{4}$ in the experimental group than in the control group (i.e., $\Delta P = \frac{1}{4}$, $\frac{1}{2}$, and $\frac{3}{4}$; see Table 12.1). In a varying-base-rate condition, the base rate of headache differed across the three studies. In a constant-base-rate condition, the

base rate of the effect remained constant: Headache never occurred without the medicine. The students were asked to assess whether the medicine interacted with unobserved causes in the background across the studies or influenced headache the same way across them. As intuition suggests, more students in the constant-base-rate condition than in the varying-base-rate condition (13 out of 15, vs. 5 out of 15, respectively) judged the medicine to interact with the background causes.

Because the changes in covariation, as measured by associative models such as ΔP (Jenkins & Ward, 1965) or RW (Rescorla & Wagner, 1972), were the same across conditions, these associative models could not explain the observed pattern of judgments. Thus, even when there is an effective intervention and there is no violation of the principles of experimental design, a statistical account will not suffice. We return to discuss the implications of these results later.

INTERVENTION VERSUS OBSERVATION

Following analogous work on humans (Waldmann & Hagmayer, 2005), Blaisdell et al. (2006) reported a result that challenges associative models: Rats are capable of distinguishing between observations and interventions. In Experiment 1, during a Pavlovian learning phase rats were trained on two interspersed pairs of associations: A light cue (L) is repeatedly followed by either a tone (T) or food (F). If the rats learned that L is a common cause of T and F (see Fig. 12.5a), then in the test phase, observing T should lead them to infer that L must have occurred (because L was the only cause of T), which should in turn lead them to predict F (because L causes F). The number of nose pokes into the food bin measures prediction of F. Consider an alternative condition in which during a test phase the rats learn that pressing on a newly introduced lever turns on T. Because generating T by means of an alternative cause does not influence its cause (L), turning T on by pressing a lever should not lead the rats to

predict F. After the learning phase, rats were allocated to either the observation or the intervention condition. The occurrences of T in the test phase were equated across the two conditions by yoking the observation rats to the intervention rats, so that when a rat in the intervention condition pressed the lever and T followed, a rat in the observation condition heard T at the same time, independently of their lever pressing. L and F never occurred during the test phase. Remarkably, the observation rats nose-poked more often than the intervention rats in the interval following T, even though during the learning phase, T and F never occurred simultaneously on the same trial.

Because all occurrences of L, T, and F were identical across the observation and intervention groups, associations alone cannot explain the difference between observing T and intervening to obtain T. Even if augmented with the assumption that interventions have special status, so that the pairing between lever pressing and T, for example, is learned at a much faster rate than purely observed pairings, there would still be no explanation for why the intervention rats apparently associate T with L less than did the observation rats. We will return to discuss a causal account of the observed difference.

A Causal Approach

A solution to the puzzles posed by the distinction between covariation and causation is to have a leap of faith that causal relations exist, even though they are unobservable (Kant, 1781/1965). This leap of faith distinguishes the diverse variants of the causal approach from all variants of the associative approach. Some psychologists have proposed that human causal learning involves positing candidate causal relations and using deductive propositional reasoning to arrive at possible explanations of observed data (De Houwer, Beckers, & Vandorpe, 2005; Lovibond, Been, Mitchell, Bouton, & Frohardt, 2003; Mitchell, De Houwer, & Lovibond, 2009). Others (Gopnik et al., 2004) have proposed that human causal learning is described by *causal Bayes nets*, a formal framework in which causal structures are represented as directed acyclic graphs (Pearl, 2000; Spirtes, Glymour, & Scheines, 1993/2000; see Sloman, 2005, for a more accessible exposition). The graphs consist of arrows connecting some nodes to other nodes, where the nodes represent variables and each arrow represents a direct causal relation between two variables;

“acyclic” refers to the constraint that the paths formed by the arrows are never loops. Others have proposed a variant of causal Bayes nets that makes stronger causal assumptions; for example, assume as a defeasible default that causes do not interact, and revise that assumption only when there is evidence against it. The stronger assumptions enable the learner to construct causal knowledge incrementally (Buehner, Cheng, & Clifford, 2003; Cheng, 1997, 2000; Griffiths & Tenenbaum, 2005; Lu, Yuille, Liljeholm, Cheng, & Holyoak, 2008; Waldmann, Cheng, Hagmayer, & Blaisdell, 2008).

These variants of the causal view, in addition to their explicit representation of causal relations, share a rational perspective (see Chater & Oaksford, Chapter 2). Thus, they all have a goal of inferring causal relations that best explain observed data. They all make use of deductive inference (for examples of the role of analytic reasoning in empirical learning, see Mermin, 2005; Shepard, 2008). It may be said that they all assume that the causal learner deduces when to induce! Our focus in this chapter is on explaining basic ways in which the causal approach provides a solution to what appears to be impasses from an associative perspective.

A THEORY OF CAUSAL INDUCTION

We use Cheng (1997)’s *causal power* theory (also called the power PC theory, short for “a causal power theory of the probabilistic contrast model”) to illustrate how a causal theory explains many of the puzzles mentioned earlier. This theory starts with the Humean constraint that causality can only be inferred, using observable evidence (e.g., covariations, temporal ordering, and spatial information) as input to the reasoning process. It combines that constraint with Kant’s (1781/1965) postulate that reasoners have a priori notions that types of causal relations exist in the universe.

This unification can best be illustrated with an analogy. The relation between a causal relation and a covariation is like the relation between a scientific theory and a model. Scientists postulate theories (involving unobservable entities) to explain models (i.e., observed regularities or laws); the kinetic theory of gases, for instance, is used to explain Boyle’s law. Boyle’s law describes an observable phenomenon, namely that $\text{pressure} \times \text{volume} = \text{constant}$ (under certain boundary conditions), and the kinetic theory of gases explains in terms of unobservable entities why Boyle’s law holds (gases consist of small particles moving at a speed proportional to their temperature,

and pressure is generated by the particles colliding with the walls of the container). Likewise, a causal relation is the unobservable entity that reasoners strive to infer in order to explain observable regularities between events. This distinction between a causal relation as an unobserved, distal, postulated entity and covariation as an observable, proximal stimulus property implies that there can be situations where evidence is observable, but inference is not licensed, and the goal of causal inference thus cannot be met. Specifically, this means that the desired distal unknown, such as causal strength, is represented as a variable (cf. Doumas & Hummel, Chapter 4; Holyoak & Hummel, 2000), separately from covariation, allowing situations where covariation has a definite value (e.g., 0, as in the ceiling effect), but the causal variable has no value.

How, then, does the causal power theory (Cheng, 1997) go beyond the proximal stimulus and explain the various ways in which covariation does not imply causation? The path through the derivation of the estimation of causal strength reveals the answers. For inferring simple (i.e., elemental) causal relations, the theory partitions all causes of effect e into the candidate cause in question, c , and a , a composite of all (observed and unobserved) alternative causes of e . “Alternative causes” of e include all and only those causes of e that are not on the same causal path to e as c . Thus, c can be thought of as a composite that includes all causes on the same causal path as c preceding e . This partitioning is a general structure that maps onto all learning situations involving candidate causes and effects that are binary variables with a “present” and an “absent” value. We focus on this type of variables because they best reveal how the associative and causal views differ.

The unobservable probability with which c produces e (i.e., the probability that e occurs as a result of c occurring), termed the *generative* causal power of c with respect to e , is represented by a variable, q_c . When $\Delta P \geq 0$, q_c is the desired unknown. Likewise, when $\Delta P \leq 0$, the *preventive* causal power of c , denoted by p_c , is the desired unknown. Two other relevant theoretical unknowns are q_a , the probability with which a produces e when it occurs, and $P(a)$, the probability with which a occurs. The composite a may include unknown or unobservable causes. Because any causal power variable may have a value of 0, or an unknown or undefined value, these variables are merely hypotheses—they do not presuppose that c and a indeed have causal influence on e . The idea of a cause producing an effect and of a cause preventing an effect are

primitives in the theory (see Goodman, Ullman, & Tenenbaum, 2011, and Tenenbaum, Kemp, Griffiths & Goodman, 2011, for an alternative view).

The theory assumes four general simplifying beliefs (Cheng, 1997; Novick & Cheng, 2004):

1) c and a influence e independently,

2) a could produce e but not prevent it,

3) causal powers are independent of the

frequency of occurrences of the causes (e.g., the causal power of c is independent of the frequency of occurrence of c), and

4) e does not occur unless it is caused.

Assumption 1 is a leap of faith inherent to this incremental learning variant of causal discovery. This is the defeasible default assumption we termed “causal invariance” earlier. Two causes influencing effect e “independently” means that the influence of each on e remains unchanged regardless of whether e is influenced by the other cause. Assumption 2 is likewise a default hypothesis, adopted unless evidence discredits it. (Alternative models apply if assumption 1 or 2 is discredited; see Novick & Cheng 2004; see Cheng, 2000, for implications of the relaxation of these assumptions.) This set of assumptions, which is stronger than that assumed in standard Bayes nets, enables causal relations to be learned one at a time, when there is information on only the occurrences of two variables, a single candidate cause and an effect. The type of learning described by the theory therefore requires less processing capacity. It is assumed that, as in associative models, when there is information on which variable is an effect, the causal learner iterates through candidate causes of the effect, grouping all potential causes other than the candidate in question as the composite alternative cause. Otherwise, the causal learner iterates through all possible variable pairs of candidate causes and effects.

These assumptions imply a specific function for integrating the influences of multiple causes (Cheng, 1997; Glymour, 2001), different from the additive function assumed by associative models. For the situation in which a potentially generative candidate cause c occurs independently of other causes, the probability of observing the effect e is given by a noisy-OR function,

$$P(e^+ | c; w_a, q_c) = q_c \cdot c + w_a - q_c \cdot c \cdot w_a \quad (3)$$

where $c \in \{0,1\}$ denotes the absence and the presence of the candidate cause c . Recall that in our

equations we denote the “presence” value of a binary variable by a “+” superscript and the “absence” value by a “−” superscript. In contrast, variables have no superscripts. As just mentioned, variable q_c represents the generative power of the candidate cause c . Because it is not possible to estimate the causal power of unobserved causes, variable w_a represents $P(a^+) \cdot q_a$. In the preventive case, the same assumptions are made except that c is potentially preventive. The resulting noisy-AND-NOT integration function for preventive causes is

$$P(e^+ | c; w^a, p_c) = w_a (1 - p_c \cdot c), \quad (4)$$

where p_c is the preventive causal power of c .

Using these “noisy-logical” integration functions (terminology due to Yuille & Lu 2008), Cheng (1997) derived normative quantitative predictions for judgments of causal strength. Under the aforementioned set of assumptions, the causal power theory explains the two conditional probabilities defining ΔP as follows:

$$P(e^+ | c^+) = q_c + P(a^+ | c^+) \cdot q_a - q_c \cdot P(a^+ | c^+) \cdot q_a \quad (5)$$

$$P(e^+ | c^-) = P(a^+ | c^-) \cdot q_a \quad (6)$$

Equation 5 “explains” that given that c has occurred, e is produced by c or by the composite a , nonexclusively (e is jointly produced by both with a probability that follows from the independent influence of c and a on e). Equation 6 “explains” that given that c did not occur, e is produced by a alone.

Explaining the Role of “No Confounding” and Why Manipulation Encourages Causal Inference But Does Not Guarantee Success

It follows from Equations 3 and 4 that

$$\Delta P_c = q_c + P(a^+ | c^+) \cdot q_a - q_c \cdot P(a^+ | c^+) \cdot q_a - P(a^+ | c^-) \cdot q_a \quad (7)$$

From Equation 7, it can be seen that there are four unknowns: q_c , q_a , $P(a^+ | c^+)$, and $P(a^+ | c^-)$! It follows that in general, despite ΔP having a definite value, there is no unique solution for q_c . This failure to solve for q_c corresponds to our intuition that covariation need not imply causation.

When there is no confounding. Now, in the special case in which a occurs independently of c (e.g., when alternative causes are held constant), $P(a^+ | c^+) = P(a^+ | c^-)$. If one is willing to assume “no confounding,” then making use of Equation 6, Equation 7 simplifies to Equation 8,

$$q_c = \frac{\Delta P}{1 - P(e^+ | c^-)} \quad (8)$$

in which all variables besides q_c are observable. In this case, q_c can be solved. Being able to solve for q_c only under the condition of *independent occurrence* explains why manipulation by free will encourages causal inference in everyday reasoning—alternative causes are unlikely to covary with one’s decision to manipulate. For the same reason, it explains the role of the principle of *control* in experimental design.

At the same time, the necessity of the “*no confounding*” condition explains why causal inferences resulting from interventions are not always correct; although alternative causes are unlikely to covary with one’s decision to manipulate, they still may do so, as our needle-puncture allergy example illustrates. Note that the “*no confounding*” condition is a *result* in this theory, rather than an unexplained axiomatic assumption, as it is in current scientific methodology (also see Dunbar & Klahr, Chapter 35).

An analogous explanation yields p_c , the power of c to prevent e

$$p_c = \frac{-\Delta P}{P(e^+ | c^-)} \quad (9)$$

Griffiths and Tenenbaum (2005) showed that if one represents uncertainty about the estimates of causal power by a distribution of the likelihood of each possible strength given the data, then Equation 8 and 9, respectively, are maximum likelihood point estimates of the generative and preventive powers of the candidate cause; that is, they are the peak of the posterior likelihood distributions.

Explaining Two Ceiling Effects

Equations 8 and 9 explain why ceiling effects block causal inference and do so under different conditions for evaluating generative and preventive causal influence. When the outcome does not occur at either a ceiling (i.e., extreme) level, both equations yield either causal power of 0 when the occurrence of c makes no difference to the occurrence of e ($\Delta P = 0$). When e always occurs (i.e., $P(e^+ | c^+) = P(e^+ | c^-) = 1$) regardless

of the manipulation, however, q_e in Equation 8 (the generative case) is left with an undefined value. In contrast, in the preventive case, when e never occurs (i.e., $P(e^+|c^+) = P(e^+|c^-) = 0$), again regardless of the manipulation, p_e in Equation 9 is left with an undefined value.⁴

As we mentioned, most causes are complex, involving not just a single factor but a conjunction of factors operating in concert, and the assumption that c and a influence e independently may be false most of the time. When this assumption is violated, if an alternative cause (part of a) is observable, the independent influence assumption can be given up for the observable alternative cause, and progressively more complex causes can be evaluated using the same distal approach that represents causal powers (see Novick & Cheng, 2004, for an extension of this approach to evaluate conjunctive causes involving two factors). Even if alternative causes are unknown, however, Cheng (2000) showed that as long as they occur with about the same probability in the learning context as in the generalization context, predictions according to simple causal power involving a single factor will hold.

Some have claimed that the causal power approach cannot account for reasoning that combines observations with interventions. As just shown, however, this approach explains the role of interventions in causal learning and how it differs from observation. Likewise indicating that this approach readily accommodates the combination, Waldmann et al. (2008) derived an equation under the causal power assumptions that explains Blaisdell et al.'s results regarding the distinction between observations and interventions in diagnostic reasoning.

Experimental Tests of a Causal Approach

We examine three findings in support of the causal approach. None of these findings can be explained by the associative view, even when augmented with the assumption that only interventions enable causal inference. The first two findings test the two leaps of faith: that causal relations exist and that they are invariant across contexts. The first finding concerns the independent causal influence assumption as manifested in a qualitative pattern of the influence of $P(e^+|c^+)$, the base rate of e , for candidate causes with the same ΔP . The second illustrates the parsimony of a causal explanation that assumes independent causal influence across different types of "effect" variables, specifically, dichotomous and continuous (Beckers, De Houwer, Pineno, & Miller,

2005; Beckers, Miller, De Houwer, & Urushihara, 2006; Lovibond et al., 2003). The third concerns the test reviewed earlier of the distinction between observation and intervention ("seeing" vs. "doing") in diagnostic causal inference (Blaisdell et al., 2006; Waldmann & Hagmayer, 2005). We consider explanations of this distinction as an illustration of the compositionality of the causal view and of the role of deductive reasoning in causal inference.

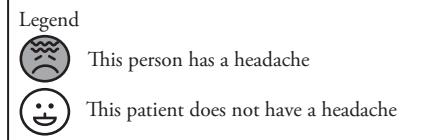

THE INDEPENDENT CAUSAL INFLUENCE ASSUMPTION AFFECTS CAUSAL JUDGMENTS: BASE-RATE INFLUENCE ON CONDITIONS WITH IDENTICAL ΔP

As we noted, a major purpose of causal discovery is to apply the acquired causal knowledge to achieve goals, and that the independent causal influence assumption is a leap of faith that justifies generalization from the learning context to the application context. Here, we see that the assumption leads to causal judgments that differ from those predicted by associative models, even those augmented with a privileged status for interventions and other principles of experimental design. In other words, this assumption not only affects the application of causal knowledge, it affects the very discovery of that knowledge itself.

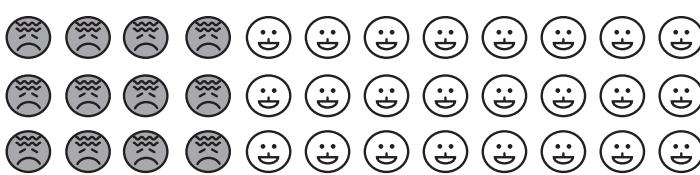

Do people have this leap of faith? Let us examine the predictions based on the causal power assumptions in greater detail. If we consider Equation 8, for any constant positive ΔP , generative causal ratings should *increase* as $P(e^+|c^+)$ increases. Conversely, according to Equation 9, for any constant negative ΔP , preventive causal ratings should *decrease* as $P(e^+|c^-)$ increases. On the other hand, according to both equations, zero contingencies should be judged as noncausal regardless of the base rate of e except when the base rate is at the respective ceiling levels.

No associative model of causal inference, descriptive or prescriptive, predicts this qualitative pattern of the influence of the base rate of e . Normative models are symmetric around the probability of .5 and therefore do not predict an asymmetric pattern either for generative causes alone or for preventive causes alone. Although some psychological associative learning models can explain one or another part of this pattern given felicitous parameter values, the same parameter values will predict notable deviations from the rest of the pattern. For example, in the RW, if $\beta_{us} > \beta_{-us}$ causal ratings for generative and preventive causes will *both* increase as base-rate increases, whereas they will *both* decrease as base-rate

increases if the parameter ordering was reversed. No consistent parameter setting will predict opposite trends for generative as for preventive causes for the same change in the base rate of e . Another prominent associative learning model, Pearce's (1987) model of stimulus generalization, can account for opposite base rate influences in positive and negative contingencies if the parameters are set accordingly, but this model would then predict a base-rate influence on noncontingent conditions.

Figure 12.3 illustrates the intuitiveness of a deviation from ΔP . The reasoning is counterfactual. $P(e^+|c^-)$, 1/3 in the figure, estimates the "expected" probability of e in the presence of c , if c had been absent so that only causes other than c exerted an influence on e . A deviation from this counterfactual probability is evidence for c being a simple cause of e . Under the assumption that the patients represented in the figure were randomly assigned to the two groups, one that received the drug and another that did not, one would reason that about 1/3 of the patients in the "drug" group would be expected to have

headache if they had not received the drug. For the remaining patients—the 2/3 who did not have already have headaches caused by other factors—the drug would be the sole cause of headaches. In this subgroup, headache occurred in 3/4 of the patients. One might therefore reason, one's best guess for the probability of the drug producing headache is 3/4. If one assumes that for every patient in the control group, regardless of whether the patient had a headache, the drug causes headache with a probability of 3/4, this estimate would result. Among those who already had a headache produced by alternative causes, headache due to the drug is not observable.

In contrast, consider what estimate would result if one assumes instead that the drug causes headache with a probability of 1/2, the estimated causal strength according to associative models such as the ΔP model. Applying that probability to every patient, one's best guess would be that 2/3 of the patients would have headaches after receiving the medicine, rather than the 5/6 shown in Figure 12.3. As should be clear, associative models give estimates

that are inconsistent with the assumption that the causes involved influenced headache independently, even though the additivity in those models is generally assumed to represent independence, and thus to justify generalization to new contexts. This inconsistency, due to the outcome variable being dichotomous, leads to irrational applications of causal knowledge to achieve desired outcomes.

Are people rational or irrational in their estimation of causal strength? To discriminate between the causal power theory and the associative approach, Buehner, Cheng, and Clifford (2003, Experiment 2) made use of the pattern of causal-strength predictions according to Equations 8 and 9 just discussed. They gave subjects a task of assessing whether various allergy medicines have a side effect on headaches, potentially causing headaches or preventing them, when presented with fictitious results of studies on allergy patients (see Fig. 12.3 for an example) in which the patients were randomly assigned to two groups, one receiving the medicine and the other not. The subjects were also asked to rate the causal strengths of each candidate after viewing the results for each fictitious study, using a frequentist counterfactual causal question that specified a novel transfer context: “Imagine 100 patients who do *not* suffer from headaches. How many would have headaches if given the medicine?” The novel context for assessing generative causal power, as just illustrated, is one in which there are no alternative generative causes of headache. By varying the base rate of the target effect, for both generative and preventive causes, the experiment manipulated (1) causal power while keeping ΔP constant, (2) ΔP while keeping causal power constant. The experiment also manipulated the base rate of e for noncontingent candidate causes. Their results clearly indicate that people make the leaps of faith assumed by the causal power theory, contrary to the predictions of all associative models, including normative associative models.

INTEGRATING CAUSAL REPRESENTATION WITH BAYESIAN INFERENCE: REPRESENTING UNCERTAINTY AND EVALUATING CAUSAL STRUCTURE

The reader might have noticed that, just like the ΔP rule, the point estimate of causal power in the causal power theory (Equations 8 and 9) is insensitive to sample size. As initially formulated, the theory did not provide any general account of how uncertainty impacts causal judgments. The point estimates are the most likely strength of the causal link that would have produced the observed data, but causal links with other

strength values, although less likely to have produced the data, could well have also, for smaller sample sizes more so than for larger sizes. The lack of an account of uncertainty in early models of human causal learning, together with methodological problems in some initial experiments testing the causal power theory (see Buehner et al., 2003), contributed to prolonging the debate between proponents of associationist treatments and of the causal power theory. For some data sets (e.g., Buehner & Cheng, 1997; Lober & Shanks, 2000), human causal-strength judgments for some conditions were found to lie intermediate between the values predicted by causal power versus ΔP . This pattern was especially salient for studies in which the causal question, which was ambiguously worded, could be interpreted to concern confidence in the existence of a causal link. Intriguingly, a subtle, statistically insignificant, but consistent trend toward this pattern seemed to occur even for the disambiguated counterfactual question illustrated earlier. These deviations from the predictions of the causal power theory perhaps reflect the role of uncertainty, which is outside the scope of the theory.

An important methodological advance in the past decade is to apply powerful Bayesian probabilistic inference to causal graphs to explain psychological results (e.g., Griffiths & Tenenbaum, 2005; Lu et al., 2008; Tenenbaum et al., 2011; see Griffiths, Tenenbaum, & Kemp, Chapter 3; for a review of recent work, see Holyoak & Cheng, 2011). This new tool enables rationality in causal inference to be addressed more fully. For example, it enables a rich representation of uncertainty and a formulation of qualitative queries regarding causal structure.

Griffiths and Tenenbaum (2005; Tenenbaum & Griffiths, 2001) proposed the *causal support* model, a Bayesian model that addresses the causal query, termed a “structure” judgment, which aims to answer, “How likely is it that a causal link exists between these two variables?” This is in contrast to the causal query regarding causal strength that has been emphasized in previous psychological research on causal learning. Strength judgment concerns the weight on a causal link, which aims to answer the query, “What is the probability with which a cause produces (alternatively, prevents) an effect?”

In terms of the graphs in Figure 12.4, the causal support model aims to account for judgments as to whether a set of observations (D) was generated by Graph 1, a causal structure in which a link may exist between candidate cause C and effect E or by a causal structure in which no link exists between C and E .

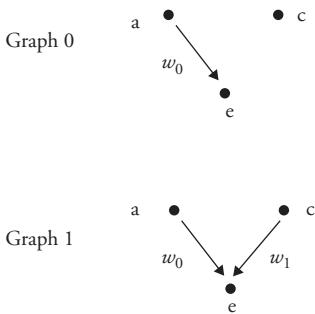

Fig. 12.4 Candidate causal structures varying in whether c causes e .

(Graph 0). Causal-strength models, by contrast, aim to account for people's best estimates of the weight w_1 on the link from C to effect E in Graph 1 that generated D , with w_1 ranging from 0 to 1.

In the causal support model, the decision variable is based on the posterior probability ratio of Graphs 1 and 0 by applying Bayes' rule. Support is defined as:

$$\text{support} = \log \frac{P(D | \text{Graph1})}{P(D | \text{Graph0})}. \quad (10)$$

ASSOCIATIVE VERSUS CAUSAL BAYESIAN MODELS: UNIFORM VERSUS SPARSE AND STRONG PRIORS

Note that adopting Bayesian inference is entirely orthogonal to the longstanding debate between causal and associationist approaches. Because mathematics is a tool rather than an empirical theory, the Bayesian approach can be causal or associative depending on whether causal assumptions are made, even while they are applied to supposedly causal graphs. As Griffiths and Tenenbaum (2005) had noted, a Bayesian model can incorporate either the noisy-logical integration functions derived from the causal power theory or the linear function underlying the Rescorla-Wagner model and the ΔP rule. In addition, a Bayesian analysis can be applied to both strength and structure judgments, as well as to other types of causal queries, such as causal attribution. For strength judgments, rather than basing predictions on the peak of the posterior distribution of w_1 in Graph 1, which corresponds to causal power and ΔP according to the respective models, a natural Bayesian extension of the causal power theory would base predictions on other functions of the posterior distribution of w_1 , such as its mean. Thus, for the fictitious data regarding the side

effect of an allergy medicine in Figure 12.3, rather than estimating that the medicine causes headache with a probability of $3/4$ or $1/2$, as predicted by the causal and associative causal-strength models, respectively, the estimate would fall slightly below $3/4$, in between those estimates.

Lu et al. (2008) developed and compared several variants of Bayesian models as accounts of human judgments about both strength and structure. In addition to directly comparing predictions based on these alternatives, Lu et al. considered two different sets of priors on causal strength. One possible prior is simply a uniform distribution, as assumed in the causal support model. The alternative "generic" (i.e., domain-general) prior tested by Lu et al. is based on the assumption that people prefer parsimonious causal models (Chater & Vitányi, 2003; Lombrozo, 2007; Novick & Cheng, 2004). Sparse and strong (SS) priors imply that people prefer causal models that minimize the number of causes of a particular polarity (generative or preventive) while maximizing the strength of each individual cause that is in fact potent (i.e., of nonzero strength).

The sparse and strong priors, although admitted post hoc, point to the role of parsimony in explanation, an interesting issue for future research. When one is presented with a Necker cube, for example, one perceives two possible orientations. The human perceptual system has implicitly screened out the infinitely many other possible non-cube-shaped objects that would project the same eight corners onto our retina. The visual system makes a parsimony assumption: It favors the simplest "explanations" of the input on our retina. The human causal learning appears to similarly favor parsimonious causal explanations.

For all four Bayesian models, Lu et al. (2008) compared the average observed human strength rating for a given contingency condition with the mean of w_1 computed using the posterior distribution. Model fits revealed that the two causal variants based on the noisy-logical integration function were much more successful overall than the associative variants. For datasets from a meta-analysis based on 17 experiments selected from 10 studies in the literature (Perales & Shanks, 2007; see also Hattori & Oaksford, 2007), the causal Bayesian models (with one or zero free parameters) performed at least as well as the most successful nonnormative model of causal learning (with four free parameters) and much better than the Rescorla-Wagner model. Thus, although both causal and associative

approaches can be given a Bayesian formulation, the empirical tests of human causal learning reported by Lu et al. favor the causal Bayesian formulation, providing further evidence for the rationality of human causal inference.

Lu et al. (2008) also evaluated structure analogs of the two causal variants of Bayesian strength models as accounts for observed structure judgments from experiments in which participants were explicitly asked to judge whether the candidate was indeed a cause. Relative to the support model, human reasoners appear to place greater emphasis on causal power and the base rate of the effect, and less emphasis on sample size.

THE INDEPENDENT CAUSAL INFLUENCE ASSUMPTION FOR DICHOTOMOUS AND CONTINUOUS OUTCOME VARIABLES

Across multiple studies on humans (Beckers, de Houwer, Pineno, & Miller, 2005; De Houwer, Beckers, & Glaudier, 2002; Lovibond et al., 2003) and even rats (Beckers, Miller, De Houwer, & Urushihara, 2006), an intriguing set of findings has emerged, showing that information regarding the additivity of the causal influences of two causes and the range of magnitudes of the outcome both influence judgments regarding unrelated candidate causes of that outcome. We illustrate the finding with parts of a broader study by Lovibond et al. (2003). In a backward blocking design, cues A and B (two food items) in combination were paired with an outcome (an allergic reaction); in a second phase, cue B alone was paired with the outcome. Thus, target cue A made no difference to the occurrence of the outcome (holding B constant, there was always an allergic reaction regardless of whether A was there). The critical manipulation in Lovibond et al. was a “pretraining compound” phase during which one group of subjects, the *ceiling* group, saw that a combination of two allergens produced an outcome at the same level (“an allergic reaction”) as a single allergen (i.e., the ceiling level). In contrast, the *nonceiling* group saw that a combination of two allergens produced a stronger reaction (“a STRONG allergic reaction”) than a single allergen (“an allergic reaction”). Following this pretraining phase, all subjects were presented with information regarding novel cues in the main training phase. Critically, the outcome in this training phase always only occurred at the intermediate level (“an allergic reaction”), both for subjects in the *ceiling* and *nonceiling* groups.

As a result of pretraining, however, subjects’ perception of the nature of the outcome in this phase would be expected to differ. For the exact same outcome, “an allergic reaction,” the only form of the outcome in that phase, whereas the *ceiling* group would perceive it to occur at the ceiling level, the *nonceiling* group would perceive it to occur at an intermediate level. As mentioned, for both groups, cue A made no difference to the occurrence of the outcome. Because the causal view represents causal relations separately from covariation, it explains why when the outcome occurs at a ceiling level, the generative effect of a cause has no observable manifestation. At a non-ceiling level, causal and associative accounts coincide: The most parsimonious explanation for no observable difference is noncausality. However, at the ceiling level, observing no difference does not allow causal inference, as explained by the causal power theory. In support of this interpretation, the mean causal rating for cue A was reliably lower for the *nonceiling* group than for the *ceiling* group.

Beckers et al. (2005) manipulated pretraining on possible levels of the outcome and on the additivity of the influences of the cues separately and found that each type of pretraining had an enormous effect on the amount of blocking. Beckers et al. (2006) obtained similar results in rats. These and other researchers have explained these results in terms of the use of propositional reasoning to draw conclusions regarding the target cue (Beckers et al., 2005, 2006; Lovibond et al., 2003; Mitchell et al., 2009). For example, a subject might reason: “If A and B are each a cause of an outcome, the outcome should occur with a greater magnitude when both A and B are present than when either occurs by itself. The outcome in fact was *not* stronger when A and B were both present as when B occurred alone. Therefore, A must not be a cause of the outcome.” These researchers have explained the impact of the pretraining in terms of learning the appropriate function for integrating the influences of multiple causes in the experimental materials (e.g., additivity vs. subadditivity) from experiences during the pretraining phase, in line with proposals by Griffiths and Tenenbaum (2005) and Lucas and Griffiths (2010).

It is important to distinguish between domain-specific integrating functions that are the outputs of causal learning, and domain-independent integrating functions that enable an output, in view of

the essential role they play in the inference process. In the causal power theory, the latter are the noisy-logicals: functions representing independent causal influence. As seen in the preceding section, whether independent causal influence is assumed in the inference process leads to different causal judgments. Moreover, independent causal influence enables compositionality. Even if we were to disregard the role of that assumption in the inference process, without it generalization of the acquired causal knowledge to new contexts would be problematic: If integrating functions were purely empirically learned, every new combination of causes, such as the combination of a target cause with unobserved causes in a new context, would require new learning (i.e., causal inference would not be compositional).

An alternative interpretation of Lovibond et al.'s (2003) results is that for all types of outcome variables, independent causal influence is always the default assumed in the causal discovery process, but the mathematical function defining independent influence differs for different types of outcome variables. For continuous outcome variables, independent causal influence is represented by additivity, as is generally known; for dichotomous outcome variables, independent causal influence is represented by the noisy-logicals, as explained earlier (see pp. 219–220 & 222–223). The unifying underlying concept is the superposition of the influences, a concept borrowed from physics. Under this interpretation, the pretraining conveys information on the nature of the outcome variable: continuous or dichotomous. Thus, subjects in their ceiling group, who received pretraining showing that two food items in combination produced an “allergic reaction” just as each item alone did, learned that the outcome is dichotomous. But subjects in their nonceiling group, who received pretraining showing that two food items in combination produced a stronger allergic reaction than each item alone, learned that the outcome is continuous.

INTERVENTION VERSUS OBSERVATION AND DIAGNOSTIC CAUSAL INFERENCE

A hallmark of a rational causal reasoner is the ability to formulate flexible and coherent answers to different causal queries. A goal of accounts of causal inference is to explain that ability. We have illustrated the causal view's answers to queries regarding causal strength and structure. (For formulations of answers to questions regarding causal attribution [how much an target outcome is due to certain causes], see Cheng & Novick, 2005; for answers to

questions regarding enabling conditions, see Cheng & Novick, 1992.) Let us consider here answers to queries involving *diagnostic* causal inference, inference from the occurrence of the effect to the occurrence of its causes. Recall Blaisdell et al.'s (2006) finding regarding rats' ability to distinguish between an event that is merely observed and one that follows an intervention. When a tone that occurred only when a light occurred during the learning phase was merely observed in the test phase, the rats in the experiment (the Observe group) nose-poked into the food bin more often than when the tone occurred immediately after that rats pressed a lever newly inserted in the test phase (the Intervene group). The Observe rats apparently diagnosed that the light must have occurred, whereas the Intervene rats diagnosed that it need not have occurred; light was never followed by food in the test phase.

Blaisdell et al.'s (2006) results were initially interpreted as support for causal Bayes nets. Note that the different diagnostic inferences in the two groups are consistent with simple deductive inference. For the Observe group, because the light was the only cause of the tone, when the tone occurred, the light must have occurred. For the Intervene group, because both the lever press and the light caused the tone, the tone occurring need not imply that the light occurred. Because causal Bayes nets (Pearl, 2000; Spirtes et al., 1993/2000) and the causal power approach (Waldmann et al., 2008) both make use of deductive inference, it is not surprising that they can also explain diagnostic reasoning.

The graphs in causal Bayes nets are assumed to satisfy the Markov condition, which states that for any variable X in the graph, conditional on its parents (i.e., the set of variables that are direct causes of X), X is independent of all variables in the graph except its descendants (i.e., its direct or indirect effects). A direct effect of X is a variable that has an arrow directly from X pointing into it, and an indirect effect of X is a variable that has a pathway of arrows originating from X pointing into it. Candidate causal networks are evaluated by assessing patterns of conditional independence and dependence entailed by the networks using the Markov and other assumptions. Candidate causal networks that are inconsistent with the observed pattern of conditional independence are eliminated, and the remaining candidate causal networks form the basis of causal judgments.

The causal Bayes nets approach explains Blaisdell et al.'s results by a distinction it makes between

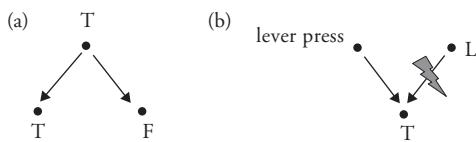

Fig. 12.5 (a) L (Light) causes T (tone) and F (food). (b) Lever press and L each causes T.

intervening to set a variable at a specific value and merely observing that value. As illustrated in Figure 12.5a, observing T allows diagnostic inference regarding L because of the arrow from L to T. But intervening to produce T severs all other incoming arrows into T, a result called graph surgery, so that the resulting causal network no longer has the arrow from L to T (see Fig. 12.5b).

Although this approach explains the results in the test phase if one assumes that the rats inferred the causal structure intended by the researchers, namely, that L is the common cause of T and F (see Fig. 12.5a), the perfect negative correlation between T and F conditional on L during the learning phase in fact violates the Markov assumption applied to this causal structure (see Rehder & Burnett, 2005; Steyvers et al., 2003 for human results indicating violations of the Markov assumption). Causal Bayes nets therefore predict from the learning phase data that there is some inhibitory connection between T and F, and that both the Intervention and Observation rats should equally avoid going to the food bin when T occurred, contrary to the responses observed.

An alternative solution, one that causal psychological theories (e.g., Cheng, 1997, 2000; Waldmann et al., 2008) inherited from traditional associative accounts (e.g., Rescorla & Wagner, 1972) is that people (and perhaps other species) incrementally construct causal networks by evaluating one (possibly conjunctive or otherwise complex) causal relation involving a single target effect at a time, while taking into consideration other causes of the effect. Motivated by consideration of limited processing capacity and of limited access to information at any one time, the incremental feature is shared by associative theorists (e.g., Jenkins & Ward, 1965 Rescorla & Wagner, 1972). Notably, whereas standard Bayes nets fail to explain Blaisdell et al.'s results, the incremental approach fully explains them. One difference is that the Markov assumption plays a different role in the latter approach: It is the consequence of the causal power assumptions

(specifically, the independence assumptions), rather than a constraint used for generating the inferences. Thus, noticing the negative correlation takes effort and thus need not occur until there is sufficient training, as is consistent with the findings in rats (Savastano & Miller, 1998; Yin, Barnet, & Miller, 1994).

In summary, the three lines of evidence just discussed all lie beyond even the augmented associative view. They converge in their support for the two leaps of faith underlying the causal view, as well as for the conviction that the causal world is logically consistent.

TIME AND CAUSALITY: MUTUAL CONSTRAINTS

We have concentrated on theoretical approaches that specify how humans take the mental leap from covariation to causation. Irrespective of any differences in theoretical perspective, all these approaches have in common that they assume that covariation can be readily assessed. This assumption is reflected in the experimental paradigms most commonly used; typically, participants are presented with evidence structured in the form of discrete, simultaneous or sequential learning trials in which each trial contains observations on whether the cause occurred and whether the effect occurred. In other words, in these tasks it is always perfectly clear whether a cause is followed by an effect on a given occasion. Such tasks grossly oversimplify the complexities of causal induction in some situations outside experimental laboratories: Some events have immediate outcomes, and others do not reveal their consequences until much later. Before an organism can evaluate whether a specific covariation licenses causal conjecture, the covariation needs to be detected and parsed in the first place.

Although the problem had been neglected for many years, the last decade has seen interesting and important developments. It has long been documented that cause-effect contiguity (one of Hume's cues toward causality) appears to be essential for causal discovery. Shanks, Pearson, and Dickinson (1989), for example, reported that in an impoverished computerized instrumental learning task, people failed to discriminate between conditions where they had strong control over an outcome ($\Delta P = .75$) and noncontingent control conditions, when their actions and the associated outcomes were separated by more than 2 seconds. In a completely different domain, Michotte (1946/1963) found that impressions of causal "launching" only

occur when the collision of the launcher with the launchee is followed immediately by motion onset in the launchee: Temporal gaps of 150 ms or more destroy the impression.

From a computational perspective, it is easy to see why delays would produce decrements in causal reasoning performance. Contiguous event pairings are less demanding on attention and memory. They are also much easier to parse. When there is a temporal delay, and there are no constraints on how the potential causes and effects are bundled, as in Shanks et al. (1989), the basic question on which contingency depends no longer has a clear answer: Should this particular instance of e be classified as occurring in the presence of c or in its absence? Each possible value of temporal lag results in a different value of contingency. The problem is analogous to that of the possible levels of abstractions of the candidate causes and the effects at which to evaluate contingency (and may have an analogous solution). Moreover, for a given e , when alternative intervening events occur, the number of hypotheses to be considered multiplies. The result is a harder, more complex inferential problem, one with a larger search space.

Buehner and May (2002, 2003, 2004) have demonstrated that prior knowledge about delayed time frames constrains the search process, such that non-contiguous relations are judged to be just as causal as contiguous ones. Buehner and McGregor (2006) have further shown that when prior assumptions about delays are sufficiently salient, contiguous relations are perceived as less causal than delayed ones—an apparent contradiction to Hume's tenets.

If causal learning operates according to the principles of Bayesian evidence integration, then these results on contiguous and delayed causation make sense: Reasoners may focus on the expected delay for a type of causal relation and evaluate observations with respect to it. In Bayesian terms, they evaluate likelihoods, the probability of the observations resulting from a hypothesis. In the earlier demonstrations of detrimental effects of delay (Michotte, 1946/1963; Shanks et al., 1989), the prior assumption would have been that there is no delay: Michotte's stimuli were simulations of well-known physical interactions (collisions), while Shanks et al. used computers, which (even in those days!) were expected to operate fast. Once these prior assumptions are modified via instructions (Buehner & May, 2002, 2003, 2004), or via constraints in the environment (Buehner & McGregor, 2006), then delayed relations pose no problem.

More recent work has found that prior expectations about time frames are relevant not only for the *extent* of delays but also with respect to their *variability*. Consider two hypothetical treatments against headache. Drug A always provides relief 2 hours after ingestion, while drug B sometimes starts working after just 1 hour, while other times it can take 3 hours to kick in. Which would we deem as a more effective drug? The answer to that question depends on how exactly temporal extent is interpreted when drawing causal conclusions. One possibility would be that causal attribution decays over time, similarly to discounting functions found in intertemporal choice (for an overview, see Green & Myerson, 2004). Under such an account, the appeal of a causal relation would decay over time according to a hyperbolic function.

One consequence of hyperbolic discounting is that variable relations may appear more attractive than stable ones, even when they are equated for mean expected delay. This conjecture is rooted in the diminishing sensitivity to delay: Variable relations accrue more net strength than constant relations matched for mean delay. And indeed, Cicerone (1976) has found that pigeons preferred variable over constant delays of reinforcement. Thus, if human causal learners approach time in a similar manner (and apply well-established principles of discounting as regards to intertemporal choice), we would expect drug B to emerge as the favorite. Interestingly, the opposite is the case: Greville and Buehner (2010) found that causal reasoners consistently prefer stable, predictable relations. Presumably we have strong *a priori* expectations that (most) causal relations are associated with a particular, relatively constant time frame. Where such expectations are violated, less learning takes place.

Cause-effect timing not only impacts assessments of causal strength but critically also constrains our ability to infer structure. Pace Hume, causes must occur before their effects, even though the intervening interval may extremely closely approximate 0 (e.g., the interval between a fist's contact with a pillow and the pillow's indentation, the interval between a cat walking into the sun and its shadow appearing on the ground). While such considerations are relatively trivial when there are only two variables involved, finding structure in multivariable causal systems gets increasingly difficult as the size of the system grows. Moreover, many structures are Markov-equivalent (Pearl, 2000), meaning that they cannot be distinguished by mere observation of the statistical patterns they produce. Lagnado

and Sloman (2004, 2006) have shown that in such situations, people rely on temporal ordering to infer causal structure. More specifically, temporal order constrains structure inference to a greater extent than the observed patterns of statistical dependencies.

As we highlighted earlier, cognitive science approaches to causality are rooted in the Humean conjecture that causality is a mental construct, inferred from hard, observable facts. Recent evidence suggests that Hume's route from sensory experience to causal knowledge is not a one-way street but in fact goes in both directions. Not only does our sensory experience determine our causal knowledge, but causal knowledge also determines our sensory experience. The latter direction of influence was first documented by Haggard, Clark, and Kalogeras (2002), who showed that sensory awareness of actions and resultant consequences are shifted in time, such that actions are perceived as later, and consequences as earlier (with reference to a baseline judgment error). Causes and effects thus mutually attract each other in our subjective experience. Originally, the effect was thought to be specific to motor action and intentional action control (Wohlschläger, Haggard, Gesierich, & Prinz, 2003). Buehner and Humphreys (2009), however, have shown that causality is the critical component of temporal binding: Intentional actions without a clear causal relation do not afford attraction to subsequent (uncaused) events. Moreover, Humphreys and Buehner (2009, 2010) have shown that the causal binding effect exists over time frames much longer than originally reported, and outside the range of motor adaptation (Stetson, Cui, Montague, & Eagleman, 2006), as would be required for action-control based approaches. Buehner and Humphreys (2010) have furthermore demonstrated a binding effect in spatial perception using Michottean stimuli—a finding that is completely outside the scope of motor-specific accounts of binding. It appears as if our perception of time and space, and our understanding of causality, mutually constrain each other to afford a maximally coherent and parsimonious experience.

Our chapter has reviewed multiple lines of evidence showing a strong preference for parsimonious causal explanations. This preference holds for scientific as well as everyday explanations. Among the many alternative representations of the world that may support predictions equally well, we select the most parsimonious. Hawking and Mlodinow (2010) note that, although people often say that Copernicus's sun-centered model of the cosmos

proved Ptolemy's earth-centered model wrong, that is not true; one can explain observations of the heavens assuming either Earth or the sun to be at rest. Likewise, although the city council of Monza, Italy, barred pet owners from keeping goldfish in curved fishbowls—on the grounds that it is cruel to give the fish a distorted view of reality through the curved sides of the bowl—the goldfish could potentially formulate a model of the motion of objects outside the bowl no less valid as ours. The laws of motion in our frame are simpler than the fish's, but theirs are potentially just as coherent and useful for prediction. But the members of the city council of Monza, like the rest of us, have such an overpowering preference for the more parsimonious model of the world that they perceive it as "truth."

Conclusions and Future Directions

Our chapter began with the question: With what cognitive assets would we endow an intelligent agent—one that has processing and informational resources similar to humans—so that the agent would be able to achieve its goals? We have taken the perspective that generalization from the learning context to the application context is central to the achievement of its goals. From this perspective, we first examined the crippling inadequacies of the associative view, which attempts to maintain objectivity by restricting its inference process to computations on observable events only. We considered variants of the associative view augmented with a special status for interventions and other principles of experimental design, in line with typical scientific causal inference.

We then considered the causal view, which resolves major apparent impasses by endowing the agent with two leaps of faith, that (1) the world is causal even though causal relations are never observable, and (2) causal laws are uniform and compositional. These empirical leaps are grounded in the conviction that existence is logically consistent. They enable the agent to incrementally construct an understanding of how the world works and coherently generalize its acquired causal knowledge. Analysis in cognitive research shows that the common belief that justifies the augmented associative view—that assumptions about independent causal influence justify the application of causal knowledge to new contexts but do not influence the output of statistical analyses—is mistaken. Likewise, the common belief that assumptions about estimations of causal strength are secondary, and do not affect judgments regarding causal structure, is mistaken.

Remarkably, observed causal judgments reveal that humans make those leaps of faith, and that their causal judgments are based on a definition of independent causal influence that is logically consistent across the learning and application contexts. The use of the sharper tool of Bayesian mathematics shows even more unequivocal support for the causal view. This tool also extends the capability to formulate answers to different kinds of causal queries.

The potential to discover how the world works must of course be accompanied by the requisite computational capabilities. We have identified three intertwined capabilities so far. The agent must be able to (1) make deductive logical inferences, (2) compute statistical regularities, and (3) represent uncertainty. The last two allow the agent to make progress in the face of errors in even its best hypotheses. The first is an essential component of the parsimony assumption and of coherent and flexible reasoning.

Three outstanding issues seem especially pertinent to us in view of our analysis and review. For each issue, a rational analysis in tandem with empirical work differentiating between alternative plausible explanations would deepen our understanding of causal learning.

1. Hypothesis revision: If causal learning is incremental, by what criteria do causal learners revise their hypotheses, and what do their criteria and revisions reveal about the intended destination of the revision process? Recent research found that for preventers with a narrow scope, which violate the independent influence assumption, people are more likely to posit a hidden cause to explain and remove the violation (Carroll & Cheng, 2010). Standard causal Bayes nets would not interpret the violation to signal a need for representation revision.
2. Category formation and causal learning: We have taken the perspective that causal discovery is the driving force underlying our mental representation of the world, not just in the sense that we need to know how things influence each other but also in the sense that causal relations define what should be considered *things* in our mental universe (Lewis, 1929). Are causal learning and category formation two aspects of the same challenge, as the goal of generalization of causal beliefs to application contexts would suggest? How do people arrive at their partitioning of the continuous stream of events into candidate causes and effects? Likewise, how do people arrive at their partitioning of events

into candidate causes and effects at particular levels of abstraction? In Lien and Cheng's (2000) experiments, human subjects were presented with causal events involving visual stimuli for which candidate-cause categories were undefined; there was no specification of either the potential critical features or the relevant level of abstraction of the features. It was found that subjects seemed to form candidate-cause categories that maximized ΔP , perhaps in an attempt to maximize the necessity and sufficiency of the cause to produce the effect in question. The topic awaits better formulations of explanations as well as additional empirical work.

3. Parsimony in causal explanations: We have encountered the critical role of parsimony in causal explanations multiple times in our chapter. Although models of parsimony (e.g., Chater & Vitányi, 2003; Lombrozo, 2007) are consistent with the psychological findings, they do not predict them. Better integration of theories of simplicity with theories and findings in causal learning would be a major advance.

Acknowledgments

Preparation of this chapter was supported by AFOSR FA 9950-08-1-0489. We thank Jessica Walker and Keith Holyoak for comments on an earlier draft.

Notes

1. More generally, for a causal tree with n nodes, the number of direct causal links would be $n - 1$ (because every node other than the root node has one and only one arrow going into it). But the number of associations between nodes (including causal ones) would be $n(n - 1)/2$, because every node in the tree is linked by an arrow to at least one other node, so that there is an non-zero association between every pair of nodes.

2. Ulrike Hahn provided this interpretation.

3. The example was provided by Sylvain Bromberger.

4. Although the theory obtains different equations for estimating generative and preventive causal powers, the choice between the two equations does not constitute a free parameter. Which of the two equations applies follows from the value of ΔP . On occasions where $\Delta P = 0$, both equations apply and make the same prediction, namely, that causal power should be 0, except in ceiling-effect situations. Here, the reasoner does have to make a pragmatic decision on whether she is evaluating the evidence to assess a preventive or generative relation, and whether the evidence at hand is meaningful for that purpose.

Analogy and Relational Reasoning

Keith J. Holyoak

Abstract

Analogy is an inductive mechanism based on structured comparisons of mental representations. It is an important special case of role-based relational reasoning, in which inferences are generated on the basis of patterns of relational roles. Analogical reasoning is a complex process involving retrieval of structured knowledge from long-term memory, representing and manipulating role-filler bindings in working memory, identifying elements that play corresponding roles, generating new inferences, and learning abstract schemas. For empirical analogies, analogical inference is guided by causal knowledge about how the source analog operates. Simpler types of relation-based transfer can be produced by relational priming. Human analogical reasoning is heavily dependent on working memory and other executive functions supported by the prefrontal cortex, with the frontopolar subregion being selectively activated when multiple relations must be integrated to solve a problem.

Key Words: analogy, role-based relational reasoning, IQ, metaphor, induction, neuroimaging, frontal cortex, symbolic connectionism, mapping, retrieval, inference, schemas, System 1, System 2, causal models, relational priming, cognitive development

Introduction

Two situations are analogous if they share a common pattern of *relationships* among their constituent elements, even though the elements themselves differ across the two situations. Identifying such a common pattern requires *comparison* of the situations. Analogy involves some of the same processes as do judgments of similarity (see Goldstone & Son, Chapter 10). Typically one analog, termed the *source* or *base*, is more familiar or better understood than the second analog, termed the *target*. By “better understood,” we mean that the reasoner has prior knowledge about functional relations *within* the source analog—beliefs that certain aspects of the source have causal, explanatory, or logical connections to other aspects (Hesse, 1966). This asymmetry in initial knowledge provides the basis for analogical transfer—using the source to generate

inferences about the target. For example, the earliest major scientific analogy, dating from the era of imperial Rome (see Holyoak & Thagard, 1995), led to a deeper understanding of sound (the target) in terms of water waves (the source). Sound is analogous to water waves in that sound exhibits a pattern of behavior corresponding to that of water waves: propagating across space with diminishing intensity, passing around small barriers, rebounding off of large barriers, and so on. The perceptual features are very different (water is wet, air is not), but the underlying pattern of relations among the elements is similar. In this example, like most analogies involving empirical phenomena, the key functional relations involve causes and their effects (see Cheng & Buehner, Chapter 12). By transferring knowledge about causal relations, the analogy provides a new explanation of why various phenomena occur (see

Lombrozo, Chapter 14). Analogy is an inductive process, and hence analogical inferences are inevitably uncertain. The wave analogy for sound proved successful; an alternative “particle” analogy did not.

In this chapter I will focus on analogy as a key example of the broader concept of *role-based relational reasoning*. After a brief review of the history of research on analogy and related concepts, such as metaphor, I will describe current views using the framework of Marr’s (1982) levels of analysis. Next, I will survey research on major subprocesses (retrieval, mapping, inference, and schema induction). This review includes both intentional and unintentional types of relational transfer, and the development of analogical abilities over the course of childhood. Finally, again applying Marr’s framework, I will consider open issues and directions for future research.

Role-Based Relational Reasoning

Analogy is a prime example of role-based relational reasoning (Penn, Holyoak, & Povinelli, 2008), as its full power depends on explicit relational representations (see Doumas & Hummel, Chapter 5). Such representations distinguish relational roles from the entities that fill those roles, while coding the bindings of entities to their specific roles. Humans are capable of making inferences about entities that cannot be reliably assigned to relational roles solely on the basis of perceptual properties. In the context of the original wave analogy, water is similar to air because each serves as a medium for the transmission of waves. The wave analogy was later extended from transmission of sound to transmission of light, and ultimately it developed into an abstract *schema*, or relational category. As another example of a relational category, something fills the role of “barrier” if it blocks the passage of something else, regardless of what type of entity the “barrier” is (perhaps a landslide, perhaps poverty). If something is known to be a barrier, its binding to that relational role is enough to infer that its removal would end the blockage. Whether any other species is capable of role-based relational reasoning is a matter of debate (see Penn & Povinelli, Chapter 27).

As the earlier examples illustrate, role-based relational reasoning is broader than reasoning by analogy between specific cases (Halford, Wilson, & Phillips, 2010). More general concepts and categories are often defined at least in part by relations (e.g., *barrier*, *parent*, *catalyst*; see Markman & Stilwell, 2001; also Rips et al., Chapter 11). Reasoning based on rules (Smith, Langston, & Nisbett, 1992), including

deductive inference (see Evans, Chapter 8; Johnson-Laird, Chapter 9), also depends critically on relations. The core property of role-based relational reasoning is that inferences about elements depend on commonalities (and sometimes differences) in the roles they play, rather than solely on perceptual features of individual elements. Although various types of inferences have this basic character, analogical inferences are especially flexible, as I will discuss in more detail later.

Functions and Processes of Analogical Reasoning

The content of analogical reasoning is extremely diverse (Holyoak & Thagard, 1995). Analogies have figured prominently in science (see Dunbar & Klahr, Chapter 35) and mathematics (Pask, 2003), and they are often used in everyday problem solving (see Bassok & Novick, Chapter 21) as well as creative cognition (Smith & Ward, Chapter 23). In legal reasoning, the use of legal precedents (relevant past cases) to help decide a new case is a special case of analogical reasoning (see Spellman & Schauer, Chapter 36). Analogies can function to sway emotions (Goode, Dahl, & Moreau, 2010; Thagard & Shelley, 2001), to influence political views (Blanchette & Dunbar, 2001; Khong, 1992), to guide consumer decisions (Markman & Loewenstein, 2010; see Lowenstein, Chapter 38), and to teach mathematics (Richland, Zur, & Holyoak, 2007). Analogy is sometimes used as part of a rational argument (Bartha, 2010; see Hahn & Oaksford, Chapter 15), using systematic connections between the source and target to generate and support plausible (though fallible) inferences about the latter.

Figure 13.1 sketches the major component processes in analogical transfer (see Carbonell, 1983; Gentner, 1983; Gick & Holyoak, 1980, 1983; Novick & Holyoak, 1991). Typically, a target situation serves as a retrieval cue for a potentially useful source analog. It is then possible to establish a *mapping*—a set of systematic correspondences that serve to align the elements of the source and target. Based on the mapping, coupled with the relevance relations within the source, it is possible to elaborate the representation of the target and derive new inferences. In the aftermath of analogical reasoning about a pair of cases, some form of relational generalization may take place yielding a more abstract schema for a category of situations (as in the case of the evolving “wave” concept), of which the source and target are both instances.

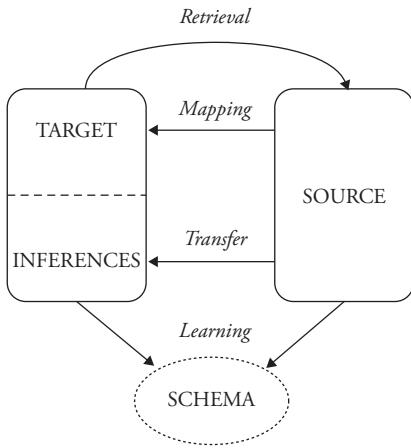

Fig. 13.1 Major components of analogical reasoning.

A Capsule History

The history of the study of analogy includes three interwoven streams of research, which respectively emphasize analogy in relation to psychometric measurement of intelligence, to metaphor and language, and to the representation of knowledge.

Psychometric Tradition

Work in the psychometric tradition focuses on four-term or “proportional” analogies, in the form A:B::C:D, such as HAND:FINGER::FOOT:?, where the problem is to infer the missing D term (TOE) that is related to C in the same way B is related to A. The pair A:B thus plays the role of source analog, and C:D that of target. Proportional analogies were discussed by Aristotle (see Hesse, 1966), and in the early decades of modern psychology became a centerpiece of efforts to define and measure intelligence. Charles Spearman (1923, 1927) argued that the best account of observed individual differences in cognitive performance was based on a general or *g* factor, with the remaining variance being unique to the particular task. He reviewed several studies that revealed high correlations between performance in solving analogy problems and the *g* factor. Spearman’s student John C. Raven (1938) developed the Raven’s Progressive Matrices Test (RPM), which requires selection of a geometric figure to fill an empty cell in a two-dimensional matrix (typically 3 x 3) of such figures. Much like a geometric proportional analogy, the RPM requires participants to extract and apply information based on visuospatial relations. (See Hunt, 1974, and Carpenter, Just, & Shell, 1990, for analyses of strategies for solving RPM problems.) The RPM proved to be an especially pure measure of *g*.

Raymond Cattell (1971), another student of Spearman, elaborated his mentor’s theory by distinguishing between two components of *g*: *crystallized* intelligence, which depends on previously learned information or skills, and *fluid* intelligence, which involves reasoning with novel information. As a form of inductive reasoning, analogy would be expected to require fluid intelligence. Cattell confirmed Spearman’s (1946) observation that analogy tests and the RPM provide sensitive measures of *g*, clarifying that they primarily measure fluid intelligence (although verbal analogies based on difficult vocabulary items also depend on crystallized intelligence). Figure 13.2 graphically depicts the centrality of RPM performance in a space defined by individual differences in performance on various cognitive tasks. Note that numerical, verbal, and geometric analogies cluster around the RPM at the center of the figure.

Because four-term analogies and the RPM are based on small numbers of relatively well-specified elements and relations, it is possible to systematically manipulate the complexity of such problems and analyze performance (based on response latencies and error rates) in terms of component processes (e.g., Mulholland, Pellegrino, & Glaser, 1980; Sternberg, 1977). The earliest computational models of analogy were developed for four-term analogy problems (Evans, 1968; Reitman, 1965). The basic components of these models were elaborations of those proposed by Spearman (1923), including encoding of the terms, accessing a relation between the A and B terms, and evoking a comparable relation between the C and D terms. As we will discuss later, four-term analogies and the RPM have proved extremely useful in recent work on the cognitive neuroscience of analogy.

Metaphor

Analogy is closely related to metaphor and related forms of symbolic expression that arise in everyday language (e.g., “the evening of life,” “the idea blossomed”), in literature (Holyoak, 1982), the arts, and cultural practices such as ceremonies (see Holyoak & Thagard, 1995, ch. 9). Like analogy in general, metaphors are characterized by an asymmetry between target (conventionally termed “tenor”) and source (“vehicle”) domains (e.g., the target/tenor in “the evening of life” is life, which is understood in terms of the source/vehicle of time of day). In addition, a mapping (the “grounds” for the metaphor) connects the source and target,

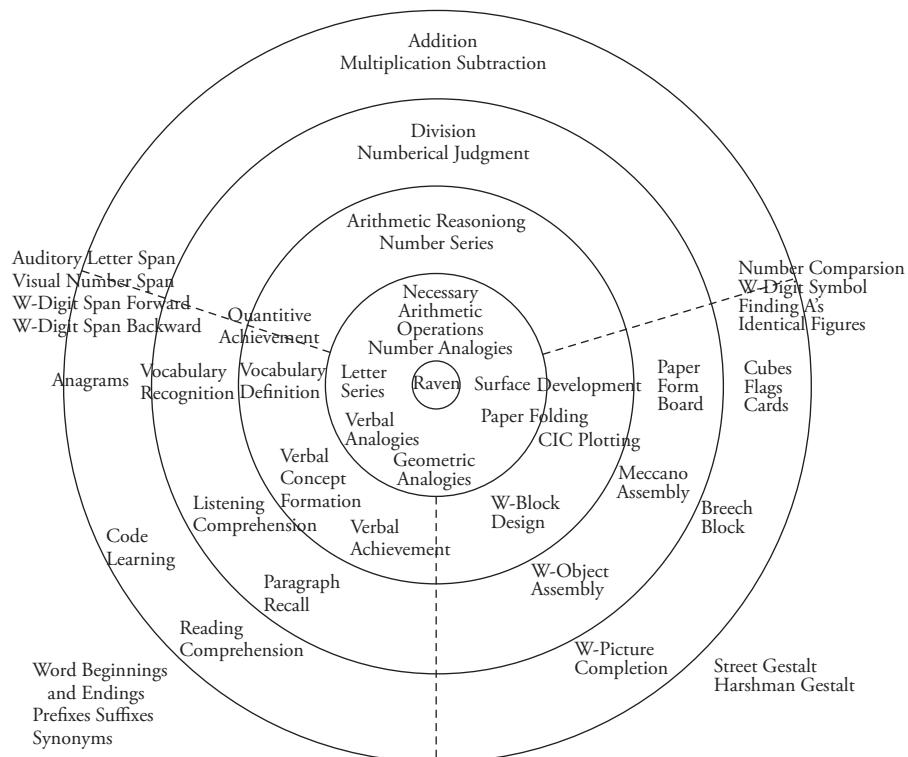

Fig. 13.2 Multidimensional scaling solution based on intercorrelations among the Raven's Progressive Matrices test, analogy tests, and other common tests of cognitive function. (Reprinted by permission from Snow, Kyllonen, & Marshalek, 1984, p. 92.)

allowing the domains to interact to generate a new conceptualization (Black, 1962). Metaphors are a special kind of analogy, in that the source and target domains are always semantically distant (Gentner, 1982; Gentner, Falkenhainer, & Skorstad, 1988), and the two domains are often blended rather than simply mapped (e.g., in “the idea blossomed,” the target is directly described in terms of an action term derived from the source). In addition, metaphors are often combined with other symbolic “figures,” especially metonymy (substitution of an associated concept). For example, “sword” is a metonymic expression for weaponry, derived from its ancient association as the prototypical weapon; “Raising interest rates is the Federal Reserve Board’s sword in the battle against inflation” extends the metonymy into metaphor.

Fauconnier and Turner (1998; Fauconnier, 2001) have analyzed complex conceptual blends that are akin to metaphor. A typical example is a description of the voyage of a modern catamaran sailing from San Francisco to Boston, which was attempting to beat the speed record set by a clipper ship that had sailed the same route over a century earlier. A magazine account written during the catamaran’s voyage

said the modern boat was “barely maintaining a 4.5-day lead over the ghost of the clipper *Northern Light*.” Fauconnier and Turner observed that the magazine writer was describing a “boat race” that never took place in any direct sense; rather, the writer was blending the separate voyages of the two ships into an imaginary race. The fact that such conceptual blends are so natural and easy to understand attests to the fact that people can readily comprehend novel metaphors.

Lakoff and Johnson (1980; also Lakoff & Turner, 1989) have argued that much of human experience, especially its abstract aspects, is grasped in terms of broad conceptual metaphors (e.g., events occurring in time are understood by analogy to objects moving in space). Time, for example, is understood in terms of objects in motion through space, as in expressions such as “My birthday is fast approaching” and “The time for action has arrived.” (See Boroditsky, 2000, for evidence of how temporal metaphors influence cognitive judgments.) As Lakoff and Turner (1989) pointed out, the course of a life is understood in terms of time in the solar year (youth is springtime, old age is winter). Life is also conventionally conceptualized as a journey. Such conventional metaphors can still

be used in creative ways, as illustrated by Robert Frost's famous poem, "The Road Not Taken":

Two roads diverged in a wood, and I—
I took the one less traveled by,
And that has made all the difference.

According to Lakoff and Turner, comprehension of this passage depends on our implicit knowledge of the metaphor that life is a journey. This knowledge includes understanding several interrelated correspondences (e.g., a person is a traveler, purposes are destinations, actions are routes, difficulties in life are impediments to travel, counselors are guides, and progress is the distance traveled).

Psychological research has focused on demonstrations that metaphors are integral to everyday language understanding (Glucksberg, Gildea, & Bookin, 1982; Keysar, 1989). There has been a debate about whether metaphor is better conceptualized as a kind of analogy (Wolff & Gentner, 2000) or a kind of categorization (Glucksberg & Keysar, 1990; Glucksberg, McClone, & Manfredi, 1997). A likely resolution is that novel metaphors are interpreted by much the same processes as are analogies, whereas more conventional metaphors are interpreted as more general schemas (Gentner & Bowdle, 2008; see discussion of schemas later in this chapter).

Knowledge Representation

The most important influence on analogy research in the cognitive-science tradition has been concerned with the representation of knowledge within computational systems (see Markman, Chapter 4). Many seminal ideas were developed by the philosopher Mary Hesse (1966), who was in turn influenced by Aristotle's discussions of analogy in scientific classification and Black's (1962) interactionist view of metaphor. Hesse placed great stress on the *purpose* of analogy as a tool for scientific discovery and conceptual change, and on the close connections between causal relations and analogical mapping. In the 1970s, work in artificial intelligence and psychology focused on the representation of complex knowledge of the sort used in scientific reasoning, problem solving, story comprehension, and other tasks that require structured knowledge. A key aspect of structured knowledge is that elements can be flexibly *bound* into the roles of relations. For example, "dog bit man" and "man bit dog" have the same elements and the same relation, but the role bindings have been reversed, radically altering the overall

meaning. How the mind and brain accomplish role binding is thus a central problem to be solved by any psychological theory that involves structured knowledge, including any theory of analogy (see Doumas & Hummel, Chapter 5).

In the 1980s, a number of cognitive scientists recognized the centrality of analogy as a tool for discovery, as well as its close connection with theories of knowledge representation. Winston (1980), guided by Minsky's (1975) treatment of knowledge representation, built a computer model of analogy that highlighted the importance of causal relations in guiding analogical inference. Other researchers in artificial intelligence also began to consider the use of complex analogies in reasoning and learning (Kolodner, 1983; Schank, 1982), leading to an approach to artificial intelligence termed *case-based reasoning* (Kolodner, 1993).

Meanwhile, cognitive psychologists began to consider analogy in relation to knowledge representation and eventually to integrate computational modeling with detailed experimental studies of human analogical reasoning. Gentner (1982, 1983; Gentner & Gentner, 1983) investigated the role of analogy in understanding scientific topics. She emphasized that in analogy, the key similarities involve relations that hold within the domains (e.g., the flow of electrons in an electrical circuit is analogically similar to the flow of people in a crowded subway tunnel), rather than in features of individual objects (e.g., electrons do not resemble people). Moreover, analogical similarities often depend on *higher order* relations—relations *between* relations. For example, adding a resistor to a circuit *causes* a decrease in flow of electricity, just as adding a narrow gate in the subway tunnel would decrease the rate at which people pass through (where *causes* is a higher order relation). In her structure-mapping theory, Gentner proposed that analogy entails finding a structural alignment, or mapping, between elements of the two domains. In this theory, a "good" alignment between two representational structures is characterized by a high degree of structural parallelism (consistent, one-to-one correspondences between mapped elements) and of systematicity—an implicit preference for deep, interconnected systems of relations governed by higher order relations, such as causal, mathematical, or other functional relations.

Holyoak and his colleagues (1985; Gick & Holyoak, 1980, 1983; Holyoak & Koh, 1987) focused on the role of analogy in problem solving, with a strong concern for the role of pragmatics in

analogy—how causal relations that impact current goals and context guide the interpretation of an analogy. Holyoak and Thagard (1989, 1995) developed an approach to analogy in which several factors were viewed as jointly constraining analogical reasoning. According to their *multiconstraint* theory, people implicitly favor mappings that maximize structural parallelism (in agreement with Gentner's, 1983, structure-mapping theory), but that also maximize direct similarity of corresponding elements and relations, and that give priority to pragmatically important elements (i.e., those functionally related to achieving a goal). The theory further specified how the joint influence of these constraints, which often converge but sometimes conflict, might be adjudicated by a process of constraint satisfaction.

Other early work dealt with role-based relational reasoning more broadly. Gick and Holyoak (1983) provided evidence that analogical comparisons can provide the seed for forming new relational categories, by abstracting the relational correspondences between examples to form a schema for a class of problems. Halford (1993; Halford & Wilson, 1980) argued that the development of the ability to map relational structures is central to cognitive development. More generally, role-based relational reasoning came to be viewed as a central part of human induction (Holland, Holyoak, Nisbett, & Thagard, 1986; see Markman, Chapter 4; Doumas & Hummel, Chapter 5), with close ties to other basic thinking processes, including causal inference (Cheng & Buehner, Chapter 12), categorization (Rips et al., Chapter 11), and problem solving (Bassok & Novick, Chapter 21).

Relational Reasoning: Levels of Analysis

To provide an overview of current conceptions of analogy, I will focus on three questions: What are the functions of human relational reasoning, by what algorithms is it achieved, and how is it implemented in the brain? These questions instantiate Marr's (1982) three levels of analysis: computation, representation and algorithm, and implementation. Cognitive scientists and cognitive neuroscientists have addressed all three levels, focusing on analogical reasoning as a central example.

Computational Goal

At the computational level, analogies are used to achieve the goals of the reasoner (Holyoak, 1985). These goals are diverse—forming and evaluating hypotheses, solving problems, understanding new

concepts, winning arguments, and so on. The focus here will be on the role of analogies and relational reasoning in pursuing what Molden and Higgins (Chapter 20) term a basic “nondirectional outcome goal”: truth, coupled with relevance to current goals. The scientist seeking a good theory, the architect creating a building design that meets the client's needs, the child trying to understand how the world works, are all basically motivated to use their prior knowledge—including specific analogs—to make true and useful inferences. Of course, inductive uncertainty is inevitable, and analogies can potentially mislead. Nonetheless, the rational reasoner (see Stanovich, Chapter 22) will use analogies to reach rationally justified inferences relevant to achieving current goals—inferences that though fallible are at least plausible, and are accompanied by an appropriate sense of their degree of uncertainty (Bartha, 2010; Lee & Holyoak, 2008).

The overarching goal of making true and useful inferences underlies the major constraints on analogical inference that have been discussed in the literature. For an analogy to be successful, the structure and content of the source must provide a good model to use in elaborating the representation of the target. To the extent that the reasoner understands the functional structure of the source (i.e., what aspects depend on which other aspects), it will be possible to focus on goal-relevant information in it while “backgrounding” other details. The functional structure may take different forms. For example, in a mathematical analogy, the functional structure will involve the mathematical or logical properties that justify a conclusion (see Bartha, 2010). For empirical knowledge (i.e., knowledge about how things happen in the real world), the aim is to transfer a *causal model* (see Cheng & Buehner, Chapter 12) from source to target. In such cases the backbone of the functional structure will be cause-effect relations—“what makes what happen” in the source domain drives potential inferences about “what makes what happen” in the target.

From the perspective of Holyoak and Thagard's (1989) multiconstraint theory, the centrality of functional structure is a basic pragmatic constraint. Causal relations constitute the prime example of “higher order” relations involved in Gentner's systematicity constraint, which has been supported by experimental evidence that analogical transfer is more robust when the source includes causal structure than when it does not (Gentner & Toupin, 1986). In general, a highly systematic source will

be rich in functional structure. A high degree of structural parallelism (that is, a consistent mapping between relevant elements of the source and target) is a logical requirement if the structure of the source is to provide an appropriate model for the structure of the target. Ambiguity will be minimized if the mapping is both consistent and one to one.

Holyoak and Thagard's (1989) constraint of semantic similarity—a preference for mappings in which similar objects are placed into correspondence—also follows from the overarching goal of seeking true and goal-relevant inferences. Direct semantic similarity of elements has often been termed “surface” similarity, in contrast to the “structural” variety. In fact, this contrast has been defined in (at least) two distinct ways in the analogy literature, indicating resemblances based either (1) on features versus relations (Gentner, 1983) or (2) on functionally irrelevant versus relevant elements of the analogs (Holyoak, 1985). In general, functional structure (the latter sense) will involve not only relations (i.e., predicates that take at least two arguments; see Doumas & Hummel, Chapter 5) but also those additional elements that participate in functional relations. For example, because an orange is round, fairly small, and firm (properties usually considered to be perceptual features, not relations), it could be considered analogous to a ball for purposes of playing catch. In this example, as in most simple empirical analogies, various perceptual properties participate in relevant causal relations and hence count as “structural” by the functional definition. In general, objects that share direct similarities are likely to have similar causal properties (see Rips et al., Chapter 11). Thus, while “distant” analogies between remote domains of knowledge may be especially creative (see Smith & Ward, Chapter 23), “close” analogies in which similar entities fill corresponding roles typically provide stronger support for plausible inferences (Medin & Ross, 1989; see also Koedinger & Roll, Chapter 40).

Representation and Algorithm

Role-based relational reasoning depends on the capacity to represent structured relations in terms of their roles, to represent the bindings of entities to roles, to find systematic correspondences between a source and target based on relational structure, and to use this structure to create new propositions about the target. Because of its dependence on explicit relations, all major computational models of analogical reasoning (e.g., Falkenhainer, Forbus, &

Gentner, 1989; Halford, Wilson, & Phillips, 1998; Hofstadter & Mitchell, 1994; Holyoak & Thagard, 1989; Hummel & Holyoak, 1997, 2003; Keane & Brayshaw, 1988; Kokinov & Petrov, 2001) are based on some form of propositional representation capable of expressing role-filler bindings (see Markman, Chapter 4; Doumas & Hummel, Chapter 5).

Most algorithmic models of analogy, formalized as computer simulations, are based on traditional symbolic representations. Traditional connectionist systems, which lack the capacity to code variable bindings, have not been successful in modeling human-like relational reasoning (see Doumas & Hummel, Chapter 5), although they may well be applicable to simpler types of relational processing (see later discussion of relational priming), some of which appear to be within the capabilities of non-human animals (see Penn & Povinelli, Chapter 27). The most promising algorithmic approach to modeling human analogical reasoning in a way that makes contact with data on its neural basis is *symbolic connectionism* (Halford et al., 1998, 2010; Hummel & Holyoak, 1997, 2003; see Doumas & Hummel, Chapter 5). Models of this type aim to represent structured relations (hence “symbolic”) within relatively complex neural networks (hence “connectionist”), and furthermore aim to operate within a human-like limited-capacity working memory.

The central role of working memory and related executive processes in analogical reasoning has long been supported by research in the psychometric tradition, as described earlier (see Fig. 13.2). More recent experimental work, both with normal and brain-damaged populations, has provided further evidence. For example, Waltz, Lau, Grewal, and Holyoak (2000) asked college students to map objects in a pair of pictorial scenes while simultaneously performing a secondary task designed to tax working memory (e.g., generating random digits). Adding a dual task diminished relational responses and increased similarity-based responses. A manipulation that increases people's anxiety level (performing mathematical calculations under speed pressure prior to the mapping task) yielded a similar shift in mapping responses (Tohill & Holyoak, 2000; also Feldman & Kokinov, 2009). Most dramatically, degeneration of the frontal lobes radically impairs relation-based mapping (Morrison et al., 2004; Waltz et al., 1999). These and many other findings (e.g., Cho, Holyoak, & Cannon, 2007) demonstrate that mapping on the basis of relations requires adequate working memory and

attentional resources to represent and manipulate role bindings. The neural substrate of working memory is relatively well understood (see Morrison & Knowlton, Chapter 6), and its genetic mechanisms are being actively investigated (see Green & Dunbar, Chapter 7). By connecting to working memory, symbolic-connectionist models provide a potential algorithmic “bridge” between the computational and implementational levels of analysis for role-based relational reasoning.

One example of a symbolic-connectionist model of analogy is LISA (Learning and Inference with Schemas and Analogies; Hummel & Holyoak, 1997, 2003; Doumas, Hummel, & Sandhofer, 2008). LISA (described more fully by Doumas & Hummel, Chapter 5) is based on the principles of Holyoak and Thagard’s (1989) multiconstraint theory of analogy. The model aims to provide a unified account of all the major components of analogical reasoning. LISA represents propositions using a hierarchy of distributed and localist units (see Fig. 13.5b; also Fig. 5.5 in Doumas & Hummel, Chapter 5). LISA includes both a long-term memory for propositions and concept meanings and a limited-capacity working memory. LISA’s working memory representation, which uses neural synchrony to encode role-filler bindings, provides a natural account of the capacity limits of working memory because it is only possible to have a finite number of bindings simultaneously active and mutually *out of synchrony*.

Analog retrieval is accomplished as a form of guided pattern matching. Propositions in a *driver* analog (typically the target) generate synchronized patterns of activation on the semantic units, which in turn activate propositions in *recipients*—potential source analogs residing in long-term memory. The resulting coactivity of elements of the target and a selected source, augmented with a capacity to learn which structures in the target were coactive with which in the source, serves as the basis for analogical mapping. LISA includes a set of *mapping connections* between units of the same type (e.g., object, predicate) in separate analogs. These connections grow whenever the corresponding units are active simultaneously, and thereby permit LISA to learn correspondences between structures in separate analogs. Augmented with an algorithm for self-supervised learning, the model can generate analogical inferences based on the mapping (by using the source as the driver to generate new relational structure in the target); and further augmented with an algorithm

for intersection discovery, the model provides a basis for schema induction.

LISA has been used to simulate a wide range of behavioral data on analogical reasoning in normal adults (Hummel & Holyoak, 1997, 2003). To take just one example, LISA predicts that mapping complex situations must be performed sequentially, because only a small number of propositions (two to three) can be active together in the driver analog. Mappings will be established incrementally, with early mappings constraining later ones (cf. Keane, 1997). Moreover, the success of the mapping process will depend on *which* propositions are activated together in the driver. In general, coherent, interconnected propositions (e.g., facts that are causally related) will provide more information that can be used to disambiguate a complex mapping. LISA therefore predicts that mapping will be more successful when the better-understood source acts as the driver while the less-understood target serves as recipient. Kubose, Holyoak, and Hummel (2002) showed that coherence of the driver impacts mapping, as LISA predicts. For example, people are more accurate in mapping the solved “general” story to the unsolved “tumor” problem than the reverse (see later discussion of “convergence” problems; Gick & Holyoak, 1980).

In addition to explaining phenomena concerning analogical reasoning by normal adults, LISA can account for numerous findings involving similarity judgments (Taylor & Hummel, 2009), developmental patterns (Doumas et al., 2008; Morrison, Doumas, & Richland, 2011), evidence of deficits in relational reasoning in older normal adults (Viskontas et al., 2004), and evidence of much more pronounced deficits in patients with lesions to their frontal or temporal cortex (Morrison et al., 2004).

Neural Substrate of Relational Reasoning

The implementation of role-based relational reasoning in the human brain involves a broad interconnected network of brain regions (see Morrison & Knowlton, Chapter 6). Although it is generally simplistic to identify cognitive functions with specific brain regions, several regions play major roles. The prefrontal cortex (PFC) is of central importance. The basic processes of the LISA model are closely related to known functions of PFC, in particular rapid learning (e.g., Asaad et al., 1998; Cromer, Machon, & Miller, 2011) and inhibitory control (e.g., Miller & Cohen, 2001). Other important brain regions include the hippocampus (critical

for storage and retrieval of episodic knowledge), the anterior temporal cortex (storage of semantic information, including semantic relations), and the parietal cortex (representation of spatial relations).

Role of Prefrontal Cortex in Relational Integration and Interference Control

The prefrontal cortex plays a central role in relational reasoning. It has been argued that this area underlies the fluid component of Spearman's g factor in intelligence (Duncan et al., 2000), and it supports the executive functions of working memory and cognitive control. With respect to relational reasoning, the PFC is critical in the maintenance and active manipulation of relations and role bindings (Knowlton & Holyoak, 2009; Robin & Holyoak, 1995). Waltz et al. (1999) found that patients with frontal-lobe damage showed a marked deficit in solving problems of the Raven's-matrix type problems that required integration of two relations compared to normal controls and patients with anterior temporal lobe damage. The frontal-lobe patients performed comparably to the other groups on less complex problems that could be solved using zero or one relation. These findings imply that prefrontal cortex is critical for the integration of multiple relations.

Other neuropsychological studies have examined the role of the PFC in controlling interference from distracting information during analogical reasoning. Morrison et al. (2004) tested patients with either frontal or temporal damage, as well as age-matched controls, on a verbal analogy task. Four-term analogy problems of the form A:B::C:D or D' were employed, where D is the analogical answer and D' is a nonanalogical foil. A semantic facilitation index (SFI) was calculated for each problem to characterize the association of the correct relational pair (C:D) relative to the distractor pair (C:D'). For example, for the problem *play:game::give: (party or take)*, the C:D pair (*give:party*, the correct analogical answer) is less associated than is the C:D' pair (*give:take*, the nonanalogical foil), yielding a negative SFI for the problem. The problems were divided into those with negative SFI, neutral SFI, and positive SFI in order to examine the effect of semantic interference on the ability to identify the analogical answer. Frontal patients were selectively impaired in the negative SFI condition relative to the positive and neutral SFI conditions, consistent with the hypothesis that the frontal cortex is necessary for control of interference. In contrast, temporal patients showed a more uniform decline in verbal analogy performance

across all three conditions, due to their loss of the conceptual information necessary to encode the relations in the analogy problem. Using four-term picture analogies, Krawczyk et al. (2008) also found that frontal patients are especially impaired on problems that include semantically related distractors.

Functional Decomposition of Prefrontal Cortex in Reasoning Tasks

Several neuroimaging studies using functional magnetic resonance imaging (fMRI) have manipulated relational complexity using variants of Raven's Progressive Matrices (RPM) problems, similar to those used by Waltz et al. (1999) in their neuropsychological studies. For matrix problems, relational integration has been shown to consistently activate prefrontal regions. In particular, bilateral middle and inferior frontal gyri, as well as parietal and occipital regions, have been found to increase activity when multiple relations must be integrated in order to arrive at a solution, compared to problems that require processing of only a single relation (Christoff et al., 2001; Kroger et al., 2002).

Among these regions, which constitute a network commonly activated in visuospatial working memory tasks, the activation pattern of the most anterior part of the PFC (termed *frontopolar*, or *rostrolateral*) has been particularly noteworthy. Christoff et al. (2001) found that the left frontopolar region remained preferentially activated even after controlling for the influence of increased problem-solving time (also Kroger et al., 2002). Similarly, studies of verbal analogical reasoning have distinguished neural substrates of reasoning from semantic processing demands within working memory. Activation in the left frontopolar region increases selectively when making judgments of analogical similarity compared to processing of semantic associations or categories (Bunge et al., 2005; Green et al., 2006; Wendelken et al., 2008). Moreover, frontopolar activation selectively increases when the semantic distance between the A:B and C:D pairs in a "true/false" verbal analogy problem is increased (Green et al., 2010), a manipulation that may increase the demands on relational processing.

Thus, based on a substantial body of findings involving solution of different types of relational reasoning problems, the frontopolar region appears to play a special role in the process of integrating multiple relational representations to arrive at a solution. Other subregions of PFC subserve additional processes involved in relational reasoning. Cho et al. (2010)

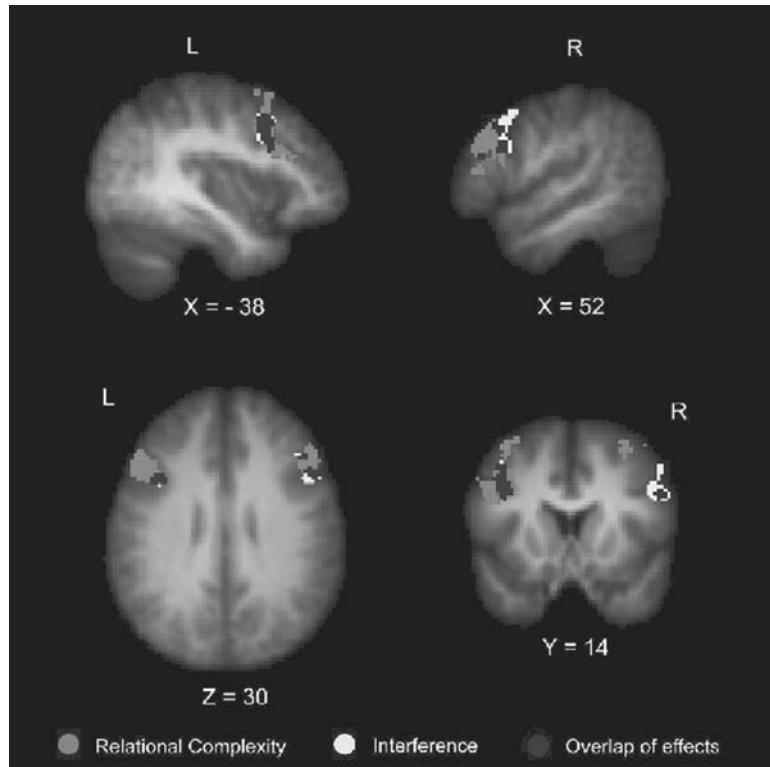

Fig. 13.3 Neuroimaging results from Cho et al. (2010). Regions showing the main effects of relational complexity (shown in red), interference (shown in yellow; small volume corrected, uncorrected cluster-forming threshold $T > 2.3$, corrected cluster extent significance threshold, $p < .05$), and regions where main effects overlapped (blue) within an a priori defined anatomical ROI mask of the bilateral MFG and IFG pars opercularis and pars triangularis. R, right; L, left. Coordinates are in MNI space (mm). (Reprinted by permission.) See color figure.

performed an fMRI study using four-term analogy problems based on cartoon figures and observed a partial dissociation between cortical regions sensitive to increase in demands on integration of multiple goal-relevant relations versus control of interference from goal-irrelevant relations (see Fig. 13.3). Problems requiring greater interference control selectively activated portions of the inferior frontal gyrus.

Component Processes of Analogical Reasoning

Let us now consider the subprocesses of relational reasoning in greater detail. A canonical instance of analogical reasoning involves (1) using retrieval cues provided by the target situation to access one or more source analogs in memory, (2) finding a mapping between a source and target, (3) using the mapping together with the functional structure of the source to make inferences about the target, and (4) generalizing the functional structure of the analogs (see Fig. 13.1).

A Paradigm for Studying Analogical Transfer

To study the entire process of analogical reasoning, including the retrieval of a source analog from

long-term memory, a key requirement is to ensure that one or more source analogs are in fact potentially available to the reasoner. Gick and Holyoak (1980, 1983) introduced a general laboratory paradigm for investigating analogical transfer in the context of problem solving. The basic procedure was to first provide people with a source analog in the guise of some incidental context, such as an experiment on “story memory.” Later, participants were asked to solve a problem that was in fact analogous to the story they had studied earlier. The questions of central interest were (1) whether people would spontaneously notice the relevance of the source analog and use it to solve the target problem, and (2) whether they could solve the analogy once they were cued to consider the source. Spontaneous transfer of the analogous solution implies successful retrieval and mapping; cued transfer implies successful mapping once the need to retrieve the source has been removed.

The source analog used by Gick and Holyoak (1980) was a story about a general who is trying to capture a fortress controlled by a dictator and needs to get his army to the fortress at full strength. Since the entire army could not pass safely along any single road, the general sends his men in small

groups down several roads simultaneously. Arriving at the same time, the groups join up and capture the fortress.

A few minutes after reading this story under instructions to read and remember it (along with two other irrelevant stories), participants were asked to solve a tumor problem (Duncker, 1945), in which a doctor has to figure out how to use rays to destroy a stomach tumor without injuring the patient in the process. The crux of the problem is that it seems that the rays will have the same effect on the healthy tissue as on the tumor—high intensity will destroy both, low intensity neither. The key issue is to figure out how the rays can be made to selectively impact the tumor while sparing the surrounding tissue. The source analog, if it can be retrieved and mapped, can be used to generate a “convergence” solution to the tumor problem, one that parallels the general’s military strategy: Instead of using a single high-intensity ray, the doctor could administer several low-intensity rays at once from different directions. In that way each ray would be at low intensity along its path, and hence harmless to the healthy tissue, but the effects of the rays would sum to achieve the effect of a high-intensity ray at their focal point, the site of the tumor.

When Gick and Holyoak (1980) asked college students to solve the tumor problem, without a source analog, only about 10% of them produced the convergence solution. When the general story had been studied, but no hint to use it was given, only about 20% of participants produced the convergence solution. In contrast, when the same participants were then given a simple hint that “you may find one of the stories you read earlier to be helpful in solving the problem,” about 75% succeeded in generating the analogous convergence solution. In other words, people often fail to notice superficially dissimilar source analogs that they could readily use. On occasions when a person did not notice the relevance of the remote source analog, he or she sometimes reported a feeling of insight (see van Steenburgh et al., Chapter 24).

Accessing Analogs in Long-Term Memory

This gap between the difficulty of retrieving remote analogs and the relative ease of mapping them has been replicated many times, both with adults (Gentner, Rattermann, & Forbus, 1993; Holyoak & Koh, 1987; Ross, 1987, 1989; Spencer & Weisberg, 1986) and with young children (Chen, 1996; Holyoak, Junn, & Billman, 1984; Tunteler &

Resing, 2002). When analogs must be cued from long-term memory, cases from a domain similar to that of the cue are retrieved much more readily than cases from remote domains (Keane, 1987; Seifert, McKoon, Abelson, & Ratcliff, 1986). For example, Keane (1987) measured retrieval of a convergence analog to the tumor problem when the source analog was studied 1–3 days prior to presentation of the target radiation problem. Keane found that 88% of participants retrieved a source analog from the same domain (a story about a surgeon treating a brain tumor), whereas only 12% retrieved a source from a remote domain (the general story). This difference in ease of access was dissociable from the ease of postaccess mapping and transfer, as the frequency of generating the convergence solution to the radiation problem once the source analog was cued was high and equal (about 86%) regardless of whether the source analog was from the same or a different domain.

The “retrieval gap” found in experimental studies of analogy is consistent with the obvious differences in the computational requirements of retrieval versus mapping. When attention is focused on two analogs, their representations will be held in working memory and explicit comparison processes can operate on relations. By definition, the question of which situations ought to be compared has already been answered. In contrast, retrieval is wide open—anything in long-term memory might potentially be relevant. As noted earlier, direct similarity of objects in the source and target is often a valid predictor of the inferential usefulness of the source. Additionally, focusing on relations in the target as retrieval cues places greater demands on working memory (see Morrison & Knowlton, Chapter 6).

Nonetheless, there is strong evidence that relational structure does play an important role in guiding analogical retrieval, both in the context of problem solving (Holyoak & Koh, 1987; Ross, 1987, 1989) and story reminding (Wharton et al., 1994; Wharton, Holyoak, & Lange, 1996). The influence of relational correspondences is greater when some degree of direct similarity of objects is also present, and when the relational correspondences favor one potential source over a nonrelational candidate competing for retrieval from long-term memory (Wharton et al., 1994). Interestingly, retrieval of verbal analogs (in the form of proverbs) is more successful when the analogs are presented in spoken rather than written form (Markman, Taylor, & Gentner, 2007), perhaps

because listening imposes a reduced processing load relative to reading. In addition, domain experts (who are more likely to focus on relevant relations as retrieval cues) are more likely than novices to access remote source analogs based on relational correspondences (Novick, 1988; Novick & Holyoak, 1991). Other evidence indicates that having people generate example cases, as opposed to simply asking them to remember cases presented earlier, can enhance structure-based access to source analogs (Blanchette & Dunbar, 2000).

UNINTENDED MEMORY ACTIVATION AND RELATIONAL PRIMING

In most of the experiments discussed so far, participants were explicitly asked to remember analogous situations stored in memory when cued with an analog, and hence were clearly aware when retrieval took place. In others (e.g., Gick & Holyoak, 1980) retrieval was not explicitly requested, but participants generally seemed to be aware of using a source analog to solve the target problem (when they in fact did so). Under some circumstances, however, people may use relations as cues to access information in long-term memory even when they have not been asked to do so. Moreover, in some cases they may not be aware that a previously encountered analog is guiding their current processing of a new example. Schunn and Dunbar (1996) performed a study in which during an initial session involving a problem in biochemistry, some subjects learned that addition of an inhibitory enzyme decreased virus reproduction. In a subsequent session the following day these same subjects were asked to solve a molecular-genetics problem, which involved an analogous inhibitory gene. Schunn and Dunbar found that subjects who had been exposed to the concept of inhibition in the initial session were more likely than control subjects to develop a solution based on inhibition for the transfer problem, even though experimental subjects evinced no signs of awareness that the earlier virus problem had influenced their solution to the gene problem. Similarly, Day and Goldstone (2011) found that participants were able to transfer strategies learned from a perceptually concrete simulation of a physical system to a task with very dissimilar content and appearance. Although recognition of the analogy between the tasks was associated with better overall performance, transfer (i.e., application of an analogous strategy) was not related to such recognition (see also Day & Gentner, 2007; Wharton & Lange, 1994).

Such apparently unintended transfer likely involves a different mechanism than does deliberate analogical mapping and inference. As we will see later, intentional relational transfer makes heavy demands on working memory and appears to be a paradigmatic example of what is sometimes termed *explicit* or System 2 processing (see Evans, Chapter 8). But as Schunn and Dunbar (1996) argued, some forms of relational transfer may be more akin to *priming*, typically considered an example of *implicit* or System 1 processing. Spellman, Holyoak, and Morrison (2001) demonstrated rapid priming based on semantic relations, using both naming and lexical decision paradigms. For example, participants were able to identify a related pair such as BEAR–CAVE as words more quickly when preceded (400 msec earlier) by BIRD–NEST (same relation) as opposed to BIRD–DESERT (unrelated). Note that although the pairs BIRD–NEST and BEAR–CAVE share the same relation (“lives in”), the objects themselves are not especially similar. Spellman et al. found that it was necessary to explicitly tell participants to pay attention to relations in order to obtain relation-based priming. However, such instructions were not essential in similar paradigms when the prime was presented for a longer duration and a relational judgment about the prime was required (Estes, 2003; Estes & Jones, 2006; see also Allen, Ibara, Seymour, Cordova, & Botvinick, 2010).

Relational priming may be especially potent when its application to objects of a certain type is overlearned. For example, Bassok, Chase, and Martin (1998) demonstrated that people are sensitive to what they termed *semantic alignment* of objects with the mathematical operation of addition. These investigators found that two sets of objects that each belong to the same general category (e.g., cats and dogs, both of which are animals) could readily be aligned with the addends of addition, whereas sets of objects that are functionally related (e.g., birds and cages) proved to be far less natural as addends. Extending this finding, Bassok, Pedigo, and Oskarsson (2008) showed that automatic activation of basic arithmetic facts (e.g., $3 + 4 = 7$) is modulated by prior presentation of aligned versus nonaligned word pairs (see also Fisher, Bassok, & Osterhout, 2010). The apparent automaticity of this phenomenon is consistent with people’s extensive experience in using the addition operation to solve problems involving a variety of semantically aligned object sets (e.g., blue and red marbles, cars and trucks, cupcakes and brownies). Importantly,

the priming effects observed in these studies did not in general aid in task performance, suggesting that priming was automatic.

Longer term priming may have contributed to the apparent unintended transfer effects observed in studies such as those of Schunn and Dunbar (1996) and Day and Goldstone (2011), as the source analog was itself processed deeply to solve a problem. Unintended transfer may not require developing a systematic mapping of the source to the target. Rather, more piecemeal transfer may occur based on activation of one or more key relational concepts (e.g., the concept of “inhibition” in the Schunn and Dunbar study).

Mapping

Mapping—the process of identifying corresponding elements of the source and target analogs—plays a central role in analogical inference. For meaningful situations such as problems or stories, adults with intact executive functions typically are able to establish correspondences based primarily on relational roles, even when direct similarity of mapped elements is low or uninformative (Gentner & Gentner, 1983; Gick & Holyoak, 1980, 1983).

ALIGNABILITY AND ATTENTIONAL FOCUS

Markman and Gentner (1993; for a review see Gentner & Markman, 1997) drew an important distinction between commonalities (the shared properties of mapped elements), alignable differences (differences between mapped elements), and nonalignable differences (differences between analogs involving unmapped elements). In Figure 13.4, for example, the car in the top picture can be mapped to the boat in the bottom picture based on their common roles (vehicles being towed). The car and boat also exhibit alignable differences. In contrast, the parking meter in the top picture has no clear corresponding element in the bottom picture, and hence it constitutes a nonalignable difference.

The basic impact of analogical mapping is to focus attention on the commonalities and (usually to a lesser extent) the alignable differences, while backgrounding the nonalignable differences. Gentner and Markman (1994) gave college students word pairs and asked them to list one difference each for as many pairs as possible under time pressure. The participants produced many more alignable than nonalignable differences. Contrary to

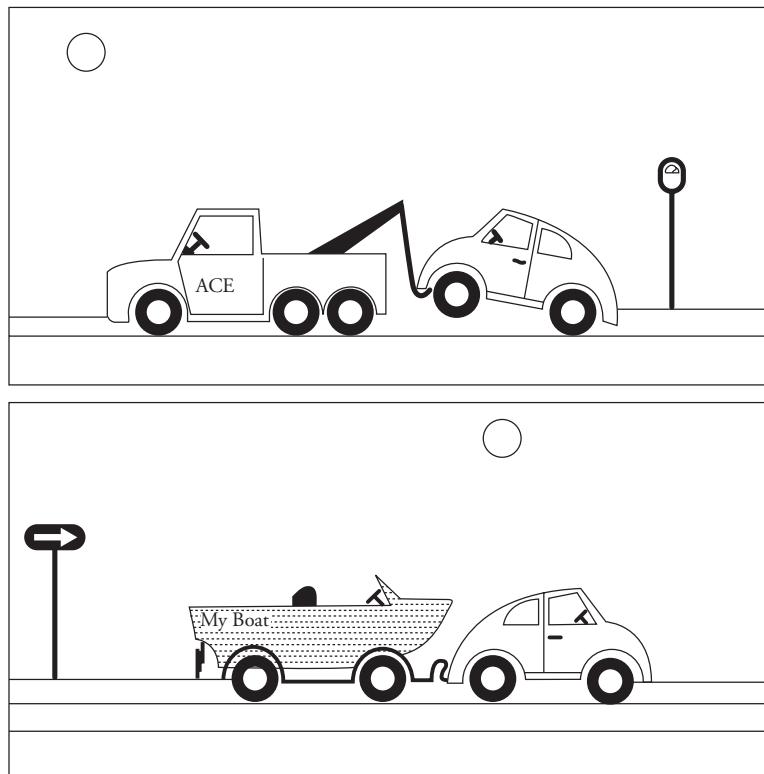

Fig. 13.4 Pictures illustrating types of analogy-based similarities and differences (Markman & Gentner, 1996). (Pictures courtesy of Art Markman.)

the commonsense idea that differences will be easier to find for dissimilar concepts, participants were actually more fluent in stating a difference for pairs of similar, alignable concepts (e.g., *hotel* – *motel*) than for dissimilar, nonalignable concepts (e.g., *kitten* – *magazine*), suggesting that the comparison process made the alignable differences especially salient. Relative to nonalignable differences, alignable differences have stronger effects on the perception of overall similarity (Markman & Gentner, 1996; see Goldstone & Son, Chapter 10), are more memorable (Markman & Gentner, 1997), and have a greater impact on choices made in a decision task (Markman & Medin, 1995).

COHERENCE IN ANALOGICAL MAPPING

The key idea of Holyoak and Thagard's (1989) multiconstraint theory of analogy is that several different kinds of constraints—similarity, structure, and purpose—all interact to determine the optimal set of correspondences between source and target. A good analogy is one that appears *coherent*, in the sense that multiple constraints converge on a solution that largely satisfies all constraints (Thagard, 2000). When constraints conflict, mappings may be ambiguous. For example, the two pictures shown in Figure 13.4 include a *cross-mapping*—the car in the top picture maps to the boat in the bottom picture on the basis of relational roles (both are vehicles being towed), but to the car in the bottom picture on the basis of direct similarity. Situations involving cross mappings are especially difficult, more so than analogies with less semantic overlap (Gentner & Toupin, 1986; Ross, 1989). Implicit cross mappings can also interfere with students' understanding of the intended interpretation of graphs and similar visuospatial representations (Gattis & Holyoak, 1996).

Comparisons based on perceptually rich stimuli, which afford an abundance of direct similarities between objects, typically lead to a lower frequency of relational responses relative to comparisons based on perceptually sparse stimuli (Markman & Gentner, 1993). In general, manipulations that increase attention to relations tend to encourage a relation-based response. For example, Markman and Gentner found that people who mapped three objects at once were more likely to map on the basis of similar relational roles than were people who mapped just one cross-mapped object, presumably because mapping multiple objects focuses greater attention on relations among them. Relational

language is an especially important influence on mapping. For preschool children, Loewenstein and Gentner (2005) found that explicitly describing a scene in terms of spatial relations increased the frequency of relation-based mappings (for a general discussion of language and thought, see Gleitman & Papafragou, Chapter 28).

In the absence of cross mappings, adults are generally able to integrate multiple constraints to establish coherent mappings, even for situations that are complex and somewhat ambiguous. For example, at the beginning of the first Gulf War in 1991, Spellman and Holyoak (1992) asked a group of American undergraduates a few questions to find out how they interpreted the analogy between the then-current situation in the Persian Gulf and World War II. The undergraduates were asked to suppose that Saddam Hussein, the President of Iraq, was analogous to Hitler (a popular analogy at the time). Regardless of whether they thought the analogy was appropriate, they were then asked to write down the most natural match in the World War II situation for various people and nations involved in the Gulf War, including the United States and its current President, George H. W. Bush. For those students who gave evidence that they knew the basic facts about World War II, the majority produced mappings that fell into one of two patterns, each coherent on relational grounds. Those students who mapped the United States to itself also mapped Bush to Franklin D. Roosevelt. Other students, in contrast, mapped the United States to Great Britain and Bush to Winston Churchill, the British Prime Minister (perhaps because Bush, like Churchill, led his nation and Western allies in early opposition to aggression). The analogy between the Persian Gulf situation and World War II thus generated a "bistable" mapping: People tended to provide mappings based on either of two coherent but mutually incompatible sets of correspondences.

Mapping is guided not only by relational structure and element similarity but also by the goals of the analogist (Holyoak, 1985). Particularly when the mapping is inherently ambiguous, the constraint of pragmatic centrality—relevance to goals—is critical (Holyoak, 1985). Spellman and Holyoak (1996) investigated the impact of processing goals on the mappings generated for inherently ambiguous analogies and found that mappings were predominately determined by those relations most relevant to the reasoner's goal.

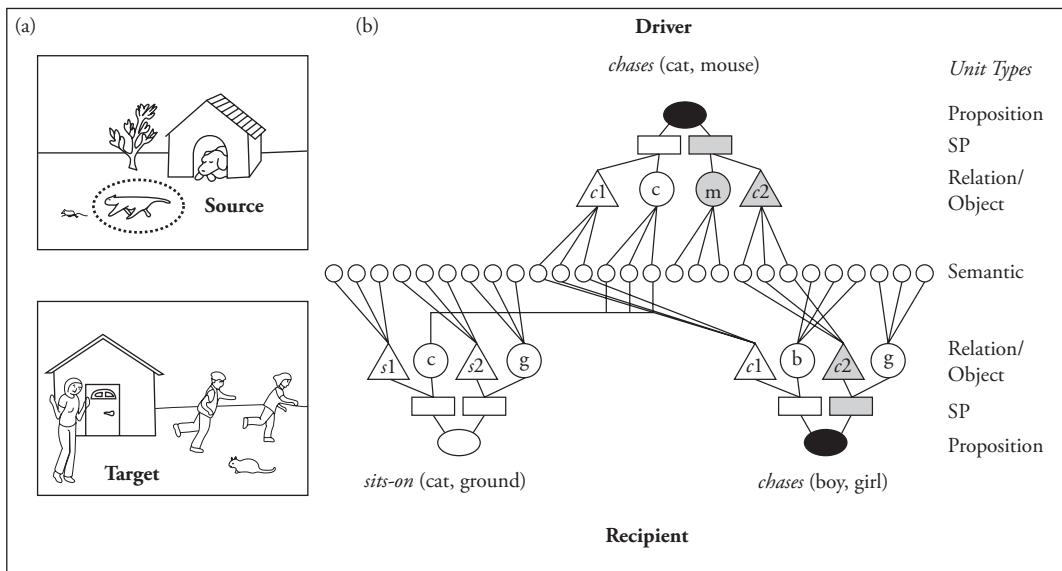

Fig. 13.5 (A) Example of one-relation/distractor scene-analogy problem (Richland et al., 2006); (B) LISA architecture as applied to this problem. In order for a reasoner to select the boy in the target as the correct analogical mapping to the cat in the source, units in the recipient representing the proposition *chases* (boy, girl) must inhibit corresponding units in the propositional structure containing the featureally similar “sitting cat” distractor. (Reprinted with permission from Morrison, Doumas, & Richland, 2011.)

DEVELOPMENTAL CHANGES IN ANALOGICAL MAPPING

Young children are particularly sensitive to direct similarity of objects. When asked to identify corresponding elements in two analogs when semantic and structural constraints conflict, their mappings are dominated by object similarity (Gentner & Toupin, 1986). The developmental transition toward greater reliance on relational structure in mapping has been termed the *relational shift* (Gentner & Rattermann, 1991). The empirical phenomenon of a relational shift is well established, but there has been some debate regarding the developmental mechanisms that may underlie it. Goswami and colleagues have argued that analogical reasoning is fundamentally available as a capacity from early infancy (and indeed, some analogical ability is apparent in 1-year-old children; Chen, Sanchez, & Campbell, 1997), but that children’s analogical performance increases with age due to the accretion of knowledge about relevant relations (Goswami, 1992, 2001; Goswami & Brown, 1989). Knowledge of relations is without doubt essential for analogical reasoning. Even for adults, expertise in a domain is a predictor of superior ability to process analogies in that domain (Novick & Holyoak, 1991).

However, although accretion of knowledge is certainly an important factor, there is now evidence

that maturational changes in cognitive functioning also drive developmental differences in analogical reasoning. These changes are associated with the maturation of the prefrontal cortex (see Diamond, 2002), which is not complete until adolescence. The prefrontal cortex underlies executive control (Diamond, 2006; see Morrison & Knowlton, Chapter 6), and in particular the capacity to manipulate complex information in working memory and to inhibit salient but task-inappropriate information and responses. A study by Richland, Morrison, and Holyoak (2006) illustrates how the need for working memory and inhibitory control influence the difficulty of analogical mapping at different ages. Figure 13.5a depicts an example of “scene-analogy” problems developed for use with children as young as 3–4 years old; Figure 13.5b illustrates how the LISA model (Hummel & Holyoak, 1997) would represent the mapping problem. For each pair of pictures, children were asked to identify the object in the bottom picture that “goes with” the object indicated by an arrow in the top picture. In some problems, such as that shown in Figure 13.5a, the child is confronted with a conflict between two possible answers, one relational and one based on perceptual and/or semantic similarity. The cat in the top picture perceptually resembles the cat in the bottom picture, but it plays a role (chasing a

mouse) that parallels the role played by the boy in the bottom picture (chasing a girl). Richland et al. found that young children were less likely to give the relational response when an alternative based on direct similarity was available. Inhibitory control is presumably required to avoid responding on the basis of direct similarity.

In addition, relational reasoning varies in its complexity, which has been linked to the number of relational roles relevant to an inference (Halford, 1993; Halford et al., 1998). The load on working memory will be less if a single relation is sufficient to determine the role-based inference (as in the example shown in Fig. 13.5a), compared to when multiple relations must be integrated to derive the inference. Richland et al. (2006) found that preschool children gave fewer relational responses when either a similar distractor was present in the bottom picture or when two relations had to be integrated. By age 13–14 years—roughly the age at which the prefrontal cortex has undergone substantial further maturation—children reliably gave the relational response even when multiple relations had to be integrated and a similar distractor was present. Children with autism, when matched to controls on measures of executive function, show comparable trends in analogical reasoning (Dawson et al., 2007; Morsanyi & Holyoak, 2010). This pattern of analogical development is consistent with what is known about the neural basis for analogical reasoning in adults, as discussed earlier.

Analogical Inference

Analogical inference—using a source analog to form a new conjecture, whether it be a step toward solving a math problem (see Bassok & Novick, Chapter 21), a scientific hypothesis (Dunbar & Klahr, Chapter 35), a basis for deciding a legal case (Spellman & Schauer, Chapter 36), or finding a diagnosis for puzzling medical symptoms (Patel et al., Chapter 37)—is the fundamental purpose of analogical reasoning (Bartha, 2010). Mapping serves to highlight correspondences between the source and target. These correspondences provide the input to an inference engine that generates new target propositions.

The basic algorithm for analogical inference used by all major computational models has been termed “copy with substitution and generation,” or CWSG (Holyoak, Novick, & Melz, 1994), and involves constructing target analogs based on unmapped source propositions by substituting the corresponding

target element (if known) for each source element, and if no corresponding target element is known, postulating one as needed. CWSG allows the generation of structured propositions about the target (as opposed to simple associations) because of its reliance on variable binding and mapping. In this key respect, inference by CWSG is similar to rule-based inferences of the sort modeled by production systems (e.g., Anderson & Lebiere, 1998; see Doumas & Hummel, Chapter 5; Koedinger & Roll, Chapter 40). However, the constraints on analogical mapping are more fluid than are the typical constraints on matching in a production system. CWSG is more flexible in that unlike production rules, there is no strict division between a “left-hand side” to be matched and a “right-hand side” that creates an inference. Rather, any subset of the two analogs may provide an initial mapping, and the unmapped remainder of the source may be used to create target inferences (giving rise to the property of *omnidirectional access* in analogical inference; Halford et al., 1998). Analogical inference might be described as a “strong weak method”—a domain-general method (see Bassok & Novick, Chapter 21) that can be extremely powerful if the requisite knowledge about a source analog is available (though useless if an appropriate source is lacking).

INTEGRATING ANALOGICAL INFERENCE WITH CAUSAL MODELS

The CWSG algorithm, and analogical inference in general, can fail in a variety of ways. If critical elements are difficult to map (e.g., because of strong representational asymmetries, such as those that hinder mapping a discrete set of elements to a continuous variable; Bassok & Olseth, 1995; Bassok & Holyoak, 1989), then no inferences can be constructed. If elements are mismapped, corresponding inference errors will result (Holyoak et al., 1994; Reed, 1987). Most important, the great fluidity of CWSG has its downside. Without additional constraints on when CWSG is invoked, *any* unmapped source proposition would generate an inference about the target. Such a loose criterion for inference generation would lead to rampant errors whenever the source was not isomorphic to a subset of the target; and such isomorphism will virtually never hold for problems of realistic complexity. Accordingly, additional constraints are required (Clement & Gentner, 1991; Holyoak et al., 1994; Markman, 1997).

Lassaline (1996) provided evidence of factors that appear to constrain analogical inferences. She had

college students read descriptions of the properties of hypothetical animals, and then rate various possible target inferences for the probability that the conclusion would be true, given the information in the premise. Participants rated potential inferences as more probable when the source and target analogs shared more attributes, and hence were more similar. In addition, the presence of a causal relation in the source made an inference more credible. For example, if the source and target animals were both described as having a weak immune system, and for the source the weak immune system was stated to “cause” an acute sense of smell, then the inference that the target animal also has an acute sense of smell would be bolstered relative to stating only that the source animal had a weak immune system “and” an acute sense of smell. The benefit conveyed by the linking relation was reduced if it was less clearly causal (“develops before”). Lassaline’s findings thus imply that although analogical inferences are influenced by the overall similarity of the analogs, causal relations in the source play an especially important role.

Work by Lee and Holyoak (2008) demonstrated the close connection between analogical inference and the operation of representations that have been termed *causal models* (Waldmann & Holyoak, 1992; see Cheng & Buehner, Chapter 12)—a network of cause-effect relations characterizing each analog. Holyoak, Lee, and Lu (2010) formalized this integration by extending a Bayesian model of causal learning (Lu et al., 2008) to deal with analogical inference. The basic idea is that for empirical analogies, the causal model of the source analog (including information about the strength distributions associated with individual causal links), coupled with the mapping of source to target, provide the input to CWSG. This procedure constrains CWSG is a way that favors accurate and useful inferences, generating as its output an elaborated causal model of the target. This causal model is then used to evaluate the probability of specific inferences about the target. By treating analogical and causal inference within a unifying theoretical framework, it proved possible to explain situations in which the strengths of inferences about the target are dissociable from the overall similarity of the source and target. Most dramatically, Lee and Holyoak showed that if the source exhibits an effect *despite* the presence of a preventive cause, then people judge the effect to be *more* likely in the target if it lacks the preventer (even though absence of the preventer reduces overall similarity of the source and target).

Rather than considering analogical inference in isolation, it is useful to view the entire transfer process as the joint product of causal learning and relational mapping: The reasoner learns the causal structure of the source, maps the source to target, applies CWSG to augment the causal model of the target, and then uses the resulting model to evaluate an open-ended range of potential inferences about the target. The model of the target generated on the basis of the source will often be imperfect, so that additional postanalogical processes of *adaptation* will be required to accommodate goal-relevant aspects of the target that are not predictable from the source (Carbonell, 1983; Holyoak et al., 1994).

ANALOGICAL INFERENCES AS “FALSE MEMORIES”

An important question concerns when analogical inferences are made, and how inferences relate to facts about the target analog that are stated directly. One extreme possibility is that people only make analogical inferences when instructed to do so, and that inferences are carefully “marked” as such, so that they will never be confused with known facts about the target. At the other extreme, it is possible that some analogical inferences are triggered when the target is first processed (given that the source has been activated), and that such inferences are then integrated with prior knowledge of the target. One paradigm for addressing this issue is based on testing for false “recognition” of potential inferences in a subsequent memory test. The logic of the recognition paradigm is that if an inference has been made and integrated with the rest of the target analog, then later the reasoner will believe that the inference had been directly presented, in effect having created a “false memory” (see Brainerd & Reyna, 2005).

Early work by Schustack and Anderson (1979) provided evidence that people sometimes falsely report that analogical inferences were actually presented as facts. Blanchette and Dunbar (2002) performed a series of experiments designed to assess when analogical inferences are made. They had college students (in Canada) read a text describing a current political issue, possible legalization of marijuana use, which served as the target analog. Immediately afterward, half the students read, “The situation with marijuana can be compared to...” followed by an additional text describing the period early in the 20th century when alcohol use was prohibited. Importantly, the students in the analogy condition were not told how prohibition mapped onto the

marijuana debate, nor were they asked to draw any inferences. After a delay (1 week in one experiment, 15 minutes in another), the students were given a list of sentences and were asked to decide whether each sentence had actually been presented in the text about marijuana use. The critical items were sentences such as “The government could set up agencies to control the quality and take over the distribution of marijuana.” These sentences had never been presented; however, they could be generated as analogical inferences by CWSG, based on a parallel statement contained in the source analog (“The government set up agencies to control the quality and take over the distribution of alcohol”). Blanchette and Dunbar found that students in the analogy condition said “yes” to analogical inferences about 50% of the time, whereas control subjects who had not read the source analog about prohibition said “yes” only about 25% of the time. This tendency to falsely “recognize” analogical inferences that had never been read was obtained both after long and short delays, and with both familiar and less familiar materials. Similar findings have been obtained by Perrott, Gentner, and Bodenhausen (2005).

It thus appears that when people notice the connection between a source and target, and they are sufficiently engaged in an effort to understand the target situation, analogical inferences will often be generated and then integrated with prior knowledge of the target. In some cases such transfer may be unintended and involve relational priming, as discussed earlier. At least sometimes, an analogical inference becomes accepted as a stated fact. Like relational priming, this is a case in which relational transfer does not necessarily improve performance of the target task (recognition memory). Such findings have important implications for understanding how analogical reasoning can operate as a tool for persuasion.

Relational Generalization and Schema Induction

In addition to generating local inferences about the target, analogical reasoning can give rise to relational generalizations—abstract schemas that establish an explicit representation of the commonalities between the source and target. *Comparison*—not simply passive accumulation of information about distributions of features across examples, but active generation of structural correspondences—lies at the heart of analogical reasoning. Comparison of multiple analogs can result not only in a specific mapping

but also in the induction of a schema, which in turn will facilitate subsequent transfer to additional analogs. The induction of such schemas has been demonstrated in both adults (Catrambone & Holyoak, 1989; Gick & Holyoak, 1983) and young children (Brown, Kane, & Echols, 1986; Chen & Daehler, 1989; Holyoak et al., 1984; Kotovsky & Gentner, 1996; Loewenstein & Gentner, 2001; Namy & Gentner, 2002).

Comparison has been shown to guide schema formation in teaching such complex topics as negotiation strategies (Loewenstein, Thompson, & Gentner, 1999, 2003; see Loewenstein, Chapter 38). There is also evidence that comparison may play a key role in learning role-based relations (e.g., comparative adjectives such as “bigger than”) from nonrelational inputs (Doumas et al., 2008), and in language learning more generally (Gentner, 2010; Gentner & Namy, 2006). An important refinement of the use of comparison as a training technique is to provide a series of comparisons ordered “easy to hard,” where the early pairs share salient surface similarities as well as less salient relational matches, and the later pairs share only relational matches. This “progressive alignment” strategy serves to promote a kind of analogical bootstrapping, using salient similarities to aid the learner in identifying appropriate mappings between objects that also correspond with respect to their relational roles (Kotovsky & Gentner, 1996).

FACTORS THAT INFLUENCE SCHEMA INDUCTION

People are able to induce schemas by comparing just two analogs to one another (Gick & Holyoak, 1983). Indeed, people will form schemas simply as a side effect of applying one solved source problem to an unsolved target problem (Novick & Holyoak, 1991; Ross & Kennedy, 1990). In the case of problem schemas, more effective schemas are formed when the goal-relevant relations are the focus rather than incidental details (Brown et al., 1986; Brown, Kane, & Long, 1989; Gick & Holyoak, 1983). In general, any kind of processing that helps people focus on the underlying functional structure of the analogs, thereby encouraging learning of more effective problem schemas, will improve subsequent transfer to new problems. For example, Gick and Holyoak (1983) found that induction of a “convergence” schema from two disparate analogs was facilitated when each story stated the underlying solution principle abstractly: “If you need a large

force to accomplish some purpose, but are prevented from applying such a force directly, many smaller forces applied simultaneously from different directions may work just as well." In some circumstances transfer can also be improved by having the reasoner generate a problem analogous to an initial example (Bernardo, 2001). Other work has shown that abstract diagrams that highlight the basic idea of using multiple converging forces can aid in schema induction and subsequent transfer (Beveridge & Parkins, 1987; Gick & Holyoak, 1983).

Although two examples can suffice to establish a useful schema, people are able to incrementally develop increasingly abstract schemas as additional examples are provided (Brown et al., 1986; Brown et al., 1989; Catrambone & Holyoak, 1989). Even with multiple examples that allow novices to start forming schemas, people may still fail to transfer the analogous solution to a problem drawn from a different domain if a substantial delay intervenes or if the context is changed (Spencer & Weisberg, 1986). Nonetheless, as novices continue to develop more powerful schemas, long-term transfer in an altered context can be dramatically improved (Barnett & Koslowski, 2002). For example, Catrambone and Holyoak (1989) gave college students a total of three convergence analogs to study, compare, and solve. The students were first asked a series of detailed questions designed to encourage them to focus on the abstract structure common to two of the analogs. After this abstraction training, the students were asked to solve another analog from a third domain (not the tumor problem), after which they were told the convergence solution to it (which most students were able to generate themselves). Finally, a week later, the students returned to participate in a different experiment. After the other experiment was completed, they were given the tumor problem to solve. Over 80% of participants came up with the converging-rays solution without any hint. As the novice becomes an expert, the emerging schema becomes increasingly accessible and is triggered by novel problems that share its structure (see Koedinger & Roll, Chapter 40). Deeper similarities have been constructed between analogous situations that fit the schema.

IMPACT OF SCHEMAS ON RELATIONAL PROCESSING

As schemas are acquired from examples, they in turn guide future analog retrieval, mapping, and inference. We have already seen how schema

induction can increase subsequent transfer to novel problems (e.g., Bassok & Holyoak, 1989; Gick & Holyoak, 1983; Loewenstein et al., 2003), as well as facilitate processing of metaphors (Gentner & Bowdle, 2008). In addition, a schema induced by comparing examples can work "backward" in memory, making it easier to retrieve analogous episodes (including autobiographical memories) that had been stored before the schema was acquired (Gentner, Loewenstein, Thompson, & Forbus, 2009).

Of course, schemas are often acquired through experience outside the laboratory. Such preexisting schemas can guide the interpretation of specific examples, thereby changing analogical mapping and inference. For example, Bassok, Wu, and Olseth (1995) examined analogical reasoning with algebra word problems similar to ones studied previously by Ross (1987, 1989). Participants were shown how to compute permutations using an example (the source problem) in which some items from a set of n members were randomly assigned to items from a set of m members (e.g., how many different ways can you assign three computers to three secretaries if there are n computers and m secretaries?). Participants were then tested for their ability to transfer this solution to new target problems. The critical basis for transfer hinged on the assignment relation in each analog—that is, what kinds of items (people or inanimate objects) served in the roles of n and m . In some problems (type OP) objects (n) were assigned to people (m ; e.g., "computers were assigned to secretaries"); in others (PO) people (n) were assigned to objects (m ; "secretaries were assigned to computers"). Solving a target problem required the participant to map the elements of the problem appropriately to the variables n and m in the equation for calculating the number of permutations.

Although all the problems were formally isomorphic, Bassok et al. (1995) demonstrated that people will typically interpret an "assign" relation between an object and a person as one in which the person *gets* the object. Importantly, the "get" schema favors interpreting the person as the recipient of the object no matter which entity occupies which role in the stated "assign" relation. These distinct interpretations of the stated "assign" statement yielded systematic consequences for analogical mapping. Given an OP source analog, Bassok et al. found that people tended to link the "assigned" object to the "received" role (rather than the "recipient" role) of the "get" schema, which in turn was then mapped

to the mathematical variable n , the number of “assigned” objects. As a result, when the target analog also had an OP structure, transfer was accurate (89%); but when the target was in the reversed PO structure, the object set continued to be linked to the “received” role of “get,” and hence erroneously mapped to n (0% correct!). Bassok et al.’s findings highlight the constructive and interactive nature of relational processing (see also Hofstadter & Mitchell, 1994).

Conclusions

Analogy is an important special case of role-based relational reasoning, a psychological process that generates inferences based on patterns of relational roles. At its core, analogy depends on comparison of situations. But humans do much more than just compare two analogs based on obvious similarities between their elements. Rather, analogical reasoning is a complex process of retrieving structured knowledge from long-term memory, representing and manipulating role-filler bindings in working memory, generating new inferences, and finding structured intersections between analogs to form new abstract schemas. For empirical analogies, analogical inference is guided by causal knowledge about how the source analog operates. Simpler types of relation-based transfer can be produced by relational priming.

Symbolic-connectionist models have the greatest promise in relating relational reasoning to its neural substrate. Human analogical reasoning is heavily dependent on working memory and other executive functions supported by the prefrontal cortex, with the frontopolar subregion being selectively activated when multiple relations must be integrated to solve a problem.

Future Directions

Computational Level

Theoretical work to date has specified qualitative constraints on analogical mapping and inference, often implemented in computer simulations. Recent efforts to integrate analogical inference with Bayesian causal models (Holyoak et al., 2010) suggest that human analogical inference may be approximately normative when the analogs can be represented as simple causal networks based on binary variables. However, a full computational-level analysis of relational reasoning using the modern Bayesian framework for induction (see Griffiths et al., Chapter 3) has not yet been offered. Given representations of

source and target analogs (including relevant prior knowledge), normative probability distributions for possible analogical mappings and inferences might in principle be derived. However, in practice this remains a challenging (perhaps even intractable) project, given that the types of relations involved in analogies are indefinitely diverse and include many different types of causal functions. One key requirement for applying the Bayesian framework to analogy will be greater theoretical integration of role-based relational representations with probabilistic inference.

Level of Representation and Algorithm

For over 30 years, a great deal of effort has been directed at the development of algorithmic models of analogical reasoning, formalized as computer simulations. In recent years, some of these models (based on the symbolic-connectionist framework) have begun to make contact with work on the neural substrate of relational reasoning. However, no model as yet comes close to providing a comprehensive account of how humans reason with relations.

One basic limitation is that human relational reasoning is far more flexible than any current simulation model (Bartha, 2010; Bassok et al., 1995; Hofstadter & Mitchell, 1994). The stage analysis typically used (for example, in this chapter) to organize analogical processing—retrieval, mapping, inference, schema induction (see Fig. 13.1)—is oversimplified. In everyday use of analogies, the entire process may be cyclic, interactive, and open ended. The effective representation of the source analog may be developed in the very process of reasoning with it. Multiple source analogs and schemas may be involved, some of them imagined rather than actual (as in the case of analogical “thought experiments”; see Bartha, 2010; Holyoak & Thagard, 1995). Typically there is no firm boundary around the information that counts as an individual analog. Causal knowledge, which is deeply embedded in the representation of individual cases, is almost inevitably linked to more general categories. Analogs, schemas, categories, and rules all interact with one another in the course of inductive inference (Holland et al., 1986). In addition, much more needs to be learned about how “full-blown” System 2 relational processing relates to simpler System 1 processing (e.g., relational priming).

A related limitation of current computational models of analogy is that their knowledge

representations typically must be hand-coded by the modeler, whereas human knowledge representations are formed autonomously. In effect, modelers have allowed themselves an indefinite number of free parameters to facilitate data-fitting. There have been recent efforts to extend analogy models to account for how humans learn basic perceptual relations from nonrelational inputs (Doumas et al., 2008). This is a welcome development, but even here, the nonrelational inputs have themselves been hand-coded by the modelers.

Closely related to the challenge of avoiding hand-coding of representations is the need to flexibly re-represent knowledge so as to render potential analogies perspicuous. Concepts often have a close conceptual relationship with more complex relational forms (Jackendoff, 1983). For example, causative verbs such as *lift* (e.g., “John lifted the hammer”) have very similar meanings to structures based on an explicit higher order relation, *cause* (e.g., “John caused the hammer to rise”). In such cases the causative verb serves as a “chunked” representation of a more elaborate predicate-argument structure. People are able to “see” analogies even when the analogs have very different linguistic forms (e.g., “John lifted the hammer in order to strike the nail” might be mapped onto “The Federal Reserve used an increase in interest rates as a tool in its efforts to drive down inflation”). A deeper understanding of human knowledge representation is a prerequisite for a complete theory of analogical reasoning.

Yet another limitation is that most research and modeling in the field of analogy has emphasized quasi-linguistic knowledge representations, but there is good reason to believe that reasoning in general has close connections to perception and action (see Hegarty & Stull, Chapter 31; Goldin-Meadow & Cook, Chapter 32). The ease of solving apparently isomorphic problems (e.g., isomorphs of the well-known Tower of Hanoi) can vary enormously depending on perceptual cues (Kotovsky & Simon, 1990). Models of analogy have not offered an adequate account of why the difficulty of solving problems and transferring solution methods to isomorphic problems is dependent on the difficulty of perceptually encoding key relations.

In addition, models of analogy have not been well integrated with models of problem solving (see Bassok & Novick, Chapter 21), despite the fact that analogy clearly affords an important mechanism for solving problems. In its general form, problem solving requires sequencing multiple operators, establishing

subgoals, and using combinations of rules to solve related but nonisomorphic problems. These basic requirements are beyond the capabilities of current computational models of analogy. The integration of analogy models with models of general problem solving remains an important research goal.

Neural Implementation

The recent advances in understanding the neural substrate of relational reasoning (in particular, the roles played by specific areas of prefrontal cortex operating within broader neural circuits) have set the stage for further work on how analogies are computed by the brain (see Morrison & Knowlton, Chapter 6). For example, tasks involving analogical processing, like those designed to elicit insight (see van Steenburgh et al., Chapter 24), should prove useful in investigating connections between the neural bases of cognition and emotion. Careful studies will be required to determine how the neural systems involved in analogical reasoning relate to those involved in other forms of role-based relational reasoning, such as deductive and linguistic inferences (e.g., Monti, Parsons, & Osherson, 2009).

Given that a significant evolutionary gap may separate human role-based relational reasoning from the capabilities of other extant primate species (Penn et al., 2008), animal models may not provide fully adequate models of human reasoning. Testing the mechanisms postulated by symbolic-connectionist models (Hummel & Holyoak, 1997), such as dynamic binding controlled by synchronous neural activity in the gamma band, and rapid cortical learning of mapping connections, will require noninvasive neuroimaging techniques that provide extremely fine temporal resolution coupled with good spatial resolution (but see Lu et al., 2006, for an example of how a behavioral priming technique may be useful for assessing the role of synchrony in perceptual representation). The emerging field of cognitive neurogenetics (see Green & Dunbar, Chapter 7) will doubtless provide deeper insights into the neural basis of human analogical reasoning.

Translational Research

In parallel with continued basic research on role-based relational reasoning, we can anticipate advances in many application areas, such as the use of analogies in teaching and learning (e.g., Richland, Stigler, & Holyoak, 2012), as aids to creative design, and in applications to computer-based search algorithms. The limits of analogical

applications are roughly coextensive with those of human imagination.

Acknowledgments

Preparation of this chapter was supported by grant N000140810186 from the Office of Naval Research, and grant R305C080015 from the Institute of Education Sciences. I thank Miriam Bassok, Alex Doumas, John Hummel, Art Markman, Bob Morrison, and Derek Penn for helpful discussions and suggestions.

Explanation and Abductive Inference

Tania Lombrozo

Abstract

Everyday cognition reveals a sophisticated capacity to seek, generate, and evaluate explanations for the social and physical worlds around us. Why are we so driven to explain, and what accounts for our systematic explanatory preferences? This chapter reviews evidence from cognitive psychology and cognitive development concerning the structure and function of explanations, with a focus on the role of explanations in learning and inference. The findings highlight the value of understanding explanation and abductive inference both as phenomena in their own right and for the insights they provide concerning foundational aspects of human cognition, such as representation, learning, and inference.

Key Words: explanation, understanding, abduction, abductive inference, inference to the best explanation, self-explanation

Introduction

This chapter considers a ubiquitous but under-studied aspect of human cognition: explanation. Both children and adults seek explanations constantly. We wonder why events unfold in particular ways, why objects have specific properties, and why others behave as they do. Moreover, we have strong intuitions about what requires explanation and what counts as an adequate answer. Where do these intuitions come from? Why are we so driven to explain the social and physical worlds around us? And more generally, what is the role of explanation in cognition?

While there is no consensus on how to address these questions, research in cognitive development and cognitive psychology is beginning to make headway in finding answers (Keil, 2006; Keil & Wilson, 2000; Lombrozo, 2006; Wellman, 2011). These new developments complement large but focused literatures in social psychology (e.g., Anderson, Krull, & Weiner, 1996; Heider, 1958; Malle, 2004),

education (e.g., Chi, 2000; Roscoe & Chi, 2008), and philosophy (e.g., Salmon, 1989; Woodward, 2010), which have respectively emphasized explanations for human behavior, explanations in pedagogy, and explanations in science. Explanation has also been of interest in other cognitive science disciplines, such as artificial intelligence, where the generation of explanations has been proposed as a mechanism for learning (e.g., DeJong, 2004).

In this chapter, I focus on recent research in cognitive psychology and cognitive development. I begin by motivating the study of explanation, what explanations are, and their importance for understanding cognition. This is followed by more extensive discussions of the roles of explanation in learning and inference. While explanations and their effects are quite diverse, the findings support a common picture according to which the process of explaining recruits prior beliefs and a host of explanatory preferences, such as unification and simplicity, that jointly constrain subsequent processing. I conclude

by considering the current status of research on explanation and highlighting promising directions for future research.

Why Explanation Matters for Cognition

The study of explanation is motivated both by everyday experience and by theoretical considerations. Seeking, generating, and evaluating explanations is a central human preoccupation from an early age, and anecdotal evidence suggests that explanations play an important role in motivating discovery, communicating beliefs, and furthering understanding. Much of the recent interest in explanation, however, stems from theoretical and empirical developments that place explanation at the core of claims about conceptual representation, learning, and inference.

Since at least the 1980s, a prominent strand of thinking within cognitive science has postulated structured mental representations that share many of the properties of scientific theories (e.g., Carey, 1985; Gopnik & Meltzoff, 1997; Murphy & Medin, 1985; Wellman & Gelman, 1992; see Gelman & Frazier, Chapter 26). These so-called naïve, folk, or intuitive theories are semicoherent bodies of belief that support prediction, explanation, and intervention for a specified domain of application, such as physics or psychology. Almost all advocates for this approach have appealed to explanation in defining intuitive theories. For example, theories have been identified with “any of a host of mental explanations” (Murphy & Medin, 1985, p. 290) and characterized in terms of “laws and other explanatory mechanisms” (Carey, 1985, p. 201). It is clear, then, that an adequate account of intuitive theories rests on an adequate account of explanation (see also Lombrozo, 2010a; Machery, 2009; Margolis, 1995).

In parallel with a focus on intuitive theories, accounts of concepts and categorization have increasingly emphasized “explanation-based” reasoning in contrast to purely statistical or similarity-based reasoning (see Rips et al., Chapter 11). For example, categorization and category learning have been described as “special cases of inference to the best explanation” (Rips, 1989, p. 53), with a concept invoked “when it has a sufficient explanatory relation to an object” (Murphy & Medin, 1985, p. 295). And in tasks such as property generalization, deviations from patterns of reasoning based on similarity are often explained by appeal to causal or explanatory beliefs (e.g., Murphy & Allopenna, 1994; Rehder, 2006), pointing to the need for an

account of what makes some beliefs “explanatory,” and how those beliefs influence reasoning.

Finally, there is increasing evidence that prior beliefs significantly impact how reasoners learn and draw inferences. Generating and evaluating explanations may be mechanisms by which prior beliefs are brought to bear on a given task (Lombrozo, 2006), especially in knowledge-rich domains. The study of explanation is therefore not only of value in its own right, but as a window onto foundational aspects of cognition ranging from conceptual representation to learning and inference.

Defining Explanation

A natural place to begin the study of explanation is with a clear characterization of the object of study. In other words, what *is* explanation? Unfortunately, this innocuous question has proven quite complex. Some researchers define explanations as answers to why- or how-questions (e.g., Wellman, 2011), others as judgments about why an outcome occurred (e.g., Krull & Anderson, 2001), yet others as hypotheses positing causes that have what is being explained as their effects (e.g., Thagard, 2000; see also Einhorn & Hogarth, 1986). In all likelihood, explanation is not unitary: Research on explanation almost certainly spans multiple kinds of judgments and distinct cognitive mechanisms. “Explanation” is likely to be a family-resemblance term, picking out a cluster of related phenomena.

A first step toward precision, if not definition, is to distinguish explanation as a *product* from explanation as a *process* (see also Chin-Parker & Bradner, 2010). As a product, an explanation is a proposition or judgment, typically linguistic, that addresses an explicit or implicit request for an explanation. As a process, explanation is a cognitive activity that aims to generate one or more explanation “products” but need not succeed in order to be engaged. Most theories of explanation from philosophy are about explanations as products, whereas empirical research has been more mixed, with some research focusing on the characteristics of the product, and other research on the characteristics and consequences of the process.

A second useful distinction is between a “complete” explanation and a “selected” explanation (for related distinctions see Goodman et al., 2006; Railton, 1981). To illustrate, consider an explanation for Carl’s decision to order a slice of carrot cake over chocolate cake. In most contexts, noting a stable preference (“carrot cake is Carl’s favorite”) can

be sufficient to explain the decision, but this explanation rests on a variety of background assumptions (for example, that a preference for carrot cake would lead someone to choose carrot cake over chocolate cake), as well as a much deeper causal structure that could potentially be traced back to the origins of the universe. A selected explanation will correspond to the small subset of this explanatory structure that is identified as “the” explanation in a given context: probably the cake preference, but probably not the big bang.

This distinction is important in understanding explanation as both product and process. When considering explanation as a product, there is the selected explanation itself—what an individual might offer in response to a why-question—as well as a more complete explanation, which includes the cognitive infrastructure that supports the selected explanation. Of course, when it comes to human cognition, the complete explanation could be quite incomplete—it’s likely that human explanatory practice proceeds in the absence of fully specified explanations, even if there is always a more complete explanation that underlies the selected explanation (Keil, 2003; Rozenblit & Keil, 2002). When considering explanation as a process, it is useful to distinguish two distinct (although not necessarily independent) inferential steps: one to the complete explanation, and a second “selection process” to identify the selected explanation (which could, in principle, be equivalent to the complete explanation).

Potential insight into how selection occurs comes from the observation that explanations are typically contrastive: They account for one state of affairs in contrast to another (see e.g., Chin-Parker & Bradner, 2010; Garfinkel, 1990; Hart & Honore, 1985; Hilton, 1996; Hilton & Slugoski, 1986; Mackie, 1980; van Fraassen, 1980). The role of an implicit contrast is illustrated by an explanation attributed to Willie Sutton, a notorious bank robber. When asked why he robbed banks, he explained: “Because that’s where the money is.” The response is humorous in part because it addresses an inappropriate contrast: Sutton has explained why he robs banks *rather than robbing other places*, but he has failed to adequately answer the question most likely intended, namely why he robs banks *rather than not robbing banks*. The contrast provides a constraint on what should figure in a selected explanation: Explanations typically identify conditions that differentiate what is being explained (the explanans) from a counterfactual case in which the contrast

holds. Aspects common to the explanans and to the contrast likely figure in the complete explanation, which supports the selected explanation but need not be found explanatory. For example, Carl’s choice of carrot cake over chocolate cake is poorly explained (if at all) by noting that “cake is delicious,” as this piece of background does not explain why he chose carrot cake *as opposed to chocolate cake*. Recognizing the contrastive nature of explanation also reveals that a full specification of what is being explained involves identifying assumptions that are implicit in an explanation request.

The distinctions between explanation as product and process and complete versus selected explanations highlight one of the challenges in the study of explanation: providing cohesive theories that are nonetheless sensitive to this diversity. Explanatory products and processes are clearly related and mutually constraining, as are complete and selected explanations. Yet a failure to recognize these distinctions can make it difficult to relate different strands of research or to appreciate their implications for cognition.

The Structure of Explanations

Within philosophy, there have been several systematic attempts to provide definitions or precise specifications of what counts as an explanation (the product), and in particular the relationship that must obtain between an explanation and what it explains. Although typically intended as normative claims about explanation in science, these theories provide a useful starting point for psychological investigation and help identify the space of possible approaches. Initiating the contemporary study of explanation in philosophy of science, Hempel and Oppenheim (1948) proposed the deductive-nomological (DN) account of explanation, according to which an explanation involves initial conditions and general laws from which one can deduce what is being explained (the explanandum). This account was later extended to address inductive rather than deductive cases (the inductive-statistical [IS] account; see Hempel, 1965), but it still faced serious problems that led most philosophers to alternative accounts (see Salmon, 1989, for a review).

Currently, there are three popular approaches to explanation within philosophy of science. The two most prominent are causal theories (see Buehner & Cheng, Chapter 12), according to which explanations identify the cause(s) for an event or property (e.g., Salmon 1984; Woodward, 2003), and

subsumption or unification theories, which claim that an explanation subsumes the explanandum under an explanatory pattern, which can but need not be a law or counterfactual-supporting generalization (e.g., Friedman, 1974; Kitcher, 1989). These two approaches have also been fruitfully combined. For example, Strevens (2008) proposes a causal theory of explanation but relies on criteria involving unification to solve the selection problem of identifying a selected explanation from a complete one. A third approach, related to causal approaches, is to identify explanations with a description of causal mechanisms, where a mechanism consists of components, operations, and their (often hierarchical) organization, which realize what is being explained (e.g., Bechtel, 2008; Craver, 2007; Darden, 2006).

While many everyday and scientific explanations in fact satisfy all of these theories, the approaches differ in their account of *why* the explanation is explanatory. For example, consider explaining a disease by appeal to a virus. According to a causal theory, an occurrence of the disease can be explained by appeal to the presence of the virus because the virus causally accounts for the occurrence of the disease. According to a subsumption/unification theory, the virus explains the disease by subsuming the instance being explained under a broader generalization—that the particular virus leads to that particular disease—which in turn conforms to a broader generalization about viruses causing diseases, and so on to potentially greater levels of abstraction. While multiple theories can thus accommodate a wide range of common cases, they face distinct challenges. In general, causal and causal mechanism approaches have a difficult time handling cases of explanation that do not seem to involve causation at all, such as mathematical explanations. In contrast, subsumption/unification theories face the problem of specifying which kinds of patterns or unifications count as explanatory. A strategy potentially amenable to both causal and subsumption theories is to identify some kind of higher order, asymmetric dependence relationship or generative process that can subsume both causal and mathematical or formal relationships, and serve as a foundation for a theory of explanation with broader scope.

Causal, subsumption/unification, and mechanism-based approaches all find some empirical support within psychology. Many investigations of explanation have been restricted to causal cases, but some accounts of the effects of explanation on learning appeal to subsumption and unification (see

later section on “Explanation and Learning”). There is also evidence that knowledge of mechanisms is often invoked in explanations and constrains inference (e.g., Ahn & Bailenson, 1996; Ahn, Kalish, Medin, & Gelman, 1995; Koslowski, 1996; Shultz, 1980). However, no studies (to my knowledge) have attempted to differentiate these theories empirically by isolating cases for which the theories generate different predictions.

The Functions of Explanation

Intertwined with questions about the structure of explanations are those about its functions. Why are people so motivated to explain, and what accounts for our systematic explanatory preferences? While many plausible functions for explanation have been proposed, both philosophers and psychologists have emphasized that explanations could be valuable because they scaffold the kind of learning that supports adaptive behavior. For example, Craik (1943) described explanation as “a kind of distance-receptor in time, which enables organisms to adapt themselves to situations that are about to arise.” Heider (1958) suggested that we explain events in order to relate them to more general processes, allowing us “to attain a stable environment and have the possibility of controlling it.” In other words, explanations put us in a better position to predict and control the future.

Gopnik (2000) provocatively compares explanation to orgasm, suggesting that the phenomenological satisfaction of explanation is our evolutionarily provided incentive to engage in theory formation, as orgasm is to reproduction. She thus explains a characteristic of the process of explanation—its typical phenomenological outcome—by appeal to the function of its products—namely useful theories about the world. But the very process of engaging in explanation could have additional benefits. For example, attempting but failing to produce accurate explanations could nonetheless support future learning (e.g., Needham & Begg, 1991) and guide future inquiry (e.g., Legare, in press), and the effects of explanation could differ depending on whether the explanations are self-generated (involving process plus product) or provided (involving only product; see, e.g., Brown & Kane, 1988; Crowley & Siegler, 1999; Rittle-Johnson, 2006 for relevant discussion and findings).

The hypothesis that explanation supports adaptive behavior predicts that seeking, generating, and evaluating explanations should have systematic cognitive

consequences. The rest of the chapter is principally devoted to documenting these consequences. Before moving on, however, a few caveats are in order. First, explanations need not share a single, common function. Accordingly, the section that follows considers different kinds of explanations and their respective consequences for cognition. And while the present focus is on the roles of explanation in learning and inference, it is worth acknowledging that explanation certainly serves additional functions, as in persuasion and the assignment of blame.

A second caveat is that whatever the functions of explanation, it is unlikely that explainers have the explicit goal of fulfilling them. The basis for explanatory judgments could be opaque to introspection or based on indirect cues, no matter that their ultimate function is to achieve particular goals. And finally, it is quite likely that many of the properties of explanation stem not from any particular benefit (be it the result of natural selection or learning) but rather arise as a side effect of other cognitive characteristics. For example, a preference for simpler explanations could be a side effect of limited working memory. These caveats, however, do not detract from the value of examining the role of explanation in learning and inference.

Different Kinds of Explanations

Not all explanations will necessarily have a common structure or function. In fact, there are a variety of proposals suggesting fundamentally different kinds of explanations. For example, within philosophy, explanations for particular events or properties are often distinguished from explanations for laws or regularities, as are “how possibly” explanations—which explain how something *could* have come about—from “how actually” explanations—which explain how something *in fact* did come about (e.g., Salmon, 1989). Within psychology, advocates for domain specificity have suggested that different domains involve unique explanatory schemata (e.g., Carey, 1985; Wellman & Gelman, 1992). And explanations for why something is the case can be distinguished from explanations for why someone believes something to be the case (e.g., Kuhn, 2001). Depending on the particular account of explanation in question, these distinctions can correspond to explanations that differ in structure, in function, in both, or in neither.

A taxonomy that has proven particularly fruitful in psychology, with roots in Aristotle (see also Dennett, 1987), identifies (at least) three kinds

of explanations: mechanistic explanations, which explain by appeal to parts and processes; teleological or functional explanations, which cite functions or goals; and formal explanations, which cite kind or category membership. For example, consider explanations for why a particular tire is round. Explaining the roundness by appeal to the tire’s manufacturing process would qualify as mechanistic; explaining by appeal to its function in generating efficient movement would qualify as functional; and explaining by appeal to the objects’ category membership (“it’s round because it’s a tire”) would qualify as formal (see Lombrozo & Carey, 2006, for an extended discussion of mechanistic and functional explanations; see Prasada & Dillingham, 2006, for a discussion of formal explanations).

A growing body of evidence suggests that these three kinds of explanation correspond to distinct cognitive processes and representations. Keil (1992, 1994, 1995), for example, posits distinct explanatory stances or “modes of construal” corresponding to mechanistic and functional explanations, and finds that children adopt explanatory stances preferentially in different domains. Developing earlier suggestions by Sully (1900) and Piaget (1929), Kelemen (1999) suggests that functional explanations are an explanatory “default” that comes more naturally to children than do mechanistic explanations. It appears that children in fact do prefer such explanations “promiscuously,” as do adults who have not been exposed to alternative scientific explanations (Casler & Kelemen, 2008), who are required to respond under speeded conditions (Kelemen & Rosset, 2009), or who suffer from Alzheimer’s disease (Lombrozo, Kelemen, & Zaitchik, 2007).

Although functional explanations appeal to effects rather than to causal mechanisms, they are not necessarily inconsistent with causal theories of explanations. In fact, Lombrozo and Carey (2006) find evidence that functional explanations are only accepted when the function invoked in the explanation played a causal role in bringing about what is being explained (or more precisely, when the function is a token of a type that played a causal role in bringing about what is being explained; see also Wright, 1976, for analysis from philosophy). Thus, a tiger’s stripes can be explained by appeal to camouflage because the appeal to camouflage is shorthand for a complex causal process, whereby the stripes of past tigers supported camouflage, and this in turn played a causal role in the existence of the current, striped tiger.

Mechanistic and functional explanations can thus both be construed as causal explanations, but there is reason to think they reflect differences in underlying reasoning. First, while functional explanations ground out in a causal story, that story can be unboundedly complex and largely unknown. Most people are happy to explain a tiger's stripes by appeal to camouflage without any knowledge of tigers' evolutionary history, and with almost no knowledge of how natural selection operates (e.g., Shtulman, 2006). This suggests that information about causal mechanisms plays a different role for functional explanations than for mechanistic explanations. Second, mechanistic and functional explanations highlight different information. Mechanistic explanations privilege causal mechanisms and underlying constituents, while functional explanations privilege functions, intentions, goals, and design.

Consistent with this observation, Lombrozo (2010b) finds that the criteria for causal ascription differ depending on whether a causal system is construed functionally or mechanistically: When a system is construed mechanistically, causal ascriptions are more sensitive to the mechanism of transmission by which a cause brought about an effect. For example, a causal factor that contributed to an outcome indirectly, by preventing another factor from preventing the outcome, will receive a lower causal rating from a "mechanistic stance," but not necessarily from a "functional stance." Additional findings suggest that functional and mechanistic explanations have differential effects on categorization (Lombrozo, 2009) and generalization (Lombrozo & Gwynne, unpublished data), and are discounted asymmetrically (Heussen, 2010).

The unique explanatory contributions of mechanistic and functional explanations may be familiar to psychologists acquainted with Marr's levels of analysis (Marr, 1982). Marr proposed that psychological phenomena can be explained at three levels, including the *computational*, which involves a specification of the goals of a system; the *algorithmic*, which identifies the representations and processes involved in carrying out the specified goal; and the *implementational*, which characterizes how the representations and processes are physically instantiated. In specifying the goals of a cognitive system, a computational-level analysis typically supports functional explanations, while the implementation level analysis typically supports mechanistic explanations. The algorithmic level can support both kinds of explanations. For example, representations

of binocular disparity can be explained (functionally) by appeal to their role in computing depth information, and also (mechanistically) by appeal to optical, retinal, and cortical processes.

The final category of "Aristotelian" explanation that has received empirical attention is formal explanation, the study of which has been pioneered by Prasada and colleagues (Prasada & Dillingham, 2006, 2009). They find that only some properties can be explained by appeal to category membership. For example, participants are willing to explain a tire's roundness by appeal to its category membership ("it's round because it's a tire"), but much less willing to thus explain a tire's blackness ("it's black because it's a tire"), even though both share the same statistical association with tires. Properties that support formal explanations have a variety of related characteristics, such as licensing normative claims (e.g., "tires ought to be round").

In sum, explanations can be classified in a number of ways. The distinction between mechanistic, functional, and formal explanations has proven particularly fruitful, as each type of explanation appears to highlight different information and have unique cognitive consequences. This distinction could also underlie differences in the types of explanations typically observed across domains (for discussion, see Lombrozo & Carey, 2006). However, there are likely to be a number of alternative classifications with potential implications for our understanding of both the structure and functions of explanations. For example, the discussion so far has focused on how *selected* explanations—the *products*—can be productively classified, but complete explanations and explanatory processes could be similarly varied. Documenting and understanding the heterogeneity of explanation is thus an important focus for future research.

Explanation and Learning

Given the intimate relationship between explanation and understanding, it is no surprise that explanation has a profound impact in learning. There are at least three ways in which explanation can influence learning. First, there is the matter of which explanations are sought, which constrains what one learns about the environment. For example, upon first encountering an elephant you're likely to wonder why it has a trunk, but less likely to wonder why the number of its legs is a perfect square. Second, processes involved in the evaluation of explanations can influence what is learned

from provided explanations, be it in educational or everyday situations. And third, the very process of generating explanations, be it for oneself or others, can influence one's own understanding and ability to generalize to novel contexts. These three impacts on learning are considered in turn.

Although explanation seeking is pervasive, people are highly selective in what they seek explanations about. This selectivity is driven in large part by what the learner already knows. For example, it seems unlikely that someone will seek an explanation for why fire trucks are red if that person already knows (or believes she knows) the answer. This is not surprising if explanation seeking is a mechanism for learning. However, generating questions requires knowing enough to appreciate what one doesn't know (Miyake & Norman, 1979). Questions are thus highly constrained by prior beliefs. For example, we ask questions for which we expect sensible answers—even young children are more likely to ask what artifacts “are for” than what animals “are for” (Greif, Kemler-Nelson, Keil, & Guitierrez, 2006).

One attractive hypothesis is that people ask questions about events or properties that violate their expectations (Isaacs, 1930; Sully, 1900; see also Berlyne, 1954; Chouinard, 2007) or concern abnormal events (Hilton, 1990; Hilton & Slugoski, 1986)—a natural prediction if explanation is to guide learners beyond what they already know. Consistent with this proposal, analyses of why-questions reveal a high prevalence of negation (e.g., “Why *didn't* X occur?”), suggesting that the questioner is grappling with an unexpected observation (Hood & Bloom, 1979; but see Callanan & Oakes, 1992). And in experimental contexts, children are more likely to explain why a block did or did not make a machine light up when the observed outcome is inconsistent with previous training (Legare, Gelman, & Wellman, 2009). However, it is quite difficult to specify when an event counts as unexpected or surprising—it surely *isn't* the case that observations with low prior probability always prompt explanation, as most observations are in fact highly unlikely (consider, for example, any long sequence of coin flips: heads, heads, tails, heads, tails...).

Questions are also, of course, guided by interests: Children seem most likely to ask about the social world (Hickling & Wellman, 2001; Hood & Bloom, 1979), although questions about the physical world are not uncommon (Callanan & Oakes, 1992). There is also some evidence that from preschool to high school, children become increasingly likely to

ask questions motivated by potential applications rather than by general curiosity (Baram-Tsabari & Yarden, 2005). Finally, questions are guided by the goals of the learner. Students aiming to learn about musical instruments in order to design a novel instrument, for example, ask different questions from those exposed to the same material with the goal of identifying a promising musical group (Graesser, Langston, & Baggett, 1993). Providing a general characterization of what, when, and why people ask is complicated by the fact that interests and question-asking are highly contingent on both the explanation seeker and the context.

Once an explanation has been offered, what are the consequences for the recipient? First, explanations are often accompanied by a sense of understanding. For example, both undergraduates and clinicians who could explain an individual's symptoms perceived those symptoms to be more “normal” (Ahn, Novick, & Kim, 2003). And in some cases, provided explanations can be highly beneficial. As one example, children's performance on false belief tasks is related to how often their mothers explain mental states (Peterson & Slaughter, 2003). Unfortunately, however, the *sense* of understanding fostered by explanations is often an unreliable guide to actual understanding (Trout, 2002, 2008), and merely receiving an explanation is often insufficient to generate actual understanding. In particular, explanations provided in instructional contexts are frequently ineffective (Wittwer & Renkl, 2008). Explanations are more likely to support learning if they are appropriately tailored to what the learner already knows and appeal to general concepts or principles (see Wittwer & Renkl, 2008, for review). Explanations can also be more effective when they occur in the context of an interactive cognitive activity (Chi, 2009), in part because the recipient is able to request additional information and receive feedback. For example, young children are more likely to repeat questions after receiving a nonexplanation or an explanation they deem inadequate (Frazier, Gelman, & Wellman, 2009; see also Chouinard, 2007), and adult learners will request further elaboration when experts provide explanations that underestimate their knowledge (Wittwer, Nuckles, & Renkl, 2008).

Perhaps surprisingly, *generating* explanations can be a more effective mechanism for learning than *receiving* explanation. This phenomenon has been demonstrated in the context of peer tutoring, where tutors often profit more than tutees (e.g., Hooper,

1992; Roscoe & Chi, 2008; Ross & Cousins, 1995). The learning benefit of engaging in explanation—be it to oneself or to others—is known as the self-explanation effect (Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Chi, de Leeuw, Chiu, & LaVancher, 1994) and has been found for preschoolers through adults, for a range of educational materials, and for both declarative and procedural knowledge (for review, see Fonseca & Chi, 2010). In a typical experiment, one group of participants is prompted to explain to themselves as they study an expository text or worked examples, such as math problems. These participants are compared with those in one or more control groups who study the same material without a prompt to explain, often with an alternative task (e.g., thinking aloud) or matched for study time. The typical finding is that participants who explain outperform their nonexplaining peers on a posttest, with the greatest benefit for transfer problems that require going beyond the material presented.

Effects of self-explanation have also been demonstrated in complex domains that arguably require a conceptual change in development. For example, prompting children to explain the correct response on Piagetian number conservation tasks leads to greater improvement than prompting them to explain their own (potentially incorrect) response, or than merely receiving feedback on the correct response (Siegler, 1995). Similarly, prompting children to explain why a character searched for an item in a particular location in a false belief task leads to greater improvement than merely predicting the character's behavior and receiving feedback, with benefits that extend to other theory of mind tasks (Amsterlaw & Wellman, 2006). These findings attest to the power of explanation as an engine for learning.

A variety of plausible mechanisms underlying the effects of explanations on learning have been proposed, many of which could operate in concert. For example, generating explanations can help learners translate declarative knowledge into usable procedures (Chi et al., 1989, 1994), integrate new material with prior beliefs (Ahn, Brewer, & Mooney, 1992; Chi et al., 1994; Lombrozo, 2006), identify and repair gaps in knowledge (Chi, 2000), or resolve potential inconsistencies (Johnson-Laird, Girotto, & Legrenzi, 2004). Other researchers have suggested that prompts to explain can increase efforts to seek explanations, leading to deeper processing, greater engagement with the task, and the reinforcement

of successful strategies over unsuccessful alternatives (Siegler, 2002). More recent work in cognitive development suggests that explanations can sometimes scaffold causal learning by presenting children with an easier task than prediction, as explaining is supported by knowledge of the outcome or property being explained (Wellman & Liu, 2007). As evidence, successful explanations precede successful predictions by preschoolers reasoning about an agent's choice between a contaminated and an uncontaminated food (Legare, Wellman, & Gelman, 2009; see also Amsterlaw & Wellman, 2006).

In comparing participants prompted to explain with those who are not so prompted, much of the research on explanation and learning focuses on explanation as a process rather than a product. This approach sidesteps questions about what kinds of utterances count as explanations. Research that has coded participant utterances for the quantity and content of explanations has tended to adopt a very broad conception of explanation, for example, including most articulated inferences that go beyond the material provided (Chi et al., 1989, 1994). It can thus be difficult to relate aspects of the structure of explanations, such as those posited by theories of explanation from philosophy, to the functional consequences of explanation for learning.

A few more recent strands of research, however, aim to relate structural accounts of explanation to functional consequences, and in so doing to elucidate why explanation has the particular learning benefits observed. In particular, research has focused on two widely accepted features of explanations: explanations tend to relate the particular property or event being explained to broader principles or regularities, and explanations often invoke causal relationships and causal mechanisms (see Woodward, 2010 for review from philosophy; see Lombrozo, 2006 for review from psychology). These properties correspond to important features of subsumption/unification and causal theories of explanation from philosophy, respectively.

Illustrating the role of subsumption and unification, Williams and Lombrozo (2010) propose the subsumptive constraints account, according to which explanation can facilitate learning by encouraging learners to understand what they are trying to explain in terms of broad, unifying generalizations (see also Wellman & Liu, 2007). If explaining exerts this particular constraint on the kind of structure learners seek, engaging in explanation should drive learners to discover and explicitly represent such

generalizations. Williams and Lombrozo (2010) tested this prediction in several experiments involving category learning. Compared to control conditions in which participants described category members, thought aloud during study, or engaged in free study, participants who explained were more likely to discover subtle, broad regularities underlying the category structure. Moreover, because the subsumptive constraints account predicts a selective advantage for explanation in discovering patterns, and not an “all-purpose” benefit in learning, it makes the novel prediction that explaining can *impair* learning when the material being explained does not support explanatory patterns, and recent findings confirm this prediction (Williams, Lombrozo, & Rehder, 2010; Kuhn & Katz, 2009; see also Dawes, 1999).

Illustrating the role of causation and causal mechanisms in mediating the role of explanation in learning are recent findings from cognitive development. Legare, Wellman, and Gelman (2010) found that children’s explanations posited unobserved causal mechanisms, such as germs, that were not spontaneously considered as a basis for prediction. This result suggests that explanations direct children to aspects of causal structure that might not be taken into account in the absence of explanatory processes (see also Legare, Gelman, & Wellman, 2009). Children who are prompted to explain how a novel, mechanical toy works also outperform peers who are prompted to observe the toy for a matched amount of time on measures that assess an understanding of causal mechanisms, but not on measures that involve memory for mechanism-irrelevant details, such as the toy’s colors (Legare & Lombrozo, unpublished data). Again, the findings suggest that explanation is not an all-purpose strategy for learning, but rather a highly selective process that influences precisely what a learner discovers and represents.

A great deal remains to be learned about the mechanisms by which explanation influences learning and how distinct mechanisms interact. Characterizing these mechanisms is important not only for understanding explanation but also for understanding the very nature of human learning and representation. One reason the self-explanation effect is so intriguing is because it challenges a simple picture of learning, modeled after learning from observations or testimony, according to which learning is identified with the acquisition of new information from the external world. Learning by explaining to oneself or to others—much like thought experiments—reveals a kind of learning that involves the reorganization,

rerepresentation, or inferential consequences of what is already known. Understanding this kind of learning could well provide a better template for understanding all types of learning (for relevant discussions of learning see Rips et al., Chapter 11; Buehner & Cheng, Chapter 12; Holyoak, Chapter 13; Bassok & Novick, Chapter 21; and Koedinger & Roll, Chapter 40).

Explanation and Inference

Although learning and inference are likely to involve similar mechanisms, research on explanation and inference has proceeded largely independently of research on explanation and learning. The former strand of research is motivated by the observation that everyday inferences face the problem of underdetermination: Many hypotheses are possible given what we know about the world. We generally don’t know for certain why the economy rallied, why the bus was late, whether a colleague’s excuse for a missed deadline was fact or fabrication, or whether Mrs. Peacock or Mr. Green committed the murder. Yet many decisions rest on identifying the best hypothesis or the probability of a given hypothesis. Explanation has thus been proposed as a mechanism for guiding such judgments, often referred to as “abductive inferences.”

The term “abduction” is associated with Charles Sanders Peirce, who distinguished abductive inferences, which posit explanatory hypotheses, from the broader class of inductive inferences, which also include inferences from a sample to a population, such as inferring that all swans are white after observing many white swans (Burch, 2010; see also Magnani, 2001). Subsequent scholars have not reliably distinguished abduction from induction, instead focusing on inferences to particular explanations. For example, Harman (1965) introduced the notion of “inference to the best explanation,” according to which “one infers, from the fact that a certain hypothesis would explain the evidence, to the truth of that hypothesis . . . one infers, from the premise that a given hypothesis would provide a ‘better’ explanation for the evidence than would any other hypothesis, to the conclusion that the given hypothesis is true” (p. 324). In other words, one relies on the existence or quality of an explanation to guide inference, an idea that has since been pursued both theoretically and empirically (see Lipton, 2004, for a nice treatment in philosophy).

Within psychology, there is mounting evidence that the quality of an explanation does serve as

a guide to its probability. Factors that boost an explanation's perceived quality include simplicity (Bonawitz & Lombrozo, in press; Lagnado, 1994; Lombrozo, 2007; Read & Marcus-Newhall, 1993; Thagard, 1989), breadth (Preston & Epley, 2005; Read & Marcus-Newhall, 1993; Thagard, 1989), consistency with prior knowledge (Thagard, 1989), and coherence (Pennington & Hastie, 1993). Several of these factors have also been shown to influence an explanation's perceived probability. For example, Lombrozo (2007) presented adults with novel diseases and symptoms. Participants learned about a patient with two symptoms that could be explained by appeal to a single disease (the "simple" explanation) or by appeal to the conjunction of two diseases (the "complex" explanation). In some conditions, participants were also presented with the base rates for the diseases, either in the form of summary frequencies or experienced cases. There were several notable results: (a) in the absence of base-rate information, participants overwhelmingly preferred the simple explanation; (b) when base-rate information was provided, the complex explanation had to be quite a bit more probable than the simpler explanation for a majority of participants to prefer it; (c) participants who selected the simple explanation when it was unlikely to be true overestimated the base-rate of the disease figuring in the simple explanation; yet (d) when the complex explanation was explicitly stated to be more likely, participants overwhelmingly chose it. These results suggest that in the face of probabilistic uncertainty, people treat simplicity as a probabilistic cue commensurate with base-rate information (see also Lu et al., 2008).

The strategy of relying on an explanation's quality as a guide to its probability appears to be widespread, but is it warranted? This has been a topic of lively debate within philosophy, and for some properties of explanations, such as simplicity, within statistics and computer science as well (see Baker, 2010, for review). For example, some have suggested that simpler explanations avoid "overfitting" data and hence will generalize more effectively to novel cases (e.g., Forster, 2000). Others have suggested that an initial bias toward simplicity results in more efficient learning insofar as a learner is likely to modify hypotheses fewer times (e.g., Kelly, 2004). Breadth and unification have more direct ties to probability, as explanations that are broader or more general will, by definition, apply to more cases and could also have stronger evidential support (Myrvold, 2003). However, it is also possible

that explanatory preferences result from cognitive limitations—for example, simpler explanations could be easier to process or remember—and that their influence on probability and inference is misguided. As one example, Pennington and Hastie (1992) find that presenting evidence to mock jurors in a chronological order, which makes the evidence easier to integrate into a coherent explanation for the events that occurred, systematically influences verdicts, in contrast to the predictions of most normative models.

In the cases considered so far, an explanation's quality is used as a guide to the probability of that *explanation*. Other findings suggest that the existence and quality of explanations can influence the judged probability of *what is being explained*. For example, Koehler (1991) reviews evidence that prompting participants to explain one outcome—say, why a Democrat might win the next election—boosts the probability assigned to that outcome. Similarly, explaining why a relationship holds—say, why people who are risk-averse might make better firefighters—increases the probability assigned to that relationship (e.g., Anderson & Sechler, 1986; see also Ross et al., 1977), as well as memory for the relevant correlation (Bower & Masling, unpublished data).

Thagard (1989) proposes a model of abductive inference that incorporates both of the influences just considered: how the quality of an explanation influences the degree of belief in that explanation *as well as* belief in what is explained. Thagard's approach, the Theory of Explanatory Coherence, involves seven principles that specify relationships between propositions and their consequences for belief. For example, the principles specify that propositions that participate in explanatory relationships (whether they do the explaining or are explained) are mutually reinforcing, as are those that provide analogous explanations. The model has been instantiated in a connectionist network and successfully used to model human judgments (e.g., Ranney & Thagard, 1988; Thagard, 2006), providing another source of evidence for the importance of explanatory evaluation in inference.

In addition to direct influences of explanatory evaluations on the probability assigned to an explanation and what it explains, explanations influence judgments in tasks that require assessing the probability of one claim in light of another. For example, Sloman (1994) provided participants with an initial claim, such as many secretaries "have a hard

time financing a house” or “have bad backs,” and asked them to evaluate the probability of a related claim, such as many furniture movers “have a hard time financing a house” or “have bad backs.” When the claims supported a common explanation (e.g., moderate income for trouble financing a house), participants provided higher probability estimates than when the claims supported different explanations (e.g., a sedentary job versus heavy lifting for back problems; see also Rehder, 2006). This could be because explanations compete (as might be expected in a framework like Thagard’s Explanatory Coherence), or because an explanation that applies to many cases is judged to be broader or more unifying and therefore of higher quality, resulting in a boost to the probability of what it explains (in keeping with the findings reviewed above).

The role of explanation in inference extends to a variety of additional judgments, including category membership (Rips et al., Chapter 11), decision making (LeBoeuf & Shafir, Chapter 16; see also Hastie & Pennington, 2000), and both legal (Spellman & Schauer, Chapter 36) and medical (Patel et al., Chapter 37) reasoning. For example, in the context of concept learning and categorization, explanatory knowledge has been shown to facilitate learning (Murphy & Allopenna, 1994; Williams & Lombrozo, 2010), influence judgments of the typicality of category members (Ahn, Marsh, Luhmann, & Lee, 2002; Murphy & Allopenna, 1994), and foster conceptual coherence (Murphy & Medin, 1985; Patalano, Chin-Parker, & Ross, 2006). In addition, the way in which a category’s features are explained can influence the relative importance of those features in making judgments about category membership: Features that support more explanations (Sloman, Love, & Ahn, 1998), causally deeper explanations (Ahn, 1998; Ahn & Kim, 2000), or explanations that are privileged by the explanatory stance adopted—mechanistic or functional (Lombrozo, 2009)—will typically be weighted more heavily. Such findings illustrate the breadth and importance of explanation’s effects.

Finally, although explanations likely benefit inference in many contexts, there are some well-documented cases in which explanatory judgments can lead people astray. For example, both children and adults tend to mistake explanations for *why* something is the case for evidence *that* something is the case (Glassner, Weinstock, & Neuman, 2005; Kuhn, 2001), especially when evidence is unavailable (Brem & Rips, 2000). People’s ability to detect

circularity in explanations is also imperfect (Baum, Danovitch, & Keil, 2008; Rips, 2002) and susceptible to extraneous factors, such as the presence of interesting but potentially irrelevant information (Weisberg, Keil, Goodstein, Rawson, & Gray, 2008). Finally, both children and adults tend to overestimate the accuracy and depth of their own explanations (Mills & Keil, 2004; Rozenblit & Keil, 2002). So while there is little doubt that explanation has a considerable influence on a wide range of everyday inferences, this influence is quite heterogeneous in scope and consequences, and almost certainly in underlying mechanisms.

Distinguishing Explanation From Other Cognitive Processes

Explanation is closely related to a variety of cognitive processes, including but not limited to inductive reasoning, deductive reasoning, categorization, causal reasoning, analogical reasoning, and learning. Can and should explanation be distinguished from these extant areas of study? From one perspective, the answer is clearly “no.” Explanation could trigger or be triggered by these processes, and it is likely to share many common mechanisms. Isolating explanation could thus result in a mischaracterization of cognitive mechanisms and their coordination. But there are also compelling reasons to study explanation and abductive inference as phenomena in their own right. The study of explanation highlights important aspects of learning, reasoning, and representation that are obscured when explanation is undifferentiated from general causal reasoning or inference. This section identifies a few distinctions that help locate the study of explanation and its unique contributions.

First, are explanation and abductive inference simply kinds of causal reasoning? One compelling reason to avoid this identification is because it assumes that all explanations are causal (see earlier section on “The Structure of Explanations”). There are broad classes of explanations that most people acknowledge as noncausal, such as mathematical and logical explanations. There are also explanations involving causal systems that are arguably noncausal. For example, consider an explanation for why a 1-inch square peg won’t fit into a 1-inch-diameter round hole. While causal factors are involved, it is arguably geometric facts that do the explanatory work (Putnam, 1975). The reverse also holds: Not all causal hypotheses are explanatory. It is the burden of a theory of explanation

to account for why the big bang is a poor explanation for cultural differences in color preferences, and more generally why some and only some causes strike us as explanations for their effects. Identifying “explanatory” causes—those that figure in a selected explanation—could be akin to what we do when we identify “the” cause of an effect or distinguish causes from enabling conditions, but it is certainly not equivalent to causal inference or to the specification of all causal factors.

Second, is it worth distinguishing explanations and abductive inference from the broader and quite heterogeneous class of inductive or deductive inferences? Again, not all explanations are straightforward examples of inference, and not all inferences are explanatory. Consider a case in which the causes of an event are firmly established: A match was struck in the presence of oxygen, and a fire ensued. In such a case, the striking of the match is likely to be selected as the explanation for the fire, not the presence of oxygen. This judgment requires an inference concerning which aspects of the causal structure are *explanatory*, but it need not be accompanied by an inference concerning which causes were present or type-level causal relationships, as these are already known. More important, explanatory inferences are a subset of everyday inferences. I can infer what the weather will be like based on a forecast, or what the 100th digit of pi is given the output of a computer program. But these inferences are not explanatory, and as a result the characteristics of abductive inference—such as a role for simplicity or breadth in determining the perceived probability of a hypothesis—need not apply.

Recognizing the unique aspects of explanation brings important questions into relief. For example, what is common between causal and noncausal explanations? Why do causal explanations privilege some kinds or aspects of causal structure over others? How do explanatory inferences go beyond inferences concerning causal and statistical structure? Do explanatory inferences involve unique mechanisms for evaluation? These questions can best be addressed through systematic investigation of the structure and functions of explanation, including new empirical findings to complement those reviewed here.

Conclusions

This chapter began by considering the role of explanation in cognition, and in particular why explanation is such a pervasive aspect of human

experience and elicits such strong intuitions. The reviewed findings confirm that the ability to evaluate and be guided by explanations is already quite sophisticated in young children and persists throughout adulthood. Moreover, explanatory preferences are highly systematic and have important consequences for core cognitive capacities that span learning and inference.

While explanations are quite heterogeneous and almost certainly impact cognition through a variety of distinct mechanisms, effects of explanations typically share a few characteristics. In particular, the process of explaining appears to recruit relevant prior beliefs along with a suite of formal constraints in the form of explanatory preferences—that is, preferences for explanations that have particular characteristics, such as simplicity or the ability to subsume and unify disparate observations. These properties of explanations (the products) account for many of the consequences of explanation (the process), which range from quite beneficial to neutral or even detrimental.

Despite a focus on both the functional consequences of explanations and how explanations are evaluated, there have been few attempts to provide comprehensive computational- or algorithmic-level accounts of explanation. In the absence of computational-level accounts, explanations and explanatory inferences lack normative benchmarks against which to assess human performance. And in the absence of algorithmic-level accounts, the relationship between explanation and other cognitive capacities remains largely opaque. Developing such accounts should thus be a high priority as research on explanation and abductive inference moves forward. The final section of the chapter identifies additional, promising avenues for future research.

Future Directions

Research on explanation is impressive in its scope and diversity, spanning cognitive psychology, social psychology, developmental psychology, education, philosophy, and beyond. However, distinct strands of research have proceeded almost independently, and until recently much of this work has not been unified under a common umbrella. A key direction for future research, then, involves the integration of different perspectives and findings across these areas. However, existing research raises more questions than it answers, and many aspects of explanations are only beginning to be explored. This section highlights a few questions that are ripe for further

investigation. The first six have already been raised in the course of the review; the final four involve additional issues.

1. Are there different kinds of explanations? If so, in virtue of what are they all explanatory?
2. What are the functions of explanation? To what extent are systematic explanatory preferences attributable to these functions, and to what extent do they result as side effects of other cognitive processes?
3. Which explanations are sought, and why? In particular, how do the characteristics of the explainer's prior beliefs interact with the environment to determine what is deemed to require explanation?
4. What are the mechanisms by which explanation guides learning? How is the role of explanation influenced by feedback on the accuracy of explanations or from further observations or testimony? When is the role of explanation beneficial, and when is it detrimental?
5. What are the criteria employed in the evaluation of explanations, and what are the consequences for learning and inference? In particular, what are the conditions under which explanatory considerations—such as an explanation's simplicity—inform assessments of probability, and is this role for explanatory considerations ever warranted?
6. What are the prospects for a normative or computational-level theory of explanation and abductive inference? How will such a theory inform empirical research, and how should the theory be constrained by empirical findings?
7. How do social and pragmatic factors influence explanations and their consequences?
8. To what extent are there individual differences and cultural variation in explanatory preferences? What is the source of this variation, and what are the consequences for learning and inference?
9. To what extent can explanation be separated from language? While typical explanations are encoded in language, they need not be. For example, Baillargeon (2004) proposed that prelinguistic infants construct explanations, while Povinelli and Dunphy-Lelii (2001) devised a clever method for assessing “explanation” in chimpanzees. As a conceptual question, how can explanation be characterized without a commitment to some language-like manifestation? And as a methodological

question, how can nonlinguistic explanations be studied empirically?

10. How are explanations generated? There has been much more research on how explanations are evaluated than on how they are generated. This is in part because explanation generation confronts many of the most difficult questions in cognitive science concerning the content and structure of general beliefs and how these are retrieved in particular contexts. How can the study of explanation generation be informed by research on representation and memory, and how might findings concerning the generation of explanations in turn contribute to these areas?

Acknowledgments

Sincere thanks to Joseph Austerweil, Thomas Griffiths, Ulrike Hahn, Keith Holyoak, G. Randolph Mayes, and Joseph Williams for comments on earlier drafts of this chapter, and NSF grant DRL-1056712 for support..

Rational Argument

Ulrike Hahn and Mike Oaksford

Abstract

Argumentation is an integral part of how we negotiate life in a complex world. In many contexts it matters, furthermore, that arguments be rational, not that they are simply convincing. Rational debate is subject to both procedural norms and to epistemic norms that allow the evaluation of argument content. This chapter outlines normative frameworks for argumentation (dialectical, logical, and Bayesian); it then summarizes psychological research on argumentation, drawn from cognitive psychology, as well as a number of applied domains.

Key Words: argumentation, logic, probability, evidence, reasoning, inference, belief change

Introduction: The Realm of Argumentation

Argumentation is an integral part of many aspects of our complex social worlds: from law, politics, academia, and business, to our personal lives. Though the term “argument” often carries negative connotations in everyday life, many different types of argumentative dialog can be distinguished, such as quarrels, bargaining or negotiation, educational dialogues, and, central to the present chapter, critical discussion (see, e.g., van Eemeren & Grootendorst, 2004; Walton, 2006a). Argumentation in the sense of a critical discussion is about rational debate and has been defined as

...a verbal and social activity of reason aimed at increasing (or decreasing) the acceptability of a controversial standpoint for a listener or reader, by putting forward a constellation of propositions intended to justify (or refute) the standpoint before a “rational judge.” (van Eemeren, Grootendorst, & Snoeck Henkemans, 1996, p. 5)

It is in this sense of rational debate that psychological research on argumentation uses the

terms “argumentation” and “argument,” and it is the emphasis on rationality that distinguishes it from social psychological research on persuasion. Persuasion research has identified a wide range of factors that affect the degree to which a persuasive communication will be effective (see, e.g., Eagly & Chaiken, 1993; Maio & Haddock, 2010; also see Molden & Higgins, Chapter 20). In contrast to argumentation, persuasion research is concerned with “what works” and why, regardless of whether it is rational. Indeed, some of the aspects identified—such as mood, likeability of the speaker, or personal involvement of the listener—do not always lead to changes in convictions in ways that one might consider rational; nevertheless, many findings within the persuasion literature are also directly relevant to argumentation and will be discussed within this chapter. Within psychology, argumentation has also been the focus of developmental and education research. Here research has focused on the way children’s argumentation skills develop (e.g., Kuhn, 1989, 1991; Means & Voss, 1996) and examined ways in which critical thinking and argument skills

might be fostered (Kuhn, 1991, 2001). Finally, argumentation has close connections to the study of reasoning because inference as studied in reasoning research is an integral part of argument (on that relationship see, e.g., Chater & Oaksford, Chapter 2; Hahn & Oaksford, 2007a; Mercier & Sperber, 2011; Oaksford & Hahn, 2007).

Argumentation, however, has not only been of interest within psychology. Most of the extant literature on argumentation resides in philosophy, where the topic has been pursued since the Greek philosophers, in particular Aristotle (2004). Most directly, argumentation has been studied within philosophical logic; relevant research can also be found, however, within the philosophy of science and within epistemology (the philosophical study of knowledge and justified belief). In all of these contexts, philosophers have typically focused on normative theories, that is, theories of how we *should* behave.

Computer scientists, finally, have sought to devise novel frameworks for dealing with dialectical information, seeking to capture the structural relationships between theses, rebuttals, and supporting arguments with the degree of explicitness necessary for the design of computational argumentation systems. The uses to which argumentation has been put, in particular within artificial intelligence, are manifold (for an overview see, e.g., Bench-Capon & Dunne, 2007). For example, argumentation has been integral to attempts to build legal expert systems, that is, systems capable of providing support for legal advice (e.g., Prakken, 2008; also see Spellman & Schauer, Chapter 36). Argumentation-based frameworks have also been employed for medical decision support systems (e.g., Fox, Glasspool, Grecu, Modgil, South, & Patkar, 2007; see also Patel et al., Chapter 37) and have gained considerable attention in the context of multiagent systems (e.g., Rahwan & Moraitsis, 2009). Finally, computer scientists have developed software for the visualization of complex, interconnected sequences of arguments such as Araucaria (see e.g., Reed & Rowe, 2004). They have also developed software foundations for large-scale, socially contributed argumentative content on the Worldwide Web, which allow Web users to contribute, visualize, and analyze arguments on a particular theme (e.g., Rahwan, Zablith, & Reed, 2007).

In short, the wealth of practical contexts in which argumentation matters is matched by the interdisciplinary breadth with which the topic is studied. It should thus come as no surprise that there is also

more than one theoretical framework that can be brought to bear on the issue of good argument.

Theoretical Frameworks

Statements about rationality necessarily contain an evaluative component. Argument, like any behavior, is rational because it is “good” relative to some standard, whether this standard be norms seeking to guarantee truth or consistency, or a suitable functional relationship to the goals of the agent in a particular environment (e.g., Nickerson, 2008; Oaksford & Chater, 2007, 2009; see also Chater & Oaksford, Chapter 2; Griffiths et al., Chapter 3; Stanovich, Chapter 22).

Norms governing rational argument can crudely be classified into two broad categories: those aimed primarily at the content or structure of an argument, and those aimed at argumentative procedure. This distinction has its origins in two different philosophical projects aimed at characterizing what makes a good argument: so-called *epistemic* accounts, which are aimed at truth or justified belief, on the one hand, and so-called dialectical or *procedural* approaches, aimed at consensus, on the other.

For millennia, logic provided the normative framework for the evaluation of inference and, with that, argument: Logic provides an epistemic standard, enforcing consistency, and where reasoning proceeds from true premises, guaranteeing the truth of the conclusions that can be reached (see Evans, Chapter 8; Johnson-Laird, Chapter 9). However, logic is severely limited in its ability to deal with everyday informal argument (see also, e.g., Hamblin, 1970; Heyssse, 1997; Johnson, 2000; as well as Boger, 2005 for further references). In particular, logic seems poorly equipped to deal with the uncertainty inherent in everyday reason.

One of the first to bring these limitations to prominence was Toulmin (1958). According to Toulmin, an argument can be broken down into several distinct components. Essential to all arguments are a claim (i.e., a conclusion in need of support), evidence (i.e., facts that are used to support the claim), and warrants (i.e., the reasons that are used to justify the connections between the evidence and the claim). Warrants may receive further support through additional, auxiliary statements as “backing.” Any of these components may be subject to qualifiers such as “sometimes,” “frequently,” or “almost always,” and may be challenged by rebuttals, that is counterarguments, which themselves involve the same structural components. The identification

of these kinds of relationships has, for example, been integral to the visualization of argument structure and educational research.¹

In the context of argument, Toulmin was skeptical of absolute truth, and his model was inspired by the dialectical nature of the adversarial legal systems of the common law tradition, where a relative truth is established through a contest between proponents of two opposing positions. In the courtroom, the provision of evidence is constrained by procedural rules; for example, not all evidence is permissible. Hence, it is not the absolute truth about whether a defendant is guilty, for instance, that a trial seeks to establish, but a trial-relative truth, in the sense of what can be established within the constraints of those procedural norms.

Law has been taken as a leading example of argumentative dialog by many subsequent theorists (e.g., Rescher, 1977), and the argumentation literature is full of legally inspired concepts such as the notion of *burden of proof*. The most well-known burden of proof in law is the presumption of innocence in criminal trials: It is up to the prosecution to establish conclusively that a defendant is guilty, and failure to do so means the defendant goes free. Many argumentation theorists posit similar rules for rational discourse (see e.g., Walton, 1988; for a more critical perspective on the burden of proof in argumentation, see Hahn & Oaksford, 2007b).²

So-called pragma-dialectical theories of argumentation, in particular, have sought to identify the procedural norms governing rational debate (e.g., van Eemeren & Grootendorst, 1984, 1992, 2004; Walton, 1995, 1998a). The general flavor of these norms is well illustrated by a few rules from van Eemeren and Grootendorst's (2004) system:

Rule 2 states that

the discussant who has called the standpoint of the other discussant into question in the confrontation stage is always entitled to challenge the discussant to defend this standpoint. (p. 137)

The next rule, Rule 3, governs the burden of proof, whereby it is the proponent of a claim who is obliged to provide sufficient support for it:

The discussant who is challenged by the other discussant to defend the standpoint that he has put forward in the confrontation stage is always obliged to accept this challenge, unless the other discussant is not prepared to accept any shared premises and discussion rules; the discussant remains obliged to defend the standpoint as long as he does not retract it and as long as

he has not successfully defended it against the other discussant on the basis of the agreed premises and discussion rules. (p. 139)

In addition to such fundamental rules, theorists have proposed more specific rules governing, for instance, mode of presentation, and some examples of such rules will be discussed later.

The dialectical model of the courtroom, finally, has also been of influence in the development of nonclassical logics (e.g., Dung, 1995), which seek to overcome some of the inadequacies of classical logic, and, in particular, seek to capture reasoning under conditions of uncertainty (for a general overview of nonclassical logics, see Prakken & Vreeswijk, 2002).

Arguably, however, there is still something missing in procedural or dialectical approaches to argument as is readily apparent from the legal model itself: This is the “final evaluation.” In the courtroom, judges and/or juries reach a final verdict, and that overall evaluation itself should be rational. Procedural rules constrain this but do not fully determine its outcome. One may have several pieces of evidence, for example, all of which are permissible but which, individually, are more or less compelling. Furthermore, different pieces of evidence, potentially varying in individual strength, must be combined into an overall degree of support.³

Such evaluation is crucially about specific *content*. Procedural rules alone are insufficient here, but so typically are the purely structural relationships between statements identified by classical and nonclassical logical systems. Knowing, in structural terms, simply that one statement “attacks” another does not allow a final evaluation of whether one is more convincing than the other, and hence outweighs it in final evaluation.

Concerning content, it has most recently been argued that Bayesian probability might provide appropriate epistemic norms for argumentation (Hahn & Oaksford, 2006a,b 2007a; Korb, 2004; Oaksford & Hahn, 2004; also see Griffiths et al., Chapter 3).⁴ The Bayesian approach to argumentation originated as an attempt to provide a formal treatment of the traditional catalog of fallacies of argumentation, examples of which are circular arguments such as “God exists, because the Bible says so and the Bible is the word of God” and so-called arguments from ignorance, such as “Ghosts exist because nobody has proven that they don’t.” According to the Bayesian account, informal arguments such as these consist of a claim (“ghosts exist”) and evidence for that claim (“nobody has

proven that they don't"). An individual's degree of belief in the claim is represented by a probability. Bayes' theorem, which follows from the fundamental axioms of probability theory, then provides a normative standard for belief revision; it thus provides a formal tool for evaluating how convinced that individuals should be about the claim in light of that particular piece of evidence. There are three probabilistic quantities involved in Bayes' theorem that determine what degree of conviction should be associated with a claim once a piece of evidence has been received: prior degree of belief in the claim, how likely the evidence would be if the claim were true, and how likely it would be if the claim were false. Specifically, Bayes' theorem states that:

$$P(h | e) = \frac{P(h)P(e | h)}{P(h)P(e | h) + P(\neg h)P(e | \neg h)} \quad \text{Eq. 1}$$

where $P(h|e)$ represents one's posterior degree of belief in a hypothesis, h , in light of the evidence, e , which can be calculated from one's initial, prior degree of belief, $P(h)$, and how likely it is that the evidence one observed would have occurred if one's initial hypothesis was true, $P(e|h)$, as opposed to if it was false, $P(e|\neg h)$. The ratio of these latter two quantities, the likelihood ratio, provides a natural measure of the diagnosticity of the evidence, that is, its informativeness regarding the hypothesis or claim in question.

We will discuss the application of Bayes' theorem to individual arguments in more detail later, and we note here simply several general characteristics. First, what values any of these quantities take depends on what the statements in question are about, that is, the specific *content* of hypothesis and evidence. Second, the Bayesian framework, through its interpretation of probabilities as subjective degrees of belief, accords with the general intuition that argumentation contains an element of audience relativity (a property widely perceived to be characteristic of real-world arguments, see, e.g., Hahn & Oaksford, 2006a, 2006b; Perelman & Olbrechts-Tyteca, 1969; Toulmin, 1958); that is, the same argument need not (rationally) have the same impact on all recipients. Nevertheless, Bayesian probability imposes real constraints on the beliefs an agent can have, both by guaranteeing probabilistic consistency between the beliefs of a given agent, and because the beliefs of different agents are, in certain cases, guaranteed to converge

as these agents observe more and more evidence (see also, e.g., Hahn & Oaksford, 2006b).

There has been (and continues to be) debate about the proper scope of the procedural and epistemic frameworks just discussed. They target different aspects of argumentation, but both in theory and practice these aspects are intertwined. Dialectical and epistemic concerns are related. For example, silencing opponents by force is undoubtedly a violation of dialectical, procedural norms for "good" argumentation; but it seems dubious even for those interested not in process, but only in truth, because the suppression of arguments in discourse means that the potentially strongest argument might not be heard (see also Goldman, 1994; Hahn & Oaksford, 2006b). Likewise, pragma-dialectical theories have used discourse rules to evaluate fallacies of argumentation (e.g., van Eemeren & Grootendorst, 1992, 2004; Walton, 1995). However, the problem that remains is that discourse rules typically do not provide enough constraints on content. It is not hard to find examples of arguments with the same structure, and in the same argumentative context, that nevertheless differ fundamentally in how intuitively compelling they seem, and this has been at the heart of recent criticisms of the pragma-dialectical approach to the fallacies (e.g., Hahn & Oaksford, 2006a). Hence, normative theories of content and procedural theories can (as we will see) clash on occasion, but they ultimately pursue complementary goals (Goldman, 1994; Hahn & Oaksford, 2006b), and both have an important role to play in shaping "rational debate."

The Psychology of Argumentation

As detailed in the Introduction, psychological research has addressed argumentation from a number of different perspectives. In the following sections our main emphasis will be on basic research concerning argument quality; then in the remainder, we will provide brief introductions to research concerned with the development of argumentation skills, and educational attempts to foster argumentation, as well as argument in a number of specific practical contexts such as science and the courtroom.

Argument Quality

Foundational research on argument quality within psychology can itself be split naturally into research concerned with procedural aspects of argumentation, in particular pragma-dialectic

norms governing rational debate, and into research concerned with the epistemic quality of the argument, and hence, the actual main substance of its content.

PROCEDURAL ASPECTS OF ARGUMENTATION

Experimental research on procedural aspects of argumentation stems from a number of sources: cognitive psychologists, educational psychologists, communication researchers, argumentation theorists, and philosophers. This diversity of disciplines and theoretical backgrounds means that relevant psychological research is found beyond the confines of mainstream psychological outlets. In the following, we provide key examples.

A central topic for cognitive psychologists with an interest in pragma-dialectical aspects of argument has been the burden of proof (e.g., Bailenson, 2001; Bailenson & Rips, 1996; Rips, 1998; see Rips, Brem & Bailenson, 1999 for reviews). As noted earlier, the notion is derived from law, where burdens of proof are explicitly specified. In the context of psychological research, the notion has been operationalized by presenting participants with argumentative dialogues and asking them to indicate which proponent in the dialog “has the most to do in order to prove that he or she is right.” Experimental manipulations involve providing a proponent’s challenge (“What is your evidence for that statement?”) earlier or later in dialogue, and whether a dialogue starts with a neutral claim (“Hi, good to see you”) and then an assertion by the second speaker, or directly with the assertion of the second speaker. Such manipulations are found to have an effect; however, it is debatable to what extent these tasks involve a burden of proof in any technical sense (see Hahn & Oaksford, 2007b). It is clear that the evaluation of a series of arguments can be influenced by the order in which the component arguments are presented (see also McKenzie, Lee, & Chen, 2002). Crucially, order will affect the interpretation of material. For example, the order in which issues are put forward by a speaker are likely to be influenced by their perceived importance. This consideration allows corresponding inferences on the part of the listener, for example, about what the speaker is most concerned about. Likewise, changes in the order in which arguments and counterarguments appear can alter the perceived relevance of claims, and the degree to which they seem responsive to what has preceded them. Not seeking to refute a prior claim can be taken to signal tacit acceptance (see e.g., Clark, 1996), or at least

the lack of a cogent counterargument, in the same way that the provision of weak (counter-) evidence can be taken to suggest that no stronger evidence is available. These latter inferences are (nonfallacious) examples of argument from ignorance, an argument form we turn to in detail later (see Harris, Corner, & Hahn, 2009). At the same time, “diffuse” responses may be seen to affect the perceived competence of the person supplying them (Davis & Holtgraves, 1984) or their credibility (O’Keefe, 1999). Social psychologists have studied extensively the effects of so-called one-sided versus two-sided messages; that is, the effectiveness of ignoring versus acknowledging counterarguments. O’Keefe (1999) provided a meta-analysis of the respective persuasive effects of such one- versus two-sided messages (for a review of studies on this topic, see also Allen, 1991). Based on a systematic evaluation of over 50 studies, O’Keefe concluded that two-sided arguments that address counterarguments are typically more persuasive than one-sided arguments; least persuasive are arguments that explicitly acknowledge counterarguments without trying to refute them. From a pragma-dialectical perspective, this ordering ties in with the fundamental procedural obligation to defend one’s position when challenged (see earlier) in that the most persuasive arguments are those that at least attempt to discharge argumentative burdens (see also, O’Keefe, 2003); however, it is not clear that these are ultimately anything other than argument *content* effects (see also O’Keefe, 1999, for discussion of this point).

As part of an ongoing project to consider the extent to which the normative quality of arguments squares with their actual persuasive effect as established within social psychological research, O’Keefe has also conducted a meta-analysis of the persuasive effects of standpoint explicitness, that is, the extent to which the degree of articulation with which a communicator presents his or her overall conclusion affects message effectiveness (O’Keefe, 1997a). From a pragma-dialectical perspective, such explicitness can be linked to procedural obligations of the proponent of an argument to avoid “concealment, evasion, and artful dodging” and present information in such a way that allows critical scrutiny. In line with such obligations, social psychological research has found that better articulation seems to give rise to greater persuasive effect. O’Keefe’s (1997b) meta-analysis revealed corresponding effects for the degree of articulation in the actual argumentative support. In short, O’Keefe’s findings demonstrate

some correspondence between what might be considered normatively desirable and what, in persuasive terms, “actually works.”

Finally, procedural norms have been empirically investigated within the framework of “argumentational integrity” or fairness (e.g., Christmann, Mischo, & Groeben, 2000; Mischo, 2003; Schreier, Groeben, & Christmann, 1995). Here, studies have sought to examine people’s sensitivity to the violation of procedural rules, such as, for example, that proponents within a debate should have equal opportunity to contribute, or that contributions to debate must be sincere. Research has also examined the persuasive costs of such rule violations, and it has sought to develop educational training programs to increase awareness of violations (Christmann, Mischo, & Flender, 2000).

PISTEMIC ASPECTS OF ARGUMENT QUALITY

Logic and probability theory combine to provide powerful tools for the evaluation of arguments. Classical logic provides minimum standards by enforcing logical consistency and the avoidance of contradictions: A statement that is contradictory can never be true, and thus it constitutes neither a claim nor evidence worth consideration. Probability theory then constrains content beyond these minimal, logical requirements (see Chater & Oaksford, Chapter 2).

Both people’s logical reasoning and their ability to deal appropriately with probabilities have been the focus of vast amounts of psychological research (for overviews, see e.g., Hardman, 2009; Manktelow, 2011). Broadly construed, all of this research is relevant. Psychological work on logical reasoning, for example, deals with very specific and very restricted “arguments.” The logical reasoning literature has often been scathing about people’s logical abilities; however, there is reason to question the applicability of much of this research to everyday argumentation. For one, it is well documented that people’s degree of conformity to logic is much affected by the exact content of materials (Manktelow, 2011; Wason & Johnson-Laird, 1972; see Evans, Chapter 8). It has been argued recently that people’s abilities in this regard are much better when they are embedded in the kinds of argumentation contexts that logical reasoning supports in everyday life (Mercier & Sperber, 2011). Furthermore, many tasks that experimenters perceive to involve deduction may not necessarily do so from the perspective of the participant. In particular, it has been argued that people typically

adopt a probabilistic interpretation of conditionals (if-then statements), and once this is taken into account their reasoning is far from bad (e.g., Evans & Over, 2004; Oaksford & Chater, 1994, 2007, 2009). This issue is discussed extensively elsewhere in this volume (Chater & Oaksford, Chapter 2), but we will also consider several types of conditional. Analogous points apply to the literature on probability judgment. For one, people argue primarily about things they care about and with which they have some degree of familiarity. Moreover, although some evidence, and hence argument, involves overt numbers, probabilities, and statistics (and hence limitations identified in previous research may readily apply), most everyday argument does *not* cite numerical quantities. Consequently, for most of the many different argument forms that arise in everyday discourse, experimental research has only just begun.

Much of that research has been centered around putative cases of human error, that is, fallacies in human reasoning. Hence, we will focus primarily on these fallacies in the following sections, before concluding with research addressing argument quality in a number of applied contexts.

Fallacies of Argumentation: A Litmus Test for Evaluation of Argument Quality

The fallacies have long been a focal point for philosophical research on argument quality. There is debate about how to best define the notion of fallacy (see, e.g., van Eemeren & Grootendorst, 2004, for discussion). On an intuitive level, fallacies are simply arguments that might *seem* correct but aren’t, that is, arguments that might persuade but really should not. Contemporary lists include more than 20 different fallacies (see e.g., Woods, Irvine, & Walton, 2004). The fallacies of circular argument (Walton, 1985, 1991) and the argument from ignorance (Walton, 1992a) have already been mentioned; other well-known fallacies are the slippery slope argument (“if we legalize assisted suicide, it will be euthanasia next;” Walton, 1992b), the ad populum argument or appeal to popular opinion (“many people think this; it cannot be wrong;” Walton, 1980, 1999), the ad hominem argument, which seeks to undermine the proponent of an argument instead of addressing the argument itself (e.g., Walton, 1987, 1998b, 2000, and references therein), the ad verecundiam argument also known as the appeal to authority (e.g., Walton, 1997), equivocation (e.g., Engel, 1986; Kirwan, 1979; Walton, 1996b; Woods & Walton, 1979), and the

ad baculum argument, which appeals to threats or force (“if you don’t like that, you might find yourself out of a job;” Walton, 2000b; Walton & Macagno, 2007). These informal arguments are pervasive in everyday discourse (for real-word examples, see also, e.g., Tindale, 2007), and critical thinking textbooks seek to educate about them. The goal of philosophical research on the fallacies has been to provide a comprehensive treatment—ideally a formal treatment—of these fallacies that can explain exactly why they are “bad” arguments (see e.g., Hamblin, 1970). In other words, the fallacies are a litmus test for our theories of argument quality.

The fallacies have also been investigated experimentally from both a broadly procedural, typically pragma-dialectical perspective (e.g., van Eemeren, Garssen, & Meuffels, 2009; Neuman, 2003; Neuman, Glassner, & Weinstock, 2004; Neuman, Weinstock, & Glasner, 2006; Neuman & Weitzman, 2003; Ricco, 2003; Rips, 2002), and from an epistemic perspective (e.g., Hahn & Oaksford, 2007a; Oaksford & Hahn, 2004; Oaksford & Chater, 2007, 2010a,b). Although in many ways such experimental work has only just started, the general finding has been that people seem quite competent at identifying fallacious arguments.

A more detailed examination of both theory and experimental work on the fallacies also demonstrates why procedural approaches to argument quality are not sufficient. This is well illustrated with one of the more widely studied arguments, the argument from ignorance:

Ghosts exist, because nobody has proven that they don’t. (1)

Historically, one of the main stumbling blocks for theoretical treatments of the fallacies was that most of the fallacies seem to involve seeming “exceptions” in the form of examples that do not seem as bad (see e.g., Walton, 1995). The following examples too are arguments from ignorance, but unlike (1) seem acceptable:

This drug is safe because clinical trials have found no evidence of side effects. (2)

and

The book is in the library, because the catalog does not say that it is on loan. (3)

Clearly, the inferences in all three of these cases are uncertain or defeasible; that is, the conclusions do not follow necessarily from the evidence.

However, they seem sufficiently likely to be true, in light of the reason or evidence provided, that we readily base our actions on such arguments in everyday life. Examples such as (2), in particular, are widespread in socioscientific debate about the acceptability of new technologies (e.g., genetically modified foods, nanotechnology). Uncertainty is, of course, also present in positive inferences such as:

This drug causes side effects, because some participants in the clinical trial exhibited flu-like symptoms. (4)

Pragma-dialectical theories seek to explain why textbook examples of the argument from ignorance are poor arguments by considering them in a wider dialectical context, and attributing their insufficiency to the violation of discourse rules within that wider, overall argument. Specifically, arguments such as (1) are typically assumed to violate the burden of proof (see e.g., van Eemeren, Garssen & Meuffels, 2009; Walton, 1992a, 1995, 1996a). As we saw earlier, the burden of proof is assumed to demand that whoever makes a claim has to provide reasons for this claim when challenged. Stating that no one has disproved the existence of ghosts as a reason for believing in them constitutes an illegitimate attempt to shift that burden onto the other party, instead of providing an adequate reason oneself.

However, such an explanation seems forced for two reasons (see also Hahn & Oaksford, 2006a, 2007a, 2007b). First, example (1) seems intuitively a weaker argument than (2) or (3) even when all are presented in isolation as they are here, that is, without any wider argumentative context and any indication of parties engaged in debate. Here it is unclear to whom obligations such as burdens of proof could be ascribed. Second, violations of one’s burden of proof are a *consequence* of providing insufficient evidence, not a *cause*. The judgment that an argument seeks illegitimately to “shift the burden of proof” does not explain an argument’s weakness; rather, it presupposes it. Weak arguments fall short of burdens of proof; strong ones do not. Consequently, it still needs to (independently) be determined why, for example, (1) is poor, in ways that (2), (3), and (4) are not.

The identification of very abstract relations such as “claim,” “warrant,” or “backing” as found in Toulmin’s and similar systems also provides no guidance here. All four examples involve a claim and a reason given in support. Rather, an epistemic standard aimed at the specific content is required

here. Logic has nothing to say about these arguments; none of them are deductively valid.⁵

The probabilistic Bayesian framework, however, does make appropriate distinctions here (Hahn & Oaksford, 2006a; Hahn & Oaksford, 2007a; Oaksford & Hahn, 2004). The standard version of Bayes' theorem provided in Eq. 1 earlier applies directly to positive arguments such as (4). The claim that "this drug causes side effects" takes the place of hypothesis h ; the reason "because some participants in the clinical trial exhibited flu-like symptoms" takes the role of evidence e . This evidence is convincing to the extent that these symptoms are more likely if the claim is true, $P(e|h)$, than if it is not, $P(e|\neg h)$, for example, because it is winter and participants can catch a flu. As noted earlier, it is the specific content of the argument that fixes these probabilistic quantities, and argument strength will vary with the likelihood ratio (diagnosticity of the evidence). Observing, for example, that 95% of the participants in the trial displayed side effects within hours of taking the drug will provide greater support than observing a few who fell ill over a several-week period. Crucially, this approach allows one to capture content specific variation in the perceived strength of arguments of the same structure.

A negative argument such as (2) requires the corresponding negative form of Bayes' theorem:

$$P(\neg h | \neg e) = \frac{P(\neg e | \neg h)P(\neg h)}{P(\neg e | \neg h)(\neg h) + P(\neg e | h)P(h)}$$

Eq. 2

Again, such negative arguments can be weaker or stronger: Failing to observe side effects in 50 studies provides far stronger evidence for the claim that the drug lacks side effects (is safe) than does observing no side effects in just a single study, and these differences are readily captured.

However, the Bayesian framework also identifies important consequences of differences in structure. Formal analysis reveals that across a broad range of possible (and in everyday life plausible) numerical values for both how likely the evidence would be if the claim were true and if it were false, positive arguments are stronger than their corresponding negative counterparts based on the same set of values (Hahn & Oaksford, 2007a; Oaksford & Hahn, 2004). This observation provides an explanation for why arguments from ignorance are typically less

convincing than corresponding arguments from positive evidence. In other words, the framework captures both characteristics of particular argument types, and of particular instantiations of these types.

From a formal perspective, there is also an important difference between different types of argument from ignorance, exemplified on the one hand by the ghosts example in (1), and, on the other, by the drug safety example in (2). Whereas the just-discussed drug safety example simply involves an inference from a negative (lack of observed ill effects in clinical trials) to a negative (lack of side effects of drug), the ghosts example involves an inference from a double negation ("no-one has proven that they don't") to a positive (ghosts exist). This so-called epistemic closure case of the argument from ignorance (see, e.g., Walton, 1996a) requires a further distinction, because people could fail to prove that ghosts don't exist not only because they tried and actually found evidence of existence, but also because they did not try at all. Hence, Hahn and Oaksford's (2007a) Bayesian formalization of this type of argument from ignorance involves three possibilities: a report of positive evidence " e ," an explicit report of negative evidence " $\neg e$," and the third possibility, n (as in "nothing"), indicating that there is simply no evidence either way (i.e., neither an explicit reporting of e or $\neg e$). Such an approach is familiar from artificial intelligence where one might distinguish three possibilities in a database search regarding a proposition (h): the search can yield affirmative information (e), negative information ($\neg e$), or return with nothing (n). Epistemic closure has been invoked here to license inferences from search failure (i.e., a query resulting in nothing) to nonexistence, given that the database is assumed to be complete.

The Bayesian formalization of epistemic closure is analogous, except that closure can be a matter of degree, ranging from complete closure, through moderate closure, to no closure at all. The corresponding version of Bayes' theorem for the ghosts example is, therefore,

$$P(h | \neg'' \neg e'') = \frac{P(\neg'' \neg e'' | h)P(h)}{P(\neg'' \neg e'' | h)P(h) + P(\neg'' \neg e'' | \neg h)P(\neg h)}$$

Eq. 3

where $P(\neg'' \neg e'' | h) + P(\neg'' \neg e'' | \neg h) + P(n | h) = 1$.

How strong this argument is depends critically on the degree of closure. If the source is epistemically closed (i.e., the database complete), then the probability of a “nothing” response is zero, and everything reduces to the familiar binary case, where $\neg\neg e$ is the same as e (and one is effectively back to Eq. 1). As epistemic closure decreases, the probability of a null response increases, and the inference must become less strong (assuming that the quality of the explicit evidence we could obtain remains the same, that is, equally diagnostic; Hahn & Oaksford, 2007a, 2008). This fact explains why some cases of this argument, such as the library case in (3), are so much better than the ghosts example in (1). Electronic library catalogs are reasonably reliable, in that when they say a book is in the library, more often than not it actually is, because libraries try hard to keep their catalogs up to date. Likewise when catalogs say that a book is on loan, it typically is, and epistemic closure is high because loans are (in principle) always recorded.

Several experimental studies have examined the extent to which people’s judgments about arguments from ignorance are concordant with Bayesian prescriptions (Corner & Hahn, 2009; Hahn, Harris, & Corner, 2009; Harris, Corner, & Hahn, 2009; Hahn, Oaksford, & Bayindir, 2005; Hahn & Oaksford, 2007a; Oaksford & Hahn, 2004). Oaksford and Hahn (2004) provided participants with short dialogs between two characters, asking them to provide evaluative judgments of how convinced of a claim one of the characters should be in light of the evidence presented by the other. Two different scenarios were used, one involving drug safety and one involving TV violence. Participants saw both positive arguments (as in (4) above) and corresponding arguments from ignorance (such as (2) above). Also manipulated were the degree of prior belief the character in receipt of the evidence already had in the claim ($P(h)$), and the amount (and hence diagnosticity) of evidence received (e.g., one versus 50 clinical studies). Oaksford and Hahn found the expected main effects of prior belief, amount of evidence, and whether the argument was positive or an argument from ignorance. Participants saw the arguments from ignorance as acceptable but less acceptable than their positive counterparts, and that degree of acceptability was influenced by the prior beliefs of the characters in the dialog and the amount of evidence in the way predicted by a Bayesian account.

That participants distinguish clearly between what should be strong and weak versions of the argument from ignorance was confirmed in further

studies. For example, Hahn and Oaksford (2007a, Exp. 3) presented participants with the classic textbook example of the ghosts (1) and the library example (2), both embedded in short dialogs as in Oaksford and Hahn (2004). Participants’ ratings of how convinced a character in that dialog should be by the argument in question was significantly lower for the ghosts argument. Hahn et al. (2005) presented participants with positive arguments, as well as both types of argument from ignorance, and a negative argument involving explicit negative evidence. Furthermore, there were four different scenarios chosen to vary intuitively in the degree of epistemic closure. Participants’ evaluations were sensitive not only to the individual argument structures but also to the variations in closure, and—as Hahn and Oaksford (2007a) show—are well fit by the respective forms of Bayes’ theorem.

Finally, Harris et al. (2009) examined how silence or “nothing” itself can support rational inference that takes the form of arguments from ignorance. Imagine the recipient of a reference request in the context of a job application, who might be informed merely that the applicant is “punctual and polite” and, on the basis of that, conclude that the applicant is poorly qualified for the job—the phenomenon of being “damned by faint praise.” Here, “punctual and polite” constitutes a positive piece of evidence, which should (marginally) increase favorable evaluation of the candidate. What is doing the damage is what is not being said, namely, the absence of any discussion of job-relevant skills. Such an inference from nothing, n , to the conclusion that the applicant is not qualified ($\neg h$) is governed by this version of Bayes’ theorem:

$$P(\neg h | n) = \frac{P(\neg h)P(n | \neg h)}{P(\neg h)P(n | \neg h) + P(h)P(n | h)}$$

Eq. 4

and is licensed wherever $P(n|h) < P(n|\neg h)$, that is, wherever the probability of a “nothing” response is less if the hypothesis is true than if it is false. In this case, the nonoccurrence itself is informative because it is suggestive of the fact that the hypothesis is false. Hence, the effect should be observed where a motivated (or positively inclined) but nonlying source is presenting an argument. By contrast, there is no reason for this negative inference in the case of a maximally uninformed source, $P(n|h) \approx P(n|\neg h)$, who simply knows nothing on the topic.

In line with this, Harris et al.'s (2009) experiment involving a fictitious academic reference found that being told that "James is punctual and polite" led to decreases in judgments of whether James should be admitted to a university course in mathematics, but only when it came from his math tutor (who was presumably well informed about his mathematical abilities), but not from his personal tutor (who had provided general guidance only). Moreover, it was not the case that punctuality and politeness were perceived to be negative themselves, as when following details about mathematical ability this information raised evaluations of James' suitability.

A further case of inference from "nothing," finally, is the argument from ignorance we mentioned earlier: The failure to provide counterarguments or evidence can be taken to indicate either tacit agreement, or, at least, that the opponent has no counterevidence available. In this case, $P(n|h) > P(n|\neg h)$, and the lack of counterevidence suggests the claim is true. Moreover, the more salient a proponent has made a claim, thus indicating its perceived importance (for example, by introducing it early on), the more motivated the opponent should be to counter it, if possible. Hence, the more $P(n|h)$ should be assumed to exceed $P(n|\neg h)$, and thus the stronger the overall inference will be. It is in this way that changes to presentation order, or one- versus two-sided presentation, can directly affect the perceived content of the overall argument at hand.

CONDITIONALS

A probabilistic approach also deals naturally with arguments and fallacies that arise with the conditional (if...then) in natural language. In this area of the psychology of reasoning, an explicitly epistemic approach has emerged that is closely related to the research on argumentation we have so far reviewed (e.g., Oaksford & Chater, 2007, 2010a,b).

Conditional Fallacies

Many accounts of the fallacies include deductive fallacies such as those attaching to the conditional, if p (antecedent), then q (consequent). Two such fallacies are denying the antecedent and affirming the consequent. These fallacies are typically included among those that require an explanation in terms of the discourse rules involved in their use in argumentation (e.g., Godden & Walton, 2004). An example of denying of antecedent (DA) is:

If a bird is a swan, then it is white.
That bird was not a swan.
Therefore, that bird was not white. (5)

Godden and Walton's approach is to point out that while clearly a truth functional fallacy—as there are nonwhite swans—deploying this line of reasoning in argument against someone who is using this conditional to argue that a particular bird was white may be a sound strategy. Of course, if whether "that bird was white" is the topic of an argument, then it is clear that the parties in the argument disagree, and hence there is some uncertainty about the bird's color. The party deploying the conditional originally ("Pro") argues that the bird is white via a modus ponens (MP) argument:

(Pro) If a bird is a swan, then it is white. That bird was a swan; therefore, it was white.

To refute Pro's argument, the respondent ("Con") must deny one of the premises. Con chooses to "deny the antecedent," that is, to deny that the bird was a swan, from which it "follows" that the bird was not white:

(Con) But that bird was not a swan; therefore, it was not white.

However, as Godden and Walton observe, in this example, the falsity of the consequent—the bird was not white—does not follow from this use of denying the antecedent in the way that it would if it were logically valid, that is, it is not truth preserving. Rather, its deployment here undermines another property of Pro's intended conclusion, what "might be called its *admissibility*, or that it follows or that it is established or that it may be concluded, or perhaps even that it should be believed" (Godden & Walton, 2004, p. 232). A subjective probabilistic approach to argument strength for the conditional can cash out this last intuition with respect to whether Pro's conclusion is believable (Oaksford & Hahn, 2007).

According to Hahn and Oaksford's (2006a, 2007a) account of argument strength, people are concerned with the subjective degree of belief they should have in the conclusion given their degrees of belief in the premises. Oaksford and Chater (2007; Oaksford, Chater, & Larkin, 2000) proposed just such a model for the conditional. We will not rehearse the theory in any detail. It depends on people possessing prior degrees of belief in the conditional, given by the conditional probability, $P_o(q|p)$, and in the marginals, $P_o(p)$, $P_o(q)$ (the "0"

subscript denotes prior probabilities; a “1” subscript denotes posterior probabilities). These probabilities define a prior probability distribution from which, for example, the probability $P_0(\neg q|\neg p)$ can also be derived. People are assumed to derive their degrees of belief in the conclusions of conditional inferences by Bayesian conditionalization. So, for modus ponens, when Pro asserts that “that bird was a swan,” for Bayesian conditionalization to apply, she is asking her audience (here Con) to assume that $P_1(p) = 1$, from which it follows that one’s degree of belief in the conclusion, $P_1(q)$, should be $P_0(q|p)$.

It is straightforward to derive contexts in which denying the antecedent is stronger than modus ponens. So if Con’s beliefs lined up pretty closely to such a context, his counterargument by denying the antecedent could be stronger than Pro’s initial argument by modus ponens. Suppose that the swans they are talking about are in a bird sanctuary containing equal numbers of white and black swans, and that most of the birds in the sanctuary are neither white nor swans. The following distribution captures these facts: $P_0(q|p) = .5$, $P_0(p) = .1$, $P_0(q) = .1$. On this distribution, a bird is nine times more likely to be white given it is a swan than that it is not a swan. However, the probability that the bird is white given it is a swan is only .5, i.e., $P_1(q) = .5$. That is, on this distribution, Pro’s argument while logically valid, only yields a .5 degree of belief in the conclusion. Con’s argument can be characterized as noting that priors matter and that it is highly unlikely that the bird was a swan; that is, Pro’s assertion that $P_1(p) = 1$ is unlikely to be true. For Bayesian conditionalization to apply, this has to be incorporated into an argument as the assumption that $P_1(p) = 0$, and so $P_1(\neg p) = 1$. The posterior probability is $P_1(\neg q) = P_0(\neg q|\neg p) = .94$. That is, on this distribution, Con’s DA argument is stronger than Pro’s MP argument, in the sense of yielding a higher degree of belief in its conclusion.

One may also avoid the fiction of Con (or Pro) asking his or her interlocutor to assume that the categorical premise is certain, $P_1(\neg p) = 1$. By using Jeffrey conditionalization—a generalization of Bayesian conditionalization to when the categorical premise is uncertain (see, e.g., Jeffrey, 2004)—one could just argue that the probability that the bird was a swan equals one’s subjective degree of belief, that is, .1, then $P_1(\neg q) = P_0(\neg q|\neg p) P_1(\neg p) + P_0(\neg q|p) P_1(p) = .94 \times .9 + .5 \times .1 = .896$. This reformulation does not change things by very much, that is, DA is still the stronger argument, and we should believe

its conclusion more than the conclusion of the MP argument. So by developing an account of argument strength using subjective probability, we can generate a measure of how much the conclusion of the DA argument “*should be believed*.” It remains for Con to persuade Pro that the distributions on which the former bases his argument map on to the way the world actually is.

We then confront an issue we have raised before (Hahn & Oaksford, 2007a): What comes first, the assessment of the strength of the respective arguments given what Con believes, or the deployment of the DA argumentative strategy? It seems clear that deploying DA in this context is appropriate because Con believes it to be the stronger argument. The burden of proof of course then returns to Con to establish that the context is as Con believes it to be.

However, there are features of this context that suggest that one might rarely be justified in deploying DA in argument. First, ignoring the priors, Pro’s MP argument is more forceful. It should lead to greater change in people’s degree of belief in the conclusion. This is because the bird is 9 times more likely to be white given it is a swan but only 1.88 times more likely not to be white given it is not a swan. Oaksford and Hahn (2007) proposed the likelihood ratio as a possible prior independent measure of argument *force*. Ignoring priors is a well-documented phenomenon in the psychology of judgment and decision making (Bar-Hillel, 1980; Kahneman & Tversky, 1973). Hence, it is understandable why despite the low prior, Pro (even if he believed the prior to be low) might view MP as a “good” argument to put forward. Con’s DA counterargument is in a sense a reminder that the priors do matter, and that in this case one should be more convinced that the bird is not white.

Second, however, one might question whether there are many circumstances in which the DA argument is justified because it is the stronger argument. One of the assertability conditions on the conditional, at least according to Adams (1998), is that $P_0(q|p)$ is high, certainly greater than .5. When this is the case, MP will usually be a stronger argument than DA, that is, $P_0(q|p) > P_0(\neg q|\neg p)$. So, by introducing the conditional, Pro may be implicitly asserting that MP is stronger than DA. This situation would seem to warrant a different argumentative strategy on Con’s part, that is, denying the conditional premise rather than the antecedent. Moreover, in the psychology of belief revision it has been found that in response to a contradiction of

the conclusion of an MP inference, people choose to revise their belief in the conditional rather than their belief in the categorical premise (Elio & Pelletier, 1997). In arguing that Pro—or Pro and Con's audience—should believe the opposite of the conclusion of the MP inference, Con is in a similar position and hence may normally choose to deny the conditional rather than the antecedent.

Deontic and Utility Conditionals

In the psychology of reasoning, it has been observed that conditional sentences frequently describe situations that have associated utilities, which may figure in various argumentative strategies and fallacies (Manktelow & Over, 1987). This observation was first made in the context of deontic reasoning (Cheng & Holyoak, 1985; Cosmides, 1989), that is, about what you should and should not do, using conditionals like,

If you are drinking beer, you must be over
18 years of age. (6)

An enforcer of such a deontic regulation will place a high utility on detecting cheaters, that is, people who are drinking beer but who are not over 18 years of age. Oaksford and Chater (1994) showed how people's behavior on the deontic version of Wason's selection task could be captured by assuming that people are attempting to maximize expected utility in their selection behavior. More recently, Perham and Oaksford (2005) showed how this calculation could be modified by emotions to explain effects when explicitly threatening words were used in the antecedent of a deontic conditional. Bonnefon (2009) has developed a classification scheme for utility conditionals where the positive or negative utility is associated with either the antecedent or consequent of a conditional, and there have been several papers investigating such effects (Evans, Neilens, Handley, & Over, 2008; Thompson, Evans, & Handley, 2005).

Evans et al. (2008) investigated a variety of conditionals expressing conditional tips, warnings, threats, and promises. For example, "If you go camping this weekend, then it will rain" is a clear warning not to go camping. The higher $P(q|p)$ and the more negative the utility associated with the consequent, $U(q)$, that is, rain, the more persuasive such a conditional warning is to the conclusion that action p should not be taken, $\neg p$, that is, you should not go camping. For warnings, Evans et al (2008) argued that the decision about whether to perform

the action p is based on the *prima facie* utility of the action itself, $U(p)$, less the expected disutility of the action to which p could lead, $P(q|p)U(q)$, that is,

$$U(p) - P(q|p)U(q) \quad \text{Eq. 5}$$

Hahn and Oaksford (2007a) provided a very similar analysis of the slippery slope argument (SSA), which has often been regarded as an argumentative fallacy.

Slippery Slope Arguments

SSAs are typically expressed in conditional form (see Corner, Hahn, & Oaksford, 2011):

If we allow gay marriage, then in the future
people will want to marry their pets. (7)

If voluntary euthanasia is legalized, then in
the future there will be more cases of "medical
murder." (8)

If we accept voluntary ID cards in the UK, we
will end up with compulsory ID cards in the
future. (9)

These examples have all actually been put forward in the media by groups arguing that the antecedent actions of (7) to (9) should not be taken. As these examples show, SSAs can vary greatly in strength. Like conditional warnings, the conclusion people are invited to draw is $\neg p$, for example, one should not allow gay marriage. (7) is weak because of the very low value of $P(q|p)$, whatever we may think of the merits of interspecies marriage. (8) is stronger because this probability is higher but also because "medical murder" is clearly so undesirable, that is, $U(q)$ is strongly negative. (9) is even stronger because $P(q|p)$ seems very close to 1 and the consequent is highly undesirable (for some).

What differs between SSAs and warnings is that, whereas for warnings $P(q|p)$ is assessed just by reference to prior world knowledge, for SSAs there seems to be an implied mechanism that leads to the consequent action from the antecedent action. This mechanism suggests that an act of categorizing an item a (gay couples) under a category F (can marry), that is, F_a , will lead to other items b (interspecies "couples") also falling under the same category, F_b . Hahn and Oaksford (2007a) proposed that such a "category boundary re-appraisal" mechanism may explain why people find slippery slope arguments so compelling.

Specifically, current theories of conceptual structure typically agree that encountering instances of a

category at the category boundary should extend that boundary for subsequent classifications, and there is a wealth of empirical evidence to support this (see Rips et al., Chapter 11). In particular there are numerous experimental demonstrations of so-called exemplar effects, that is, effects of exposure to particular instances and their consequences for subsequent classification behavior (e.g., Lamberts, 1995; Nosofsky, 1986, 1988a, 1988b). For example, observing that a dog that weighs 10 kg is considered underweight invites the conclusion that a dog that weighs 10.5 kg is also underweight. With only the information that a 5 kg dog is underweight, and a 15 kg dog is overweight, however, one might not be so compelled to draw this conclusion. This is because of the similarity between 10 kg and 10.5 kg and the comparative dissimilarity with either 5 kg or 15 kg. Similarly, one may argue that (7) is a poor argument and so $\text{Pr}(q|p)$ is low because of the dissimilarity between same-sex human relations and interspecies relations, and that hence it is clear that there is no likelihood of slippage of the category “can marry” from one case to the other.

Corner, Hahn, and Oaksford (2011) have shown that people’s confidence in judging that various acts fall under a certain category is directly related to their willingness to endorse a corresponding SSA, and that this relationship is moderated by the similarity between the acts. For example, participants who are told that *assault in possession of a knife* has been categorized as having a tariff of *less than 20 years imprisonment* may confidently decide that *assault in possession of a gun* would also be given the same tariff. These same participants also endorse the slippery slope argument to the conclusion that *assault in possession of a knife* should be given a tariff of greater than 20 years because giving it less than 20 years may lead to *assault in possession of a gun* also being given the lower tariff. In this condition in Corner et al.’s (2011) Experiment 3, decision confidence in the categorization judgment and SSA endorsement were substantially correlated, $r(25) = .47$. When *assault without a weapon* is substituted for *assault in possession of a knife*, that is, an offense less close to *assault in possession of a gun* in similarity space, decision confidence and SSA endorsement rates become less correlated. In this dissimilar condition in Corner et al.’s (2011) Experiment 3, the correlation between decision confidence in the categorization judgment and SSA endorsement fell dramatically, $r(24) = .04$. The moderating effect of similarity was confirmed in a moderated regression analysis (Aguinis, 2004).

In sum, current work on conditionals and associated arguments shows that a Bayesian account of argument strength with associated utilities (SSAs) and without them (Denying the antecedent) provides a rational understanding of how these apparent fallacies of reasoning and argumentation function. The assessment of the conditional probability, $P(q|p)$, is central for assessing argument strength in both cases. For conditional inferences and fallacies, this is a reflection of world knowledge and can be assessed using the generic Ramsey Test for conditionals (Edgington, 1995; Ramsey, 1931). The Ramsey Test runs as follows: Add the antecedent, p , to your stock beliefs, make adjustments to accommodate this belief, and read off your degree of belief in the consequent, q and this then is $P(q|p)$. However, the Ramsey test is a philosophical prescription crying out for a psychological, algorithmic level explanation (Oaksford & Chater, 2007, 2010b,c). Constraint satisfaction processes in neural networks provide one possible implementation (Oaksford & Chater, 2010b). We have argued that for many SSAs, $P(q|p)$ is determined via category boundary reappraisal processes, which may represent a further algorithmic instantiation of the Ramsey Test (Corner, Hahn, & Oaksford, 2011; Hahn & Oaksford, 2007a).

CIRCULAR ARGUMENTS

The best-known fallacy within the catalog is circularity or “begging the question.” It is also the fallacy that has attracted the most attention and that, arguably, generates the most confusion. Different types of circular argument have been distinguished. One, often termed *equivalency circularity* (see e.g., Walton, 2005), takes the form “ A , therefore A .” This argument type has been theoretically puzzling to philosophers because it is logically valid, and thus in some ways “good;” but it is unlikely to occur very often in practice. A second type is the so-called *dependency circularity*, of which one example is so-called self-dependent justification as in “God exists because the Bible says so and the Bible is the word of God.” Here the evidence presupposes, and in that sense depends on, the very conclusion it is seeking to support; specifically, the Bible cannot be the word of God if God does not exist, which of course is the claim at stake. Though this example will strike most as a rather weak argument, it has been pointed out that many scientific inferences are also self-dependent in that they involve theory-laden observations, and that this self-dependence does *not* necessarily rule them out as legitimate arguments

(for actual scientific examples see Brown, 1993, 1994). This is revealed by a probabilistic analysis (e.g., Hahn & Oaksford, 2007a; Shogenji, 2000), which makes clear that self-dependent arguments as found frequently in science can be acceptable, because the conclusion can be held tentatively, and evidence diagnostic of that conclusion will, when actually observed, increase the posterior of degree belief we have in that conclusion (even though the conclusion itself is involved in the interpretation of the evidence).

There have been a number of psychological experiments examining people's awareness of circularity and their ability to distinguish stronger from weaker circular arguments (e.g., Hahn & Oaksford, 2007a; Rips, 2002). While such studies have generally found that people perform competently, there is clearly a limit here. Psychological researchers themselves frequently accuse others of circularity, and closer inspection suggests that this charge is often overused (Hahn, 2011). Moreover, the distinctions between different types of circular arguments are not always appreciated.

In fact, circular arguments provide a key demonstration of how useful and important the formal tools of probability theory are. Bayesian prescriptions often seem intuitively obvious, and there is a view that the theory of probabilities is "at bottom nothing but common sense reduced to calculus" (Laplace, 1814/1951). However, there are cases where our everyday intuitions break down. Circularity is a case in point. To provide one more example, we might find it intuitive that a sequence or chain of supporting evidence cannot be circular. This is to say that we might find it intuitive that a chain of evidence $E_0, E_1 \dots E_n$ where E_1 supports E_0 , E_2 supports E_1 , and so on (in the familiar sense of support $P(E_0|E_1) > P(E_0|\neg E_1)$) cannot ultimately loop back on itself and have E_n supported only by E_0 , that is, the very piece of evidence support was being sought for. However, Atkinson and Peijnenburg (2010) show mathematically that this is entirely possible, both for finite and infinite loops, and that the presence of such loops does not preclude the possibility that the probability of $P(E_0)$ be well defined. To illustrate with one of their examples:

A: Peter read parts of the philosopher Kant's magnum opus the "Critique of Pure Reason."

B: Peter is himself a philosopher.

C: Peter knows that Kant defended the synthetic a priori.

Here it is both possible and plausible that A is supported (i.e., made more probable) by B, which in turn is supported by C which itself is supported by A. Although one might intuitively suspect that the circularity here means that the (unconditional) probability assigned to A must always remain "up in the air," this is mathematically not so, and given an appropriate assignment of conditional probabilities ($P(A|B)$, $P(B|C)$, $P(C|A)$), a definite value for $P(A)$ ensues.

SUMMARY

The fallacies discussed so far are arguably the most prominent in the philosophical literature, but as noted earlier, they by no means exhaust the catalog of fallacies. The theoretical issues that the remaining fallacies raise parallel those discussed so far (see Hahn & Oaksford, 2006a), but the majority have not yet been the subject of psychological research. Moreover, argumentation theorists have identified many further, nonfallacious argumentation schemes (see Walton, Reed, & Macagno, 2008), which have not been examined by psychologists. Reasoning research within psychology has gradually started to move beyond the very narrow set of (deductive) paradigms that have dominated it for the last decades, and this wealth of different types of argument should provide both fertile and practically important ground.

Argumentation Applied

The practical importance of argumentation to our everyday lives is reflected in the fact that there has also been a wealth of psychological research on argumentation in applied contexts, and this body of research, if anything, exceeds that of the fundamental research we have described so far. Research into the development of children's argument skills is frequently closely tied to the educational goal of fostering and improving such skills (e.g., Anderson, Chinn, Chang, Waggoner, & Yi, 1997; Brem & Rips, 2000; Genishi & DiPaolo, 1982; Glassner, Weinstock, & Neuman, 2005; Kuhn, 1989, 1991, 2001; Means & Voss, 1996).

A considerable amount of this research has been concerned specifically with science (Kuhn, 1993). Much of it has been focused on tracking the development and quality of scientific reasoning (i.e., the use of hypotheses and evidence) in children (see, e.g., Klaczynski, 2000; Kuhn, Cheney & Weinstock, 2000; Kuhn & Udell, 2003; also Dunbar & Klahr, Chapter 35) and has been linked to educational

policy and programs designed to address deficits in scientific literacy (for reviews, see, e.g., Norris & Phillips, 1999; Sadler, 2004; see also Koedinger & Roll, Chapter 40).

A popular strategy in analyzing student use and recognition of different types of scientific argument has been to apply Toulmin's (1958) model. The ability to use (and recognize in other people) different aspects of argumentation such as data or warrants is used as an indicator of comprehension and rhetorical competence (e.g., Driver, Newton, & Osborne, 2000; Erduran, Simon, & Osborne, 2004; Jiminez-Aleixandre, 2002; Jiminez-Aleixandre, Rodriguez, & Duschl, 2000; Kortland, 1996; von Aufschaiter, Erduran, Osborne, & Simon, 2008). However, the limitations of this scheme discussed earlier have made themselves felt. In the words of Driver et al. (2000), "Toulmin's analysis...is limited as, although it can be used to assess the structure of arguments, it does not lead to judgments about their correctness..." (p. 294). Toulmin's model is a powerful tool for specifying the component parts of arguments and classifying them accordingly. It deals only, however, with the structure of different arguments, not their content.

Some researchers have developed their own, typically qualitative, evaluation schemes (e.g., Korpan, Bisanz, Bisanz, & Henderson, 1997; Kuhn, Shaw, & Felton, 1997; Norris, Phillips, & Korpan, 2003; Patronis, Potari, & Spiliotopoulou, 1999; Ratcliffe, 1999; Takao & Kelly, 2003), but these do not necessarily extend in applicability even to other studies.

In short, norms for the evaluation of argument content have been missed in this area. In fact, the Bayesian framework seems particularly suited to this context, as it has been so influential in the philosophy of science where it has been used to explain the ways in which scientists construct, test, and eliminate hypotheses, design experiments, and statistically analyze data (e.g., Bovens & Hartmann, 2003; Earman, 1992; Howson & Urbach, 1993). Corner and Hahn (2009) also demonstrate the utility of Bayesian probability as a heuristic framework for psychological research in this area. Specifically, they sought to examine whether there were systematic differences in the way participants evaluated arguments with scientific content (e.g., about genetically modified foods or climate change) and arguments about mundane, everyday topics (e.g., the availability of tickets for a concert). Although these arguments differ radically in content, they can be compared to each other, because both can

be compared to Bayesian prescriptions. Are people's evaluations more normative in one of these areas, and if yes, where do the systematic deviations and discrepancies reside? Once again, probability theory provides a tool for fine-grained analysis.

Finally, there has been considerable interest in argument and evidence within the courtroom (see Spellman & Schauer, Chapter 36). This is part of extensive psychological research into jury decision making involving mock juries. This research has often focused on the role of narratives or "stories" in legal argument. A story, in this sense, is a series of interrelated episodes that involves initiating events, goals, actions, consequences, and accompanying states (typically) in the order in which they occurred (e.g., Pennington & Hastie, 1981). Experimental research with mock juries has sought support for the claim that evidence is most naturally organized within such stories, and when presented in this way, is more memorable and has greater persuasive effects (see e.g., Pennington & Hastie, 1981, 1986, 1988, 1992; Voss & van Dyke, 2001).

A narrative structure is, however, not the only way in which legal arguments are made (see e.g., Schum, 1993), and, in terms of persuasive success not necessarily always the most effective (see Spiecker & Worthington, 2003). Other factors that have been examined are, for example, the impact of the comprehensiveness of opening statements by prosecution and defense and the extent to which these statements foreshadow subsequent arguments (Pyszczynski & Wrightsman, 1981; see also Pyszczynski, Greenberg, Mack, & Wrightsman, 1981). Many have examined issues surrounding possible bias through prior beliefs (e.g., Giner-Sorolla, Chaiken, & Lutz, 2002; on biased assimilation more generally (see Lord & Taylor, 2009; also see Molden & Higgins, Chapter 20); and there has been research into how argument evaluation and overall decisions interact (Carlson & Russo, 2001; Holyoak & Simon, 1999; Simon, Pham, Le, & Holyoak, 2001). Finally, there have been many studies concerned with different aspects of testimony (see e.g., Eaton, Ball, & O'Callaghan, 2001; Ivkovic & Hans, 2003; McQuiston-Surrett & Saks, 2009; Skolnick & Shaw, 2001; Weinstock & Flaton, 2004).

Normative concerns are integral to the legal process and the study of argument evaluation within law. However, law has, historically, tended to mistrust Bayesian probability and its appropriateness for capturing uncertainty in law (see, e.g., Tillers & Green, 1988); and psychological research

evaluating testimony relative to Bayesian prescriptions has been focused on quantitative, statistical evidence (in particular, probability estimates associated with biological profile evidence such as blood typing, hair fibers, and DNA; for a review see, e.g., Kaye & Koehler, 1991). Such studies reveal difficulties for many (mock) jurors in dealing with explicit numerical information. Beyond this, the dominant experimental finding here has been that participants underweight the evidence relative to Bayes' theorem. This finding is consistent with a long line of studies within social psychology examining quantitative aspects of belief revision (e.g., Edwards, 1968; Fischhoff & Beyth-Marom, 1983; but see also Corner, Harris, & Hahn, 2010; Erev, Wallsten, & Budescu, 1994). One contributing factor to this apparent deficit could be that participants treat the expert sources providing the evidence as less reliable than the experimenters assume. Schklar and Diamond (1999) specifically examined this possibility and found that basing calculations of "normative" posteriors on participants' own assessments significantly decreased the gap between normative and descriptive, although it did not remove it entirely.

The issue of testimony, of course, extends beyond just the courtroom. It can be argued that the majority of our knowledge depends, in one form or other, on the testimony of others (e.g., Spellman & Tenney, 2010). Hence, it is fundamental to argument evaluation that not just the content of an argument but also its source be taken into account. In general, the same evidence presented by a less reliable source *should* lead to a smaller change in degree of belief; moreover, characteristics of the argument or evidence itself and of the reporting source should interact multiplicatively from a normative, Bayesian perspective (see, e.g., Schum, 1981). Initial studies involving simple day-to-day arguments find support for the position that participants have some basic sensitivity to this general relationship (Hahn, Harris, & Corner, 2009; see that paper also for discussion of social psychological research on this issue).

That the utility of the Bayesian framework extends beyond overtly statistical contexts is also illustrated by recent work on the notion of coherence, that is, the extent to which multiple testimonies "fit together." Coherence is a central notion within the story model mentioned earlier, and recent work within Bayesian epistemology by the philosophers Stephan Hartmann and Luc Bovens has sought to understand how, when, and why informational coherence impacts belief change (Bovens & Hartmann, 2003).

A recent experimental investigation found that participants' judgments (regarding witness reports to the police on the putative location of a body) corresponded closely to Bayesian predictions, and clearly went beyond a simple averaging strategy (Harris & Hahn, 2009).

Finally, as was argued in the context of research on science education and communication earlier, the Bayesian framework can provide an invaluable methodological tool. Many of the questions that have been asked about testimony, such as whether it is more or less convincing than physical evidence (e.g., Skolnick & Shaw, 2001), or whether expert witnesses are more convincing when they provide qualitative or quantitative evidence (e.g., McQuiston-Surrett & Saks, 2009; for research on qualitative versus quantitative arguments more generally see also the reviews of Hornikx, 2005, 2007, and the studies of Hoeken & Hustinx, 2009) can only really be addressed if the specific *content* of the evidence is controlled for. It is in the nature of these particular research questions that it is typically not possible to exactly equate the content, and vary only the dimension of interest, thus leaving results inherently confounded. However, the Bayesian framework can contribute to such research because it allows such content-specific variation to be factored out (Corner & Hahn, 2009). Priors, posteriors, and likelihoods provide a common currency within which different types of arguments can be contrasted in search of presentation or domain-specific systematic differences.

Conclusions and Future Directions

Rather trivially, reviews of research literatures often end with calls for more research. However, in the case of argumentation, empirical research has, in many ways, genuinely only just commenced. The range of material discussed in this chapter has, to our knowledge, not even previously been brought together, and there are undoubtedly aspects where this synthesis remains incomplete. Procedural and epistemic norms for argument evaluation can now be brought together in order to develop a unified comprehensive treatment that was not previously possible. As outlined in the Introduction, argumentation is an inherently interdisciplinary field with enormous theoretical and practical interest. Psychology has a central role to play in this. Decades of social psychological research have found that argument quality seems the most influential factor in persuasion, but persuasion research has lacked the theoretical tools to address the question

of what makes an argument “good.” This issue has been identified time and again as the most serious gap in persuasion research (see, e.g., Fishbein & Ajzen, 1981, 2009; Johnson, Maio, & Smith-McLallen, 2005; O’Keefe, 1995). As detailed in this chapter, norms for argument quality exist; it remains to be explored in detail how sensitive people are to these.

Acknowledgments

Many thanks go to Adam Corner, Adam Harris, and Nick Chater for their role in helping shape our views on argument. Many thanks also to Jos Hornikx, Hans Hoeken, Lance Rips, and Keith Holyoak for helpful comments on earlier versions of the chapter.

Notes

1. It should be noted that Toulmin’s system is not the only, or even oldest, system like this. One of the most influential systems for representing dependencies between arguments is the Wigmore chart (for an introduction to this and other systems for displaying argument structure, see, e.g., Schum, 1994).

2. It is worth noting that there have always been connections between legal argument and other types of argumentation, in particular within the rhetorical tradition, for example, in Whately (1828), but Toulmin’s work gave considerable impetus to the view that legal argument constitutes a role model for rational debate more generally.

3. It is not enough for parties in a debate to simply agree upon a procedure or criteria for evaluation in order for the debate to qualify as rational (but see van Eemeren & Grootendorst, 2004, p. 151): basing argument evaluation on the reading of entrails, position of the stars, or drawing of lots, for example, would seem incompatible with rational debate even if both parties approved of these methods.

4. In its emphasis on probabilities, the Bayesian approach to argumentation has close links to early work on attitude change involving the subjective probability model, or “probabilogical model,” of cognitive consistency (McGuire 1960a, 1960b, 1960c; Wyer, 1970; Wyer & Goldberg, 1970), which has also had some application in argumentation studies (e.g., Allen, Burrell, & Egan, 2000; Hamble, 1977). The probabilogical model draws on the law of total probability to relate experimentally induced changes in one or more propositions to attendant changes in another (typically logically) related proposition (see also, Eagly & Chaiken, 1993, Ch. 5, for an introduction).

5. Nor are any of the many nonclassical logics described in Prakken and Vreeswijk (2002) helpful here. Though often aimed specifically at dealing with uncertainty, the support and consequence relationships they specify are, like Toulmin’s system, too undifferentiated to distinguish the four cases. In addition, desirable core properties of classical logic are typically lost.

Decision Making

Robyn A. LeBoeuf *and* Eldar Shafir

Abstract

This chapter reviews selected psychological research on human decision making. The classical, rational theory of choice holds that decisions reflect consistent, stable preferences, which are unaffected by logically immaterial changes in context, presentation, or description. In contrast, empirical research has found preferences to be sensitive to logically irrelevant changes in the context of decision, in how options are described, and in how preferences are elicited. Decisions are also swayed by affect and by decisional conflict and are often driven by the reasons that are most accessible at the moment of choice, leading to preference reversals when, for example, different reasons are made accessible. More broadly, decision makers tend to adopt a “local” perspective: They accept decisions as described and focus on the most salient attributes, even when a more “global” perspective, less influenced by local context and frame, might yield decisions that are less biased by temporary and irrelevant concerns. Future directions and implications for theory and practice are discussed.

Key Words: choice, uncertainty, loss aversion, framing, preference reversals, intertemporal choice, priming

Introduction

People make countless decisions every day, ranging from ones that are barely noticed and soon forgotten (“What should I drink with lunch?” “What should I watch on TV?”), to others that are highly consequential (“How should I invest my retirement funds?” “Should I marry this person?”). In addition to having practical significance, decision making plays a central role in many academic disciplines: Virtually all of the social sciences—including psychology, sociology, economics, political science, and law—rely on models of decision-making behavior. This combination of practical and scholarly factors has motivated great interest in how decisions are and should be made. Although decisions can differ dramatically in scope and content, research has uncovered systematic regularities in how people make decisions and has led to the formulation of

general psychological principles that characterize decision-making behavior. This chapter provides a selective review of those regularities and principles. (For further reviews and edited collections, see, among others, Bazerman & Moore, 2008; Connelly, Arkes, & Hammond, 2000; Dawes & Hastie, 2001; Goldstein & Hogarth, 1997; Kahneman & Tversky, 2000; Koehler & Harvey, 2004; Lichtenstein & Slovic, 2006; and Weber & Johnson, 2009.)

The classical treatment of decision making, known as the “rational theory of choice” or the “standard economic model,” posits that people have orderly preferences that obey a few simple and intuitive axioms. When faced with a choice, people are assumed to gauge each alternative’s “subjective utility” and to choose the alternative with the highest. In the face of uncertainty about whether outcomes will obtain, people are thought to calculate an option’s subjective

expected utility, which is the sum of its subjective utilities over the possible outcomes weighted by these outcomes' estimated probabilities of occurrence. Deciding then is simply a matter of choosing the option with the greatest expected utility; choice is thus thought to *reveal* a person's subjective utility functions and, hence, her underlying preferences (e.g., Keeney & Raiffa, 1976; Savage, 1954; von Neumann & Morgenstern, 1944).

While highly compelling in principle, the standard view has met with persistent critiques addressing its inadequacy as a description of how decisions are actually made. For example, Simon (1955) suggested replacing the rational model with a framework that accounted for a variety of human resource constraints, such as bounded attention and memory capacity, as well as limited time. According to the bounded rationality view, it was unreasonable to expect decision makers to exhaustively compute options' expected utilities.

Other critiques have focused on systematic violations of even the most fundamental requirements of the rational theory of choice. According to the theory, for example, preferences should remain unaffected by logically inconsequential factors such as the specific procedure used to elicit preferences or the precise manner in which options are described (Arrow, 1951, 1988; Tversky & Kahneman, 1986). However, a series of compelling demonstrations showed that choices failed to obey simple consistency requirements (see Chater & Oaksford, Chapter 2) and were, instead, affected by nuances of the decision context that were not subsumed by the normative accounts (e.g., Lichtenstein & Slovic, 1971, 1973; Tversky & Kahneman, 1981). This research suggested that preferences are constructed, not merely revealed, in the making of decisions, leading to significant and systematic departures from normative predictions (Lichtenstein & Slovic, 2006; Payne, Bettman, & Johnson, 1992; Slovic, 1995).

The mounting evidence has forced a clear division between normative and descriptive treatments. The rational model remains the normative standard against which decisions are often judged, both by experts and by novices (cf. Stanovich, 1999). At the same time, substantial research has made considerable progress in developing models of choice that are descriptively more faithful. Descriptive accounts as elegant and comprehensive as the normative model are not yet (and may never be) available, but research has uncovered robust principles that play a central role in decision making. In what follows,

we review some of these principles, and we consider the fundamental ways in which they conflict with normative expectations.

Choice Under Uncertainty

For some decisions, the availability of options is essentially certain (as when choosing items from a menu, or cars at a dealer's lot). Other decisions are made under uncertainty. They are "risky" when the probabilities of the outcomes are known (e.g., gambling or insurance), or, as with most real-world decisions, they are "ambiguous," in that precise likelihoods are not known and must be estimated by the decision maker. When deciding under uncertainty, a person must consider both the desirability of the potential outcomes and their likelihoods; much research has addressed the manner in which these factors are estimated and combined.

Prospect Theory

When facing a choice between a risky prospect that offers a 50% chance to win \$200 (and a 50% chance to win nothing) versus an alternative of receiving \$100 for sure, most people prefer the sure gain over the gamble, although the two prospects have the same expected value. (The expected value is the sum of possible outcomes with each outcome weighted by its probability of occurrence. The expected value of the gamble above is $.50 * \$200 + .50 * 0 = \100 .) Such preference for a sure outcome over a risky prospect of equal expected value is called *risk aversion*; people tend to be risk averse when choosing between prospects with positive outcomes. The tendency toward risk aversion can be explained by the notion of diminishing sensitivity, first formalized by Daniel Bernoulli (1738/1954). Bernoulli proposed that preferences are better described by *expected utility* than by *expected value*, and he suggested that "the utility resulting from any small increase in wealth will be inversely proportionate to the quantity of goods previously possessed" (p. 25), thus effectively predicting a concave utility function. (A function is concave if a line joining two points on the curve lies below the curve.) The expected *utility* of a gamble offering a 50% chance to win \$200 (and 50% nothing) is $.50 * u(\$200)$, where u is the person's utility function ($u(0) = 0$). As illustrated in Figure 16.1, diminishing sensitivity and a concave utility function imply that the subjective value attached to a gain of \$100 is more than half of the value attached to a gain of \$200: $u(100) > .5 * u(200)$. This entails preference

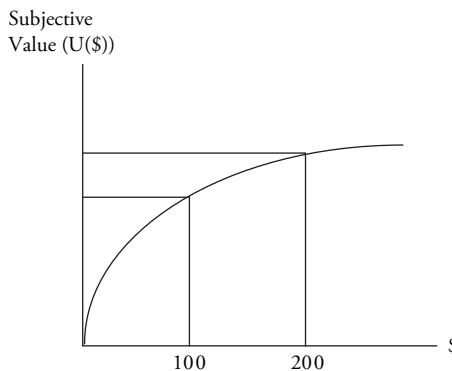

Fig. 16.1 A concave function for gains.

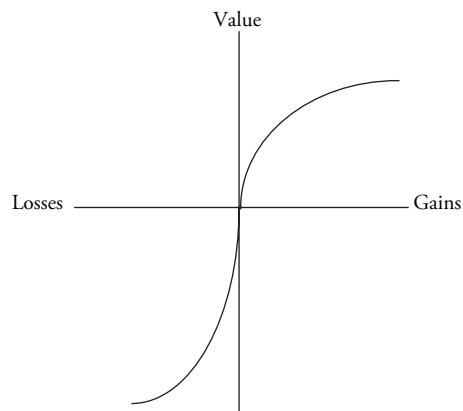

Fig. 16.2 Prospect theory's value function.

for the sure \$100 gain over the gamble and, hence, risk aversion.

However, when asked to choose between a prospect that offers a 50% chance to lose \$200 (and a 50% chance of nothing) versus losing \$100 for sure, most people prefer the risky gamble over the certain loss. This is because diminishing sensitivity applies to negative as well as to positive outcomes: The impact of an initial \$100 loss is greater than that of an additional \$100 loss, implying a convex value function for losses. A gamble offering a 50% chance to lose \$200 thus has a greater (i.e., less negative) expected subjective value than does a sure \$100 loss: $.5^*u(-\$200) > u(-\$100)$, because one does not lose twice as much utility when losing \$200 as when losing \$100. Such preference for a risky prospect over a sure outcome of equal expected value is described as *risk seeking*. With the exception of prospects that involve very small probabilities, risk aversion is generally observed in choices involving gains, whereas risk seeking tends to hold in choices involving losses.

These insights led to the S-shaped value function that forms the basis for prospect theory (Kahneman & Tversky, 1979; Tversky & Kahneman, 1992), a highly influential descriptive theory of choice. The value function of prospect theory, illustrated in Figure 16.2, has three important properties: (a) it is defined on gains and losses rather than total wealth, capturing the fact that people normally treat outcomes as departures from a current reference point (rather than in terms of final assets, as posited by the rational theory of choice); (b) it is steeper for losses than for gains—thus, a loss of \$X is more aversive than a gain of \$X is attractive, capturing the phenomenon of *loss aversion*; and (c) it is concave for gains and convex for losses, predicting, as described

earlier, risk aversion in the domain of gains and risk seeking in the domain of losses.

In addition, according to prospect theory, probabilities are not treated linearly; instead, people tend to overweight small probabilities and to underweight large ones (Gonzalez & Wu, 1999; Kahneman & Tversky, 1979; Prelec, 2000). Among other things, this nonlinearity has implications for the attractiveness of gambling and insurance (which typically involve low-probability events); and it yields substantial discontinuities at the endpoints, where the passage from impossibility to possibility and from high likelihood to certainty can have inordinate impact (Camerer, 1992; Kahneman & Tversky, 1979). The weighting of probabilities can also be influenced by factors such as the decision maker's feeling of competence in a domain (Heath & Tversky, 1991) or by whether the options involve nonmonetary instead of monetary outcomes (McGraw, Shafir, & Todorov, 2010; Rottenstreich & Hsee, 2001). Such attitudes toward value and chance lead to substantial sensitivity to contextual factors when making decisions, as discussed later in this chapter.

The Framing of Risky Decisions

The previously discussed attitudes toward risky decisions appear relatively straightforward, and yet they yield choice patterns that conflict with normative standards. Perhaps the most fundamental of these patterns is the “framing effect” (Tversky & Kahneman, 1981, 1986). Because risk attitudes differ when outcomes involve gains as opposed to losses, the same decision can elicit conflicting risk attitudes depending on whether it is framed as involving gains or losses. In one example, financial services professionals considered advising a client who had \$6,000

invested in the stock market during a market downturn. Some respondents chose between a strategy that would save \$2,000 of the money with certainty and another strategy that offered a 1/3 chance that all \$6,000 would be saved (but a 2/3 chance that nothing would be saved). Others chose between a strategy in which \$4,000 would be lost with certainty and another that offered a 1/3 chance that no money would be lost (and a 2/3 chance that all \$6,000 would be lost). All respondents thus faced the same choice: Both groups chose between saving \$2,000 (and losing \$4,000) with certainty versus risking all of the money (at 2/3 chance) for a 1/3 chance that nothing will be lost (Roszkowski & Snelbaker, 1990; see Tversky & Kahneman, 1981). People, however, tend to “accept” the provided frame and to consider problems as presented, failing to reframe them from alternate perspectives. As a result, most people considering the problem in terms of money saved (i.e., a choice between “gains”) showed a risk-averse preference for the certain outcome, whereas most of those considering the problem in terms of money lost (i.e., a choice between “losses”) showed a risk-seeking preference for the probabilistic strategy. This pattern violates the normative requirement of “description invariance,” according to which logically equivalent descriptions of a decision should yield the same preference (see Keren, 2011; Kühberger, 1995; Levin, Schneider, & Gaeth, 1998 for reviews).

The acceptance of problem frame, combined with the nonlinear weighting of probabilities and, in particular, with the elevated impact of perceived “certainty,” has a variety of normatively troubling consequences. Consider, for example, the following choice between gambles (Tversky & Kahneman, 1981, p. 455):

- A. A 25% chance to win \$30
- B. A 20% chance to win \$45

Faced with this choice, the majority (58%) of participants preferred option B. Now, consider the following extensionally equivalent problem:

In the first stage of this game, there is a 75% chance to end the game without winning anything, and a 25% chance to move into the second stage. If you reach the second stage, you have a choice between:

- C. A sure win of \$30
- D. An 80% chance to win \$45

The majority (78%) of participants now preferred option C over option D, even though, when

combined with the first stage of the problem, options C and D are equivalent to A and B, respectively. Majority preference thus reverses as a function of a logically irrelevant contextual variation. In this case, the reversal is due to the impact of apparent certainty (which renders option C more attractive than option A) and to people’s tendency to contemplate decisions from a “local” rather than a “global” perspective. As noted, a combination of the two stages in the last problem would have easily yielded the same representation as that of the first problem. But rather than amalgamating across events and decisions, as is often assumed in normative analyses, people tend to contemplate each decision separately, which can yield conflicting attitudes across choices. We return to the issue of local versus global perspectives in a later section.

As a further example of framing, risk attitudes can reverse even within the domain of losses, depending on the context of decision. Thus, people tend to prefer a sure loss to a risky prospect when the sure loss is described as “insurance” against a low-probability, high-stakes loss (Hershey & Schoemaker, 1980). The insurance context brings to mind a social norm, making the insurance premium appear more like an investment than a loss, with the low-probability, high-stakes loss acquiring the character of a neglected responsibility rather than a considered risk (e.g., Hershey & Schoemaker, 1980; Kahneman & Tversky, 1979; Kunreuther & Pauly, 2005; Slovic, Fischhoff, & Lichtenstein, 1988).

The framing of certainty and risk also affects people’s thinking about financial transactions through inflationary times, as illustrated by the following example. Participants were asked to imagine that they were in charge of buying computers (currently priced at \$1,000) that would be delivered and paid for 1 year later, by which time, due to inflation, prices were expected to be approximately 20% higher (and equally likely to be above or below the projected 20%). All participants essentially faced the same choice: They could agree to pay either \$1,200 (20% more than the current price) upon delivery next year, or they could agree to pay the going market price in 1 year, which would depend on inflation. Reference points were manipulated to make one option appear certain while the other appeared risky: Half the participants saw the contracts framed in nominal terms, so that the \$1,200 price appeared certain, whereas the future nominal market price (which could be more or less than \$1,200) appeared risky. Other participants saw the contracts framed in

real terms, so that the future market price appeared appropriately indexed, whereas precommitting to a \$1,200 price, which could be lower or higher than the actual future market price, seemed risky. In both conditions, respondents preferred the contract that appeared certain, preferring the fixed price in the nominal frame, and the indexed price in the “real” frame (Shafir, Diamond, & Tversky, 1997). As with many psychological tendencies, the preference for certainty can mislead in some circumstances, but it may also be exploited for beneficial ends, such as when the certainty associated with a particular settlement is highlighted to boost the chance for conflict resolution (Kahneman & Tversky, 1995).

Riskless Choice

Not all decisions involve risk or uncertainty. For example, when choosing items in a store, we can be fairly confident that the displayed items are available. (Naturally, there could be uncertainty about one’s eventual satisfaction with an item, but we leave those considerations aside for the moment.) The absence of uncertainty, however, does not eliminate preference malleability, and many of the principles discussed earlier affect even riskless decisions. Recall that outcomes can be framed as gains or losses relative to a reference point, that losses typically “loom larger” than comparable gains, and that people tend to accept the presented frame. These factors, even in the absence of risk, can yield problematic decision patterns.

Loss Aversion and the Status Quo

A fundamental fact about the making of decisions is loss aversion: According to loss aversion, the pain associated with giving up a good is greater than the pleasure associated with obtaining it (Tversky & Kahneman, 1991). This yields “endowment effects,” wherein merely possessing a good (such that parting with it is rendered a loss) can lead to higher valuation of the good than if it were not in one’s possession. A classic experiment illustrates this point (Kahneman, Knetsch, & Thaler, 1990). Participants were arbitrarily assigned to be *sellers* or *choosers*. The sellers were each given an attractive mug, which they could keep, and were asked to indicate the lowest amount for which they would sell the mug. The *choosers* were not given a mug but were instead asked to indicate the amount of money that the mug was worth to them. An official market price, \$X, was to be revealed; all those who valued the mug at more than \$X received a mug, whereas

those who valued the mug below \$X received \$X. All participants, whether sellers or choosers, essentially faced the same task of determining a price at which they would prefer money over the mug. Since participants were randomly assigned to be sellers or choosers, standard expectations are that the two groups would value the mugs similarly. Loss aversion, however, suggests that the sellers would set a higher price (for what they were about to “lose”) than the choosers. Indeed, sellers’ median asking price was twice that of choosers.

Another manifestation of loss aversion is a general reluctance to trade, illustrated in a study in which half of the participants were given a decorated mug while the others were given a bar of Swiss chocolate (Knetsch, 1989). Later, each subject was shown the alternative gift and offered the opportunity to trade his or her gift for the other. Because the initial allocation of gifts was arbitrary and transaction costs minimal, economic theory (specifically, the Coase theorem) predicts that about half the participants would exchange their gifts. Loss aversion, on the other hand, predicts that most participants would be reluctant to give up a gift in their possession (a loss) to obtain the other (a gain). Indeed, only 10% of the participants chose to trade (see also Kahneman, Knetsch, & Thaler, 1990). This outcome contrasts sharply with the standard analysis, in which the value of a good does not change when it becomes part of one’s endowment.

Loss aversion thus promotes stability rather than change. In particular, it predicts a strong tendency to maintain the status quo, because the disadvantages of departing from it loom larger than the advantages of its alternative (Samuelson & Zeckhauser, 1988). Consider, for example, two candidates, Frank and Carl, who are running for election during difficult times and have announced target inflation and unemployment figures. Frank proposes a 42% yearly inflation rate and 15% unemployment, whereas Carl envisions 23% inflation and 22% unemployment. When Carl’s figures represent the status quo, Frank’s plans entail greater inflation and diminished unemployment, whereas when Frank’s figures are the status quo, Carl’s plan entails lower inflation and greater unemployment. As predicted, neither departure from the “current” state was endorsed by the majority of respondents, who preferred whichever candidate was said to represent the status quo (Quattrone & Tversky, 1988).

A striking tendency to maintain the status quo was observed in the context of retirement-savings

decisions made by employees at a Fortune 500 company. Employee enrollment in a 401(k) savings plan was compared under two conditions: when employees had to actively take steps to enroll (and thus, nonparticipation was the default) versus when employees were automatically enrolled upon hiring but could take steps to unenroll (and thus participation was the default). In both cases, the transaction costs of switching away from the default were minimal, but the effect of changing the default was substantial: When nonparticipation was the default, only 37% of those who had been employed for between 3 and 15 months had enrolled, but when participation was the default, 86% of those employed for an identical length of time remained enrolled (Madrian & Shea, 2001; see Johnson, Hershey, Meszaros, & Kunreuther, 1993 for a similar example involving automobile insurance). Another naturally occurring experiment was observed in decisions regarding organ donation (Johnson & Goldstein, 2003). In some European nations, people are by default organ donors unless they elect not to be, whereas in other European nations they are, by default, not donors unless they choose to be. Observed rates of organ donors are almost 98% in the former nations and about 15% in the latter, a remarkable difference given the low transaction costs and the significance of the decision.

The status quo bias can affect decisions in many domains (see also Tversky & Kahneman, 1991) and can also hinder the negotiated resolution of disputes. If each disputant sees the opponent's concessions as gains but its own concessions as losses, agreement will be hard to reach because each will perceive itself as relinquishing more than it stands to gain. Because loss aversion renders forgone gains more palatable than comparable losses (cf. Kahneman, 1992), an insightful mediator may do best to set all sides' reference points low, thus requiring compromises over outcomes that are mostly perceived as gains.

Loss aversion continues to inspire research, with recent work identifying potential moderators and boundary conditions. For example, research suggests that loss aversion may not emerge for amounts of money that are small (Harinck, Van Dijk, Van Beest, & Mersmann, 2007) or for goods that are inherently intended to be exchanged, such as money that one intends to spend or products that one intends to sell (Novemsky & Kahneman, 2005). Furthermore, the endowment effect may reverse for alternatives that primarily differ on *negative* dimensions (e.g., two jobs that each have a negative feature). Instead

of being reluctant to trade such items, people seem to be especially likely to trade them, in part because "losing" a negative feature (e.g., giving up working on weekends) looms larger than "gaining" a negative feature (e.g., taking on a longer commute; Brenner, Rottenstreich, Sood, & Bilgin, 2007).

Semantic Framing

The tendency to adopt the provided frame can affect riskless choice via "attribute-framing" effects, which alter the perceived quality of items by changing their descriptions (Levin et al., 1998). A package of ground beef, for example, can be described as 75% lean or as 25% fat. Not surprisingly, it tends to be evaluated more favorably under the former description than the latter (Levin, 1987; see also Levin, Schnittjer, & Thee, 1988). Similarly, a community with a 3.7% crime rate tends to be allocated greater police resources than one described as 96.3% "crime free" (Quattrone & Tversky, 1988). Attribute-framing effects are not limited to riskless choice; for example, people are more favorably inclined toward a medical procedure when its chance of success, rather than failure, is highlighted (Levin et al., 1988).

Part of the impact of such semantic factors may be due to spreading activation (Collins & Loftus, 1975) wherein positive words (e.g., "crime free") activate associated positive concepts, and negative words activate negative concepts. The psychophysical properties of numbers also contribute to these effects. A 96.3% "crime free" rate, for example, appears insubstantially different from 100% and suggests that "virtually all" are law abiding. The difference between 0% and 3.7%, in contrast, appears more substantial and suggests the need for intervention (Quattrone & Tversky, 1988; see Keren, 2011, for more on the mechanisms that contribute to framing effects). Like the risk attitudes described earlier, such perceptual effects often seem natural and harmless in their own right, but they can generate preference inconsistencies that appear perplexing, especially given the rather mild and often unavoidable manipulations (after all, things need to be described one way or another) and the trivial computations required to translate from one frame to another.

Conflict and Reasons

Choices can be hard to make. People often approach difficult decisions by looking for a compelling rationale to choose one option over another.

At times, compelling rationales are easy to come by and to articulate, whereas other times no compelling rationale presents itself, rendering the conflict between options hard to resolve. Such conflict can be aversive and can lead people to postpone the decision or to select a “default” alternative. The tendency to rely on compelling rationales that minimize conflict appears benign; nonetheless, it can generate preference patterns that are fundamentally different from those predicted by normative accounts based on value maximization.

Decisional Conflict

One way to avoid conflict in choice is to opt for what appears like no choice at all, namely, the status quo. In one example (Tversky & Shafir, 1992a), participants who were purportedly looking to buy a CD player were presented with a Sony player that was on a 1-day sale for \$99, well below the list price. Two-thirds of the participants said they would buy such a CD player. Another group was presented with the same Sony player but also with a top-of-the-line Aiwa player selling for \$159. In this group, only 54% expressed interest in buying either option, and a full 46% preferred to wait until they learned more about the various models. The addition of an attractive option increased conflict and diminished the number who ended up with either player, despite the fact that most participants preferred the initial alternative to the status quo. This violates what is known in the normative approach as the regularity condition, according to which the “market share” of an existing option—here, the status quo—cannot be increased by enlarging the offered set (see also Tversky & Simonson, 1993).

A related pattern was observed in a grocery store, where shoppers were offered the chance to taste any of 6 jams in one condition, or any of 24 jams in the other (Iyengar & Lepper, 2000). In the 6-jams condition, 40% of shoppers stopped to have a taste and, of those, 30% proceeded to purchase a jam. In the 24-jam condition, a full 60% stopped to taste, but only 3% purchased. Presumably, the conflict between so many attractive options proved hard to resolve. Further studies found that those choosing goods from a larger set later reported lower satisfaction with their chosen option than those choosing from a smaller set. Conflict among options thus appears to make people less happy about choosing, as well as less happy with their eventual choice.

Decisional conflict tends to favor default alternatives, much as it advantages the status quo. In one

study, students agreed to fill out a questionnaire in return for \$1.50. Following the questionnaire, half of the respondents were offered the opportunity to exchange the \$1.50 (the default) for a choice between two prizes: a metal *Zebra* pen or a pair of plastic *Pilot* pens. The remaining participants were only offered the opportunity to exchange the \$1.50 for the *Zebra*. The pens were shown to participants, who were informed that each prize regularly costs just over \$2.00. Only 25% opted for the payment over the *Zebra* when *Zebra* was the only alternative, but a reliably greater 53% retained the payment when both pen types were offered (Tversky & Shafir, 1992a). Whereas the majority of participants took advantage of the opportunity to obtain a valuable alternative (the *Zebra*) when there was only one such alternative, the availability of competing valuable alternatives increased the tendency to retain the default option.

Related effects have been documented in decisions made by expert physicians and legislators (Redelmeier & Shafir, 1995). In one scenario, neurologists and neurosurgeons were asked to decide which of several patients awaiting surgery ought to be operated on first. Half of the respondents were presented with two patients, a woman in her early fifties and a man in his seventies. Others saw the same two patients along with a third, a woman in her early fifties highly comparable to the first, so that it was difficult to find a rationale for choosing one woman over the other. As predicted, more physicians chose to operate on the older man when the presence of two highly comparable women introduced decisional conflict than when the choice was between only one younger woman and the man (58% versus 38%, respectively).

Thus, the addition of some options can generate conflict and reduce the tendency to choose. Other options, on the other hand, can lower conflict and increase the likelihood of making a choice. *Asymmetric dominance* (or the *attraction effect*) refers to the fact that in a choice between options A and B, a third option, A', can be added that is clearly inferior to A (but not to B), thereby increasing the choice likelihood of A (Huber, Payne, & Puto, 1982). For example, a choice between \$6 and an elegant pen presents some conflict for participants. But when a less attractive pen is added to the choice set, the superior pen clearly dominates the inferior pen. This dominance provides a rationale for choosing the elegant pen and leads to an increase in the percentage of those choosing that pen over the cash. Along related lines, the *compromise effect*

occurs when the addition of a third, extreme option makes a previously available option appear as a reasonable compromise, thus increasing its popularity (Simonson, 1989; Simonson & Tversky, 1992).

Standard normative accounts do not deny conflict, nor, however, do they assume any direct influence of conflict on choice. (For people who maximize utility, there does not appear to be much room for conflict: Either the utility difference is large and the decision is easy, or it is small and the decision is of little import.) In actuality, however, people are concerned with making the “right” choice. This concern can render decisional conflict influential beyond mere considerations of value. Conflict is an integral aspect of decision making, and the phenomenology of conflict, which can be manipulated via the addition or removal of alternatives, yields predictable and systematic violations of standard normative predictions.

Reason-Based Choice

The desire to make the “right” choice often leads people to look for good reasons when making decisions, and considering this reliance on reasons helps make sense of phenomena that appear puzzling from the perspective of value maximization (Shafir, Simonson, & Tversky, 1993). Relying on good reasons seems like sound practice; after all, the converse, making a choice without good reason, seems unwise. At the same time, abiding by this practice can be problematic because the reasons that come to mind often are fleeting, are limited to what is introspectively accessible, and are not necessarily those that guide, or ought to guide, the decision. For example, participants who were asked to analyze *why* they felt the way that they did about a set of jams showed less agreement with “expert” ratings of the jams than did those who did not analyze their preferences (Wilson & Schooler, 1991). Similarly, among participants who chose a poster to take home, those who analyzed their reasons for liking the poster were less satisfied with their choice weeks later, compared to those who did not analyze their reasons (Wilson et al., 1993). A search for reasons can alter preference in line with reasons that come readily to mind, but those reasons may be heavily influenced by the momentary context. A heavy focus on a biased set of temporarily available reasons can cause one to lose sight of one’s (perhaps more valid) initial feelings (Wilson, Dunn, Kraft, & Lisle, 1989).

Furthermore, a wealth of evidence suggests that people are not always aware of their reasons for

acting and deciding (Nisbett & Wilson, 1977). In one example, participants, presented with four identical pairs of stockings and asked to select one, showed a marked preference for the option on the right. However, despite the evidence that choice was governed by position, no participant mentioned position as the reason for the choice. Respondents easily generated “reasons” (in which they cited attributes such as stocking texture), but the reasons they provided bore little resemblance to those that actually guided choice (Nisbett & Wilson, 1977).

Finally, and perhaps most normatively troubling, a reliance on reasons can induce preference inconsistencies because contextual nuances can render certain reasons more or less apparent. In one study (Tversky & Shafir, 1992b), college students were asked to imagine that they had just passed a difficult exam and now had a choice for the Christmas holidays: They could buy an attractive vacation package at a low price, they could forgo the vacation package, or they could pay a \$5 fee to defer the decision by a day. The majority elected to buy the vacation package, and less than a third elected to delay the decision. A second group was asked to imagine that they had failed the exam and would need to retake it after the holidays. They were then presented with the same choice and, as before, the majority elected to buy the vacation package, and less than a third preferred to defer. However, when a third group of participants was asked to imagine that they did not know whether they had passed or failed the exam, the majority preferred to pay to defer the decision until the next day, when the exam result would be known. Only a minority was willing to commit to the trip without knowing. Apparently, participants were comfortable booking the trip when they had clear reasons for the decision—celebrating when they passed the exam or recuperating when they had failed—but were reluctant to commit when their reasons for the trip were uncertain. This pattern, which violates the Sure Thing Principle (Savage, 1954), has been documented in a variety of contexts, including gambling and strategic interactions (e.g., Prisoner’s Dilemmas; see also Shafir, 1994; Shafir & Tversky, 1992).

The tendency to delay decision for the sake of further information can have a significant impact on the ensuing choice. Consider the following scenario (Bastardi & Shafir, 1998):

You are considering registering for a course in your major that has very interesting subject

matter and will not be offered again before you graduate. While the course is reputed to be taught by an excellent professor, you have just discovered that he will be on leave, and that a less popular professor will be teaching the course.

One group was asked whether they would register for the course, and a majority (82%) said they would. Another group was presented with the same scenario but told that they would not know until the next day whether the regular or the less popular professor would be teaching the course. They could wait until the following day (when they would know who will be teaching) to decide whether to take the course; 56% elected to wait. Those who chose to wait then learned that the less popular professor would be teaching the course; upon receiving the news, nearly half of this group decided not to take the course. Overall, a total of 29% chose not to register for the course in the uncertain version (where they pursued the information) as compared to only 18% in the simple version (when the information was known from the start), a significant 60% increase in turning down the course. The decision to pursue information apparently focuses attention on the information obtained and brings forth particular decision rationales, ultimately distorting preference (Bastardi & Shafir, 1998). Similar patterns have been replicated in a variety of contexts, including one involving nurses in a renal-failure ward, more of whom expressed willingness to donate a kidney (to a hypothetical relative) when they had purportedly elected to be tested and then learned that they were eligible donors than when they had known they were eligible from the start (Redelmeier, Shafir, & Aujla, 2001). A reliance on reasons in choice leaves decision makers susceptible to a variety of contextual and procedural nuances that render salient alternative potential reasons, and thus may lead to inconsistent choices.

Processing of Attribute Weights

Choices can be complex, requiring the evaluation of multiattribute options. Consider, for example, a choice between two job candidates: One did well in school but has relatively unimpressive work experience and moderate letters of recommendation, whereas the other has a poor scholastic record but better experience and stronger letters. To make this choice, the decision maker must somehow combine the attribute information, which requires determining not only the quality or value of each attribute but

also the extent to which a shortcoming on one attribute can be compensated for by strength on another.

Attribute evaluation may be biased by a host of factors known to hold sway over human judgment (for a review, see Griffin, Chapter 17). Moreover, researchers have long known that people have limited capacity for combining information across attributes; because of unreliable attribute weights in human judges, simple linear models tend to yield normatively better predictions than the very judges on whom the models are based (Dawes, 1979; Dawes, Faust, & Meehl, 1989). In fact, people's unreliable weighting of attributes makes them susceptible to a host of manipulations that alter attribute weights and yield conflicting preferences (see Shafir & LeBoeuf, 2004, for a further discussion of multiattribute choice).

Compatibility

One way in which attribute weighting can be manipulated is by changing how a preference is elicited. Imagine a person deciding among simple monetary gambles, which differ on payoffs and the chance to win. That person's preferences can be assessed in different, but logically equivalent, ways (see Schkade & Johnson, 1989, for a review). For example, participants may be asked to choose among the gambles or, alternatively, they may estimate their maximum willingness to pay for each gamble. Notably, these logically equivalent preference elicitation procedures often result in differential weightings of attributes and, consequently, in inconsistent preferences.

Consider two gambles: One offers an 8/9 chance to win \$4 and the other a 1/9 chance to win \$40. People typically *choose* the high-probability, low-payoff gamble but assign a higher *price* to the high-payoff, low-probability gamble, thus expressing conflicting preferences (Grether & Plott, 1979; Lichtenstein & Slovic, 1971, 1973; Tversky, Slovic, & Kahneman, 1990). This pattern illustrates the principle of *compatibility*, according to which an attribute's weight is enhanced by its compatibility with the response mode (Slovic, Griffin, & Tversky, 1990; Tversky, Sattath, & Slovic, 1988): A gamble's potential payoff is weighted more heavily in pricing, where the price and the payoff are in the same monetary units, than in choice, where neither attribute maps onto the response scale (Schkade & Johnson, 1989). As a consequence, the high-payoff gamble is valued more in pricing relative to choice.

For another type of response compatibility, imagine having to choose, versus having to reject, one of

two options. Logically speaking, the two tasks are interchangeable: If people prefer one option, they will reject the second, and vice versa. However, people tend to focus on the relative strengths of options (compatible with choosing) when they choose and on weaknesses (compatible with rejecting) when they reject. As a result, options' positive features loom larger in choice, whereas their negative features are weighted relatively more during rejection. In one study, respondents were presented with pairs of options, such as vacation destinations, that included an enriched option, with various positive and negative features (e.g., gorgeous beaches and great sunshine, but cold water and strong winds), and an impoverished option, with no real positive or negative features, hence neutral in all respects (Shafir, 1993). Some respondents were asked which destination they preferred; others decided which to forgo. Because positive features are weighed more heavily in choice and negative features matter relatively more during rejection, the enriched destination was most frequently chosen *and* rejected. Overall, its choice and rejection rates summed to 115%, significantly more than the impoverished destination's 85%, and more than the 100% expected if choice and rejection were complementary (see also Downs & Shafir, 1999; Wedell, 1997), consistent with the notion that attributes are weighted more heavily when compatible with the response mode.

Separate Versus Comparative Evaluation

Decision contexts can also facilitate or hamper attribute evaluation, and this can alter attribute weights. Not surprisingly, an attribute whose value is clear can have greater impact than an attribute whose value is vague. Similarly, attributes may prove difficult to gauge in isolation but easier to evaluate in comparative settings, leading to what are known as *evaluability* effects. In one study, participants considered two second-hand music dictionaries: one with 20,000 entries but a slightly torn cover and another with 10,000 entries and an unblemished cover. Because people have only a vague notion of how many entries to expect in a music dictionary, when participants saw these one at a time, they were willing to pay more for the dictionary with the new cover than for the one with a cover that was slightly torn. When the dictionaries were evaluated concurrently, however, the number-of-entries attribute became easier to evaluate and was weighted more heavily: Most participants preferred the dictionary with more

entries, despite the inferior cover (Hsee, 1996; Hsee, Loewenstein, Blount, & Bazerman, 1999).

As another example, consider a job that pays \$80,000 a year at a firm where one's peers receive \$100,000, compared to a job that pays \$70,000 while coworkers are paid \$50,000. Consistent with the fact that most people prefer higher incomes, a majority of second-year MBA students who compared the two options preferred the job with the higher absolute—despite the lower relative—income. When the jobs are contemplated separately, however, the precise merits of one's own salary are hard to gauge, but earning less than comparable others renders the former job relatively less attractive than the latter, where one's salary exceeds that of one's peers. Indeed, the majority of MBA students who evaluated the two jobs separately anticipated higher satisfaction in the job with the lower salary but the higher relative position, obviously putting more weight on relative pay in the context of separate evaluation (Bazerman, Schroth, Shah, Diekmann, & Tenbrunsel, 1994).

In the same vein, decision principles that are hard to apply in isolated evaluation may prove decisive in comparative settings, producing systematic fluctuations in attribute weights. Kahneman and Ritov (1994), for example, asked participants about their willingness to contribute to several environmental programs. One program was geared toward saving dolphins in the Mediterranean Sea; another funded free medical checkups for farm workers at risk for skin cancer. When asked which program they would rather support, the vast majority chose the medical checkups for farm workers, presumably following the principle that human lives come before those of animals. However, when asked separately for the largest amount they would be willing to pay for each intervention, respondents, moved by the animals' vivid plight, were willing to pay more for the dolphins than for workers' checkups. In a similar application, potential jurors awarded comparable dollar amounts to plaintiffs who had suffered either physical or financial harm, as long as the cases were evaluated separately. However, in concurrent evaluation, award amounts increased dramatically when the harm was physical as opposed to financial, affirming the notion that physical harm is the graver offense (Sunstein, Kahneman, Schkade, & Ritov, 2002).

Attribute weights, which are normatively assumed to remain stable, systematically shift and give rise to patterns of inconsistent preferences. Notably, discrepancies between separate versus concurrent

evaluation have profound implications for intuition and for policy. Outcomes in life are typically experienced one at a time: A person lives through one scenario or another. Normative intuitions, on the other hand, typically arise from concurrent introspection: We entertain a scenario along with its alternatives. When an event triggers reactions that stem from its being experienced in isolation, important aspects of the experience will be misconstrued by intuitions that arise from concurrent evaluation (Shafir, 2002; see also Hsee & Zhang, 2004).

Local Versus Global Perspectives

Many of the inconsistencies described earlier would not have arisen were decisions considered from a more global perspective. The framing of decisions, for instance, would be of little consequence were people to go beyond the provided frame to represent the decision outcomes in a description-independent, canonical manner. Instead, people tend to accept the decision problem as it is presented, largely because they may not have thought of other ways to look at the decision and also because they may not expect their preferences to be susceptible to presumably incidental alterations. (Note, incidentally, that even if they were to recognize the existence of multiple perspectives, people may still not know how to arrive at a preference independent of a specific formulation; cf. Kahneman, 2003.) In this section, we review several additional decision contexts where a limited or myopic approach guides decision making, and where inconsistent preferences arise as a result of a failure to adopt a more “global” perspective. Such a perspective requires one to ignore momentarily salient features of the decision in favor of other, often less salient, considerations that have long-run consequences.

Repeated Decisions

Decisions that occur on a regular basis are often more meaningful when evaluated “in the long run.” For example, the choice to diet or to exercise makes little difference on any one day and can only be carried out under a long-term perspective that trumps the person’s short-term preferences for cake over vegetables, or for sleeping late rather than going to the gym early. People, however, often do not take this long-term perspective when evaluating instances of a recurring choice; instead, they tend to treat each choice as an isolated event.

In one study, participants were offered a 50% chance to win \$2,000 and a 50% chance to lose

\$500. Although most participants refused to play this gamble once, the majority were eager to play the gamble five times, and, when given the choice, preferred to play the gamble six times rather than five. Apparently, fear of possibly losing the single gamble is compensated for by the high likelihood of ending up ahead in the repeated version. Of note, other participants were asked to imagine that they had already played the gamble five times (outcome as yet unknown) and were given the option to play once more. In this formulation, a majority of participants rejected the additional play. Although participants preferred to play the gamble six times rather than five, once they had finished playing five, the additional opportunity was immediately “segregated” and treated as a single instance, which participants preferred to avoid (Redelmeier & Tversky, 1992). The tendency to frame gambles “narrowly” (i.e., isolated from other risks) may help to explain people’s reluctance to invest in the stock market, despite historically high mean returns (Barberis, Huang, & Thaler, 2006). Indeed, the attractiveness of stocks increases when people consider long-term (instead of short-term) return distributions, suggesting they do not (or cannot) spontaneously convert information about isolated outcomes into an aggregate representation (Benartzi & Thaler, 1999).

In a related vein, physicians can think of their patients “individually” (i.e., patient by patient) or “globally” (e.g., as groups of patients with similar problems). Physicians are more likely to take extra measures, such as ordering expensive tests or recommending an in-person consultation, when they consider the treatment of an individual than when they consider a larger group of similarly afflicted patients (Redelmeier & Tversky, 1990). Personal concerns loom larger when patients are considered individually than when “patients in general” are considered, with the latter group more likely to highlight efficiency concerns. Because physicians tend to see patients one at a time, this predicts a pattern of individual decisions that is inconsistent with what these physicians would endorse from a more global perspective. For a more mundane example, people report greater willingness to wear a seatbelt—and to support pro-seatbelt legislation—when they are shown statistics concerning the lifetime risk of being in a fatal accident, instead of the dramatically lower risk associated with any single auto trip (Slovic et al., 1988; see Kahneman, 2003 for a discussion of the tendency to adopt “narrow” framings).

Similar patterns prompted Kahneman and Lovallo (1993) to argue that decision makers often err by treating each decision as unique, rather than categorizing it as one in a series of similar decisions made over a lifetime (or, in the case of corporations, made by many workers). They distinguish an “inside view” of situations and plans, characterized by a focus on the peculiarities of the case at hand, from an “outside view,” guided by an analysis of a large number of similar cases. Whereas an outside view based, for example, on base rates, typically leads to a more accurate evaluation of the current case, people routinely adopt an inside view, which typically overweights the particulars of the given case at the expense of base-rate considerations. Managers, for example, despite knowing that past product launches have routinely run over budget and behind schedule, may convince themselves that this time will be different because the team is excellent or the product exceptional. The inside view can generate overconfidence (Kahneman & Lovallo, 1993), as well as undue optimism regarding the chances of completing projects on time (e.g., the planning fallacy, Buehler, Griffin, & Ross, 1994) or under budget (Peetz & Buehler, 2009). The myopia that emerges from treating repeated decisions as unique leads to overly bold predictions and to the neglect of considerations that ought to matter in the long run.

Mental Accounting

Specific forms of myopia arise in the context of “mental accounting,” the behavioral equivalent of accounting done by firms, wherein people reason about and make decisions concerning matters such as income, spending, and savings. Contrary to the assumption of “fungibility,” according to which money in one account, or from one source, is a perfect substitute for money in another, the labeling of accounts and the nature of transactions have a significant impact on people’s decisions (Thaler, 1999). For example, people’s reported willingness to spend \$25 on a theater ticket is unaffected by having incurred a \$50 parking ticket, but it is significantly lowered when \$50 is spent on a ticket to a sporting event (Heath & Soll, 1996). Respondents apparently bracket expenses into separate accounts, so that spending on entertainment is affected by a previous entertainment expense in a way that it is not if that same expense is “allocated” to, say, travel. Along similar lines, people who had just lost a \$10 bill were happy to buy a \$10 ticket for a play, but were less willing to buy the ticket if, instead of the money, they had just lost a similar \$10 ticket

(Tversky & Kahneman, 1981). Apparently, participants were willing to spend \$10 on a play even after losing \$10 cash, but they found it aversive to spend what was coded as \$20 on a ticket.

Finally, consider the following scenario, which respondents saw in one of two versions:

Imagine that you are about to purchase a jacket for \$125 [\$15] and a calculator for \$15 [\$125]. The calculator salesman informs you that the calculator you want to buy is on sale for \$10 [\$120] at the other branch of the store, located 20 minutes drive away. Would you make the trip to the other store? (Tversky & Kahneman, 1981, p. 457)

Faced with the opportunity to save \$5 on a \$15 calculator, a majority of respondents agreed to make the trip. However, when the calculator sold for \$125, only a minority was willing to make the trip for the same \$5 savings. A global evaluation of either version yields a 20-minute voyage for \$5 savings; people, however, seem to make decisions based on “topical” accounting (Kahneman & Tversky, 1984), wherein the same \$5 saving is coded as a substantial ratio in one case, and as quite negligible in the other.

Specific formulations and contextual details are neither spontaneously reformulated nor translated into more comprehensive or canonical representations. As a consequence, preferences prove highly labile and dependent on what are often theoretically, as well as practically, unimportant and accidental details. An extensive literature on mental accounting, as well as behavioral finance, forms part of the growing field of behavioral economics (see, e.g., Camerer, Loewenstein, & Rabin, 2004; Thaler 1993, 1999).

Decisions Regarding the Future

TEMPORAL DISCOUNTING

A nontrivial task is to decide how much weight to give to outcomes extended into the future. Various forms of uncertainty (regarding nature, one’s own tastes, and so on) justify some degree of discounting in calculating the present value of future goods. Thus, \$1,000 received next year is typically worth less than \$1,000 received today. As it turns out, observed discount rates tend to be unstable and are often influenced by factors, such as the size of the good and its temporal distance, that are not subsumed under standard normative analyses (see Ainslie, 2001; Berns, Laibson, & Loewenstein, 2007; Frederick, Loewenstein, & Donoghue, 2002; Loewenstein & Thaler, 1989, for review). For example, although

some people prefer an apple today over two apples tomorrow, virtually nobody prefers one apple in 30 days over two apples in 31 days (Thaler, 1981). Because discount functions are nonexponential (see also Loewenstein & Prelec, 1992), a 1-day delay has greater impact when that day is near than when it is far. Similarly, when asked what amount of money in the future would be comparable to receiving a specified amount today, people require about \$60 in 1 year to match \$15 now, but they are satisfied with \$4,000 in a year instead of \$3,000 today. This implies discount rates of 300% in the first case and 33% in the second. To the extent that one engages in a variety of transactions throughout time, imposing wildly disparate discount rates on smaller versus larger amounts ignores the fact that numerous small amounts will eventually add up to be larger, yielding systematic inconsistency.

Discount rates fluctuate even when all the particulars of a transaction are held constant and only “irrelevant” aspects change. For example, people exhibit higher discount rates when future transactions are described in terms of the amount of time until their occurrence (“in 3 months”) than in terms of their dates of occurrence (“on June 13th”; LeBoeuf, 2006; Read, Frederick, Orsel, & Rahman, 2005). The amount-of-time frame may focus more attention on the intervening delay and thus make the transaction feel farther away. Indeed, some have argued that an understanding of the perception of future time can shed light on some discounting anomalies. For example, although discount rates increase as time periods shrink (e.g., people discount more per unit time when waiting for 3 months than when waiting for a year; Thaler, 1981), this may happen in part because the perception of time is nonlinear: One year may not seem four times as long as 3 months. When discount rates are calculated with respect to *subjective* time, rates no longer fluctuate with the (subjective) size of the time interval (Zauberman, Kim, Malkoc, & Bettman, 2009). Along similar lines, future losses seem nearer in time than do equidistant future gains (Bilgin & LeBoeuf, 2010), a finding that may partially explain why losses are discounted less steeply than gains (i.e., the “sign effect”; Thaler, 1981).

Excessive discounting yields myopia, which is often observed in people’s attitudes toward future outcomes (see e.g., Elster & Loewenstein, 1992). In one experiment, the high-school dropout rate was reduced by one-third when dropouts were threatened with the loss of their driving privileges

(Loewenstein & Thaler, 1989). This immediate consequence apparently had a significantly greater impact than the far more serious but more distant socioeconomic implications of failing to graduate from high school. Loewenstein and Thaler also discuss physicians’ typical lament that warning about the risk of skin cancer from excessive sun exposure has less effect than the warning that such exposure can cause large pores and acne. In fact, “quit smoking” campaigns have begun to stress the immediate benefits of quitting (e.g., normal heart rate restored within 20 minutes, reduction of carbon monoxide in the blood within 12 hours) even more prominently than the long-term benefits (American Lung Association, 2011). Similar reasoning applies in the context of promoting safe-sex practices and medical self-examinations, where immediate gratification or discomfort often trumps much greater, but temporally distant, considerations.

FUTURE EVENTS

Whereas some of the research reviewed earlier looks at the perceived distance of future events, other research has examined how future events themselves are perceived. Distant future events tend to be represented abstractly, in terms of a few high-level features, whereas more proximal events are represented concretely, in richer low-level detail (Trope & Liberman, 2003). These differing representations can lead to preference reversals, especially when high- and low-level features differ in valence. For example, people may commit to a conference presentation in the distant future (when the abstract benefits of such presentations are salient) but may regret the decision as it becomes nearer and concrete thoughts about the hassle of traveling arise. Changes in construal level can be induced not just by changes in temporal distance but also by incidental tasks that prompt more concrete or abstract thinking, causing preferences to fluctuate even when the temporal distance to an event remains fixed, a finding with implications for self-control and decision making (Fujita, Trope, Liberman, & Levin-Sagi, 2006; Trope & Liberman, 2003; Trope, Liberman, & Wakslak, 2007). Again, people appear not to consider decisions comprehensively and are instead influenced by features that, often arbitrarily, happen to be salient.

Frames of Mind

Inconsistent decisions can also occur when highly transient frames of mind are momentarily triggered,

highlighting values and desires that may not reflect one's more global preferences. These influences may be automatic, making them sometimes difficult to avoid, detect, or correct (see Wegner & Bargh, 1998, for a review of automaticity; for a related analysis of intuitive judgment, see Kahneman, 2003 and Kahneman & Frederick, 2005). Because choices often involve delayed consumption, failure to appreciate the labile nature of preferences may lead people to select currently favored, but later disliked, options.

PRIMING

At the most basic level, transient mindsets arise when specific criteria, desires, or goals are made momentarily accessible. Grocery shopping while very hungry, for example, is likely to lead to purchases that would not be made under normal circumstances (cf. Loewenstein, 1996). In one study of the susceptibility to temporary goal accessibility, participants first completed a task in which they were exposed to words related to either prestige goals or thrift goals. In an ostensibly separate task, participants then chose between more expensive Nike-brand socks or less expensive Hanes-brand socks. Those for whom thrift goals had been primed were more likely to choose Hanes than those for whom prestige goals had been primed (Chartrand, Huber, Shiv, & Tanner, 2008). Momentary priming thus affected ensuing preferences, rendering accessible certain criteria that had not previously been considered important, despite the fact that product consumption was likely to occur long after such momentary criterion salience dissipated (see Bettman & Sujan, 1987; Mandel & Johnson, 2002; Verplanken & Holland, 2002; Wheeler & Berger, 2007).

IDENTITIES

At a broader level, preferences fluctuate along with momentarily salient identities. A working woman, for example, might think of herself primarily as a mother when in the company of her children but may see herself primarily as a professional while at work. The list of potential identities can be extensive (Turner, 1985), with some of a person's identities (e.g., "mother") conjuring up strikingly different values and ideals from others (e.g., "CEO"). Although choices might be expected to reveal stable and coherent preferences that correspond to the wishes of the self as a whole, choice often fluctuates along with happenstance fluctuations in the salience of these identities. In one study,

college students whose "academic" identities had been made salient were more likely to opt for more academic periodicals (e.g., *The Economist*) than were those whose "socialite" identities had been evoked. Similarly, Chinese Americans whose American identities were evoked adopted more stereotypically American preferences (e.g., for individuality and competition over collectivism and cooperation) than when their Chinese identities had been made salient (LeBoeuf, Shafir, & Bayuk, 2010). Preference tends to align with currently salient identities and even with attitudes that are semantically linked to those identities (Morris, Carranza, & Fox, 2008). This creates systematic tension anytime there is a mismatch between the identity that does the choosing and the one that does the consuming. Indeed, people enjoy their chosen options less when the identity salient at the moment of consumption conflicts with, rather than matches, the identity that was salient at the moment of choice (LeBoeuf et al., 2010).

EMOTIONS AND DRIVES

Emotions can have similar effects, influencing the momentary evaluation of outcomes and, thus, choice. The anticipated pain of a loss is apparently greater for people in a positive than in a negative mood; this leads to greater risk aversion among those in a good mood as they strive for "mood maintenance" (e.g., Isen, Nygren, & Ashby, 1988). Furthermore, risk judgments tend to be more pessimistic among people in a negative than in a positive mood (e.g., Johnson & Tversky, 1983).

However, valence is not the sole determinant of an emotion's influence. For example, anger, a negative emotion, seems to increase appraisals of individual control, leading to optimistic risk assessment and to risk seeking, whereas fear, also a negative emotion, is not associated with appraisals of control and promotes risk aversion (Lerner & Keltner, 2001; Lerner & Tiedens, 2006). Disgust, on the other hand, evokes an implicit tendency to "expel" objects from one's possession; thus, people who had just watched a disgusting movie clip set a lower price for an item they were selling than did people in a neutral mood (Lerner, Small, & Loewenstein, 2004). Sadness, on the other hand, evokes a goal to change one's circumstances and to repair them; people who are sad actually show a reversal of the classic endowment effect, as they are (comparatively) eager to part with items they own but also eager to acquire new items (Lerner et al., 2004; see also Cryder, Lerner, Gross, & Dahl, 2008).

Emotions, or “affect,” also influence the associations or images that come to mind in decision making. Because images can be consulted quickly and effortlessly, an “affect heuristic” has been proposed, wherein the affective assessment of options and outcomes guides decisions (Slovic, Finucane, Peters, & MacGregor, 2002). Furthermore, “anticipatory emotions” (e.g., emotional reactions to being in a risky situation) can influence the cognitive appraisal of decision situations and can affect choice (Loewenstein, Weber, Hsee, & Welch, 2001), just as drives and motivations can influence reasoning more generally (see Molden & Higgins, Chapter 20). Emotion and affect influence decision making, but because they are transient, with emotions and drives constantly fluctuating, such influence contributes to reversals of preferences.

Inconsistency thus often arises because people do not realize that their preferences are being momentarily altered by situationally induced sentiments. Evidence suggests, however, that even when people are aware of being in the grip of a transient drive or emotion, they are not always able to “correct” adequately. Instead, people tend to exhibit “empathy gaps,” wherein they underestimate the degree to which various contextual changes will alter their drives, emotions, and preferences (e.g., Van Boven, Dunning, & Loewenstein, 2000). For example, cigarette smokers who had just smoked underestimated the strength of the cravings they would feel following a period of cigarette deprivation. Despite the fact that these smokers were familiar with such craving, they could not simulate its strength when not actually experiencing it, which might help explain why smokers are overly optimistic about the ease of quitting (Sayette, Loewenstein, Griffin, & Black, 2008). Empathy gaps can further contribute to myopic decisions, as people honor present feelings and inclinations, not fully appreciating the extent to which these may be attributable to factors that may soon dissipate.

METACOGNITIVE INFLUENCES

Decisions can also be influenced by metacognitive experiences that arise while processing stimuli. Much recent research has documented the effects that fluency, the subjective experience of ease or difficulty people have when processing information, can have on decisions (see Alter & Oppenheimer, 2009 for a review). For example, when choice options are more difficult to process (e.g., because they are in a hard-to-read font), people are more likely to defer a

decision than when the options are easier to process (e.g., in a clearer font), although the options themselves have not changed (Novemsky, Dhar, Schwarz, & Simonson, 2007). As another example, stocks with more pronounceable names and ticker symbols outperform those with less pronounceable names and symbols on their initial days of trading, apparently because people make more positive inferences about stocks that are more fluently processed (Alter & Oppenheimer, 2006). Ease of processing can thus be seen to inform decision behavior, even when it is triggered by features irrelevant to the decision (see also Simmons & Nelson, 2006).

Conclusions and Future Directions

A review of the behavioral decision-making literature shows people’s preferences to be highly malleable and systematically affected by a host of factors not subsumed under the compelling and popular normative theory of choice. People’s preferences are heavily shaped, among other things, by particular perceptions of risk and value, by influences on attribute weights, by the tendency to avoid decision conflict and to rely on compelling reasons for choice, by salient identities and emotions, and by a general tendency to accept decision situations as they are described, rarely reframing them in alternative, let alone canonical, ways.

It is tempting to attribute many of the effects to shallow processing or to a failure to consider the decision seriously (see, e.g., Grether & Plott, 1979; Smith, 1985; see Shafir & LeBoeuf, 2002, for discussion of such critiques). For example, it seems plausible that people who consider a problem more carefully might notice that it can be framed in alternate ways. This would allow a consideration of the problem from multiple perspectives and perhaps lead to a response unbiased by problem frame or by other “inconsequential” factors (cf. Sieck & Yates, 1997). Evidence suggests, however, that the patterns discussed here cannot be attributed to laziness, inexperience, or lack of motivation. The same general effects are observed when participants are provided with greater incentives (Grether & Plott, 1979; see Camerer & Hogarth, 1999 for a review), when they are asked to justify their choices (Fagley & Miller, 1987; LeBoeuf & Shafir, 2003; Levin & Chapman, 1990), when they are experienced or expert decision makers (Camerer, Babcock, Loewenstein, & Thaler, 1997; McNeil, Pauker, Sox, & Tversky, 1982; Redelmeier & Shafir, 1995; Redelmeier, Shafir, & Aujla, 2001), when they are high in cognitive ability

(Stanovich & West, 2008), or when they naturally think more deeply about problems (LeBoeuf & Shafir, 2003; Levin, Gaeth, Schreiber, & Lauriola, 2002; see Weber & Johnson, 2009 for a review of individual differences in decision making). These findings suggest that many of the attitudes triggered by specific choice frames are at least somewhat entrenched, with extra thought or effort only serving to render the dominant perspective more compelling, rather than highlighting the need for debiasing (Arkes, 1991; LeBoeuf & Shafir, 2003; Thaler, 1991).

Research in decision making is active and growing. Among interesting current developments, a thriving stream of research is investigating systematic dissociations between *experienced* utility, that is, the hedonic experience an option actually brings, and *decision* utility, the utility implied by the decision. Misprediction of experienced utility is common, as research on *affective forecasting* has repeatedly shown (Wilson & Gilbert, 2005). One of the most consistent findings is that people believe that future events (ranging from dramatic life changes to everyday occurrences, such as the outcomes of sporting events) will have a greater and longer lasting impact than they actually do (Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998; Schkade & Kahneman, 1998; Wilson, Wheatley, Meyers, Gilbert, & Axsom, 2000). People also mispredict which experiences will make them happier, thus pursuing experiences that are ultimately less satisfying than they could be (Carlsmith, Wilson, & Gilbert, 2008; Wilson, Centerbar, Kermer, & Gilbert, 2005). A productive avenue for future research would be to investigate these affective forecasting errors with an eye toward helping people choose the experiences that will maximize their overall well-being.

Among other current and future directions, decision-making research is increasingly being enriched by a fuller consideration of the psychological processes that underlie judgment and choice phenomena. Researchers are using insights about attention, perception, memory, goal pursuit, and learning (to name just a few) to help them better understand how judgments and decisions are formed and why they sometimes prove inconsistent (Weber & Johnson, 2009). Along related lines, an active direction for decision-making research lies in the area of neuroeconomics, which gains insights into judgments and decisions by exploring their neural underpinnings (Loewenstein, Rick, & Cohen, 2008; see Camerer & Smith, Chapter 18). Not all current work on decision making is focusing increasingly “inward” on

the individual, however. Another active line of work is also exploring how established insights about decision making can be used to shape public policy decisions, so that behaviorally informed policies, which take into account decision makers’ natural tendencies and limitations (Barr, Mullainathan, & Shafir, 2008; Shafir, in press; Thaler & Sunstein, 2008), can be implemented.

A full description of human decision making needs to incorporate the issues discussed here as well as other tendencies not reviewed in this chapter, including various other judgment biases (see Griffin, Chapter 17), as well as people’s sensitivity to fairness (Kahneman, Knetsch, & Thaler, 1986a, 1986b; Rabin, 1993), aspiration levels (Lopes & Oden, 1999), and sunk costs (Arkes & Blumer, 1985; Gourville & Soman, 1998), among others. A successful descriptive model must allow for violations of normative criteria such as procedure and description invariance, dominance, regularity, and, occasionally, transitivity. It must also allow for the eventual incorporation of additional psychological processes that affect choice, as the refinement of descriptive theories is an evolving process. In any event, the product that emerges is, and will continue to be, quite distant from the elegant normative treatment. At the same time, acknowledged departures from the normative theory need not weaken that theory’s normative force. After all, normative theories are themselves empirical projects, capturing what, upon careful reflection, people consider ideal. As we improve our understanding of how decisions are made, we may be able to formulate prescriptive procedures to guide decision makers, in light of their limitations, to better capture their normative wishes.

Of course, there are instances where people have very clear preferences which no amount of subtle manipulation will alter (cf. Payne et al., 1992). At other times, we appear to be at the mercy of factors that we would prefer to consider inconsequential. This conclusion, well accepted within psychology, is becoming increasingly influential not only in decision research, but in public policy and the social sciences more generally. Prominent researchers in law, politics, medicine, sociology, and economics are exhorting their colleagues to pay attention to findings of the sort reviewed here in an attempt to formulate new ways of thinking about and predicting behavioral phenomena. Given the academic, personal, and applied import of decision making, these should be important developments for our understanding of why people act and decide as they do.

Judgmental Heuristics: A Historical Overview

Dale W. Griffin, Richard Gonzalez, Derek J. Koehler, and Thomas Gilovich

Abstract

The Heuristics and Biases approach to judgment under uncertainty began 40 years ago with the publication of a study of the statistical foibles on the part of research psychologists and statisticians (Tversky & Kahneman, 1971). Since then, this research program has substantially influenced the working assumptions of psychologists and economists about the role of normative models of probability judgment and decision making, while providing a new language of judgmental heuristics. We provide a historical overview of the Heuristics and Biases research program that describes its intellectual antecedents and the special role of the rational actor model in shaping its methods, and we review the program's evolution over the course of three waves of research and theory development.

Key Words: judgment, heuristics, biases, rationality, subjective probability, representativeness, availability, anchoring, adjustment

“Predictions are difficult to make, especially about the future.” This statement, attributed by different sources to a United Nations official, Niels Bohr, and Yogi Berra, may be taken as self-excusing, self-mocking, or simply confused. Although it is difficult to consider all relevant factors when evaluating the probability of a sports team winning, a stock increasing in value, or a relationship leading to marriage, when we consider such matters—*even briefly*—a feeling of certainty or uncertainty seems to “pop out.” For example, when a respected British politician was asked whether Kosovo peace talks would lead to a settlement, he stated—with confidence and after only a brief pause—that “the balance of probabilities are 40–60 against.” How did he do that?

According to the “Heuristics and Biases” (H&B) approach to human judgment, people typically use cognitive shortcuts that make assessments of likelihood quick and easy but prone to systematic error.

Such shortcuts occur not only in predictions but in retrospective judgments of probability as well, and they can be recognized through signature “biases,” as we describe later. Consider a recent article in a major national newspaper. The article, titled the “20 million to 1 family,” described how a couple had “broken all records by having eight children born in symmetrical girl-boy, girl-boy, girl-boy, girl-boy order.” The explanation of this strange rendering of the odds based on judgmental heuristics is that people incorrectly (but easily and effortlessly) judge the target sequence of births to be extremely unlikely because the symmetrical pattern of births does not match and is *not representative* of a random series. Formal probability theory, in contrast, prescribes that any sequence of four boys and four girls is as likely as any other.

Based partly on their experience teaching statistics and on their observations of judgments and predictions in applied settings, Daniel Kahneman and

Amos Tversky (Kahneman & Tversky, 1972, 1973; Tversky & Kahneman, 1971, 1974) proposed that intuitive judgments under uncertainty are typically controlled by judgmental “heuristics” rather than by the formal laws of probability. Kahneman and Tversky were not the first to suggest that classical “rational” models of statistical reasoning fail to describe actual human reasoning in many settings, but their program of research was both more radical and more influential than most others. Their challenge to rational models influenced theory and research not only in cognitive psychology but also in social psychology, economics, philosophy, political science, medical decision making, and legal studies.

We first discuss the meaning of “rationality” that is most relevant to the heuristics and biases program, review the negative and positive messages of the original program, explore the chief criticisms of that program, and finally present extensions to the original heuristics and biases research. Our presentation is historical in focus and organization, and readers seeking a more focused treatment of recent reconceptualizations are advised to consult Kahneman and Frederick’s (2005) chapter in the previous edition of this Handbook.

The Rational Model

The classical model of rational choice (see Chater & Oaksford, Chapter 2) is central to the discipline of economics, and at its heart is the guiding principle of maximizing subjective expected utility (SEU). According to this model, which provides a behavioral definition and measure of rationality, the “rational actor” assesses the attractiveness of a given option by evaluating the probability of each possible resultant outcome and combining that subjective probability with the subjective utility or personal value of each outcome. The rational economic actor then chooses the best option on the basis of the optimal probability-weighted utility. Economic theories that guide public policy in areas as diverse and important as taxation, environmental safety, stock market and banking regulation, and Social Security rely on the central assumption that individuals and organizations are rational in this sense. Underpinning this model is a series of axioms, or simple rules of logic, that are defined to be both intuitively and formally compelling in their abstract form. This axiomatic foundation provides a series of sharp tests that clearly assess the degree to which observed judgments fit this specific (and widely applied) rational model. The behavioral findings

of Kahneman and Tversky (and many colleagues) question the fundamental assumptions of this normative model by showing how these axiomatic tests fail under well-specified conditions.

There are many events for which it is easy to calculate the “correct” probability (e.g., the chance of drawing a given hand of cards). But in other cases, such as the prediction of peace in our time, the appropriateness of the probability judgment can only be tested by examining its *coherence* relative to other judgments (e.g., the probability of a subcategory must be less than or equal to its superordinate category), and by examining its *calibration* when aggregated together with several other judgments equated on probability (i.e., events predicted with .70 probability must occur 70% of the time). Note that coherence can be satisfied with respect to purely internal criteria, whereas calibration is specifically defined with respect to external criteria: how many things actually happened in the world. Violations of rationality in this model, then, do not imply anything about the relative importance of “hot” emotional versus “cool” cognitive factors; by this definition, rationality requires only that people follow the rules of subjective probability and evaluate their own preferences consistently.

The most widely used benchmark of the coherence of probability assessment is Bayes’ rule, which has been described as the “master rule” of categorical inference or categorical prediction (see Fischhoff & Beyth-Marom, 1983, for an early psychologically oriented discussion of Bayesian hypothesis testing; also Griffiths, Tenenbaum, & Kemp, Chapter 3). Bayes’ rule defines how to use probability theory to update the probability of a hypothesis given some data. For example, when inferring the probability that a patient has heart disease (H1) on the basis of a positive diagnostic test (D), a rational physician would (implicitly or explicitly) calculate the following quantity, where H2 refers to the probability that the patient does not have heart disease.

$$\frac{P(H1|D)}{P(H2|D)} = \frac{P(D|H1)}{P(D|H2)} * \frac{P(H1)}{P(H2)}$$

The first quantity on the right-hand side is the likelihood ratio, which expresses the *relative likelihood* that a patient known to have heart disease would yield the test result D (for data) compared to a patient known not to have heart disease. The likelihood ratio thus reflects the *diagnosticity* of the given evidence D. In general, diagnosticity increases

with increasing separability of the two competing hypotheses, increasing quality of the diagnostic data, and increasing sample size of the diagnostic data. For example, a given blood pressure reading would be more diagnostic in distinguishing between heart disease and a healthy heart than between heart disease and another vascular disease; it would be more diagnostic if it were taken by an experienced physician than by a beginning medical student; and it would be more diagnostic if it were based on the average of many readings than based on a single reading. The second quantity on the right-hand side is the prior odds ratio, which reflects the relative prevalence of the two outcomes in the relevant population, that is, the relative probability of encountering a given member of each class (in the frequentist approach to probability, the chance of encountering a given member in one of many random draws).

The strength of inference that can be drawn from a given body of evidence depends on the relative balance of the likelihood ratio and the prior odds ratio. If, for example, the diagnostic test has good validity such that the likelihood ratio is 9:1 in favor of heart disease given a positive test result, then a prior odds ratio of 1:9 against heart disease leaves the rational physician with posterior odds of 1:1, or a .5 probability that the patient has heart disease. If, on the other hand, prior odds of 1:9 against are matched by a likelihood ratio of 1:9 against, then the posterior odds are 1:81 against, or a little over a .01 probability that the patient has heart disease.

The use of Bayes' rule to describe "ideal" probabilistic judgment in frequentistic settings, with repeated, exchangeable events such as drawing balls from an urn, is entirely uncontroversial. However, when Bayes' rule is used to prescribe the updating of subjective probabilities about a unique event, some controversy entails (e.g., Savage, 1954). In particular, some statisticians argue that probability theory can only be applied to the frequentist case. However, as many applied researchers (including Keynes, 1921) have argued, if probabilistic statements about unique, real-world events are excluded from the domain of probability theory, nothing interesting is left. Wars, depressions, mergers, marriages, deaths and divorces may happen with some regularity, but each is experienced as a unique event. Are probability judgments about such events without guidelines or standards? For now, it is enough that the classical economic model of rationality—using the principle of coherence—requires subjective probability judgments to follow Bayes' rule.

Historical Antecedents of the Heuristics and Biases Program

In the 1950s, inspired by the use of expert judgment in engineering systems developed during World War II, by the cognitive revolution that required human judgment to be modeled in terms of computer systems, and by the increasing contact between experimental psychology and economic decision-making models, a number of research programs examined the issues of coherence and calibration in human probabilistic judgment. Herbert Simon (1957), early in his Nobel Prize-winning research on economic models, argued that "full" rationality was an unrealistic assumption because of processing limitations in living systems (and, incidentally, in virtually all computers currently available). He proposed a limited form of rationality, termed "bounded rationality," that accepted the limited search and computational ability of human brains but nonetheless assumed that after a truncated search and after considering a limited subset of alternatives, people did act and reason rationally, at least in terms of achieving their goals.

It is worthwhile digging deeper into the Simonian critique, as Simon borrowed the use of the term "heuristic" from computer science and artificial intelligence to describe simplified yet highly efficient human reasoning principles, setting the stage for all future work on heuristics of judgment and decision making. Simon was trained in the field of public administration, and he was originally interested in modeling how bureaucracies worked (a goal more focused on "description" than on "prescription"). The phenomena that Simon and his colleagues observed could be described as "muddling through"—large organizations seemed to operate on simple rules of thumb in an environment in which no one person or department knows everything but somehow everyone knows just enough to produce an adequate outcome. Later, he turned his attention to the psychology of problem solving, with a particular interest in expert judgment. Simon did not build his theories of bounded rationality on specific psychological principles or processes: He explicitly noted that psychological theories of choice processes were not yet sufficiently developed to inform economics. Instead he used general psychological principles to outline some broad, realistic constraints on rational models as models of actual decision making. These general psychological principles reflected the zeitgeist of cognitive psychology at the time, which focused on the limits of memory and attention.

Simon's realistic constraints set the stage for the study of judgmental heuristics and the field of judgment and decision making more generally. In his theories of bounded rationality, he asserted that people simplify the choice process by searching for a satisfactory rather than an optimal outcome. *Satisficing*, he argued, generally consists of three elements: a strategy that examines local or easy options before looking further afield, a stopping rule that specifies an *aspiration level* that must be met and hence how far afield the search should continue, and a simplified assessment of future value that provides a rather vague clue as to the actual value of the choice. There is another less well-known side to Simon's critique: He also maintained that such simplified methods of choice can do surprisingly well relative to optimizing methods and that "bounded rationality" could still be evolutionarily successful.

Simon offered the field of economics (at least) two other familiar psychological insights that were to echo repeatedly in the development of behavioral models of judgment and decision making. First, the human mind (as well as the aggregate mind of the organization) can only hold on to two or three alternatives at one time. Second, attention is a precious and costly commodity, a fact that must be considered in any description of how judgment and choice processes actually operate. Thus, in the vocabulary later introduced by Kahneman and Tversky, Simon had both a negative agenda (explaining how ideal, rational models were unrealistic and descriptively invalid) and a positive agenda (providing guidelines as to how humans—and animals—might actually make highly sensible, if simplified, choices).

Research by Ward Edwards (reviewed in Edwards, 1968) was designed to test rationality assumptions more directly. Using bags full of colored poker chips to explore how people revised, or "updated," their probabilities in the face of new evidence, Edwards concluded that people are not always well calibrated (that is, their probability judgments are not accurate but biased) but are generally coherent in their judgments. In particular, he and his colleagues concluded that *in general* people do reason in accordance with the rules of probability (as summarized by Bayes' rule); however, they give new evidence too little weight and thus are "conservative." It is important to our later arguments to note that conservatism was only the most *common* finding in this research program. Systematic exceptions were found when participants were given new evidence of low probative weight; in this case, judgments were

typically "radical," giving too much weight to the new evidence.

The work by Simon and by Edwards and colleagues is generally seen as the main predecessor of the H&B approach. However, there were several other flourishing research programs on subjective probability in the 1950s and 1960s that cast further doubt on the rationality assumption. For example, Adams and Adams (1961) examined the calibration of subjects' probability judgments about their own knowledge and found consistent "overconfidence:" For most probability levels, the actual percentage of correct answers to general knowledge questions was too low to justify the judged probability of being correct. Researchers using the Signal Detection model (which also has a Bayesian foundation) to study human perceptual judgments (e.g., Pollack & Decker, 1958) found that the correspondence between the rated probability of a "signal" being present and its actual probability depended on the difficulty of the recognition problem. When the stimulus was relatively difficult to recognize (e.g., because a tone was degraded with random noise or because a visual stimulus was very small), receivers' subjective probability judgments were too close to 1.0, that is, they were overconfident. When the stimulus was relatively easy to recognize, receivers' subjective probability judgments corresponded closely to the actual probability of receiving a signal and sometimes were even too low.

Throughout the 1950s, J. Cohen (e.g., Cohen & Hansel, 1956) studied intuitive conceptions of probability in children and adults, especially in terms of belief in "chance" and "luck" in gambling and risk-taking behavior. He concluded that intuitive conceptions of probability were qualitatively different than those described by the axioms of probability theory. Anomalies in conceptions of randomness noted by Cohen and others included two particularly robust phenomena: the gambler's fallacy and probability matching. The gambler's fallacy is the belief (implicit or explicit) that the "law of averages" requires that the probability of a given outcome of a chance device (e.g., Tails when tossing a coin) increases with a run of the alternate outcome (e.g., tossing Heads many times). Probability matching is the practice of predicting the more common event in proportion to the base-rate frequency of that event (e.g., if a roulette wheel was designed to end up "red" on 70% of spins, a probability-matching bettor would bet "red" on 70% of the trials, instead of betting "red" on *every* trial, which would maximize the expected number of wins).

About the same time, Paul Meehl was describing two fundamental challenges to the optimality of clinical judgment. First, he noted that clinical prediction was almost entirely based on characteristics of the case being judged with little or no concern for the relative prevalence or “base rates” of the possible outcomes (Meehl & Rosen, 1955). Second, he compiled a list of studies that compared the accuracy of clinical prediction with actuarial or formula-based prediction: Formulas did better (Meehl, 1954). Some time afterward, Oskamp (1965) demonstrated how trained clinical judges become increasingly miscalibrated (overconfident) as they gained more data about a case. Later, Mischel (1968) challenged the validity of clinical interviews to predict future behavior in very different situations. Most important for the present review, he pointed to the discrepancy between judges’ beliefs and the empirical evidence of poor predictive validity.

These diverse findings and perspectives set the stage for Kahneman and Tversky’s judgmental heuristics account of intuitive probability. The H&B program was not a comprehensive attempt to explain the anomalies that littered the field of human judgment, but naturally it was influenced by what came before. It was an attempt to describe some of the most notable elements of human judgment that Kahneman and Tversky observed in the classroom and in the real world. Simon and Edwards had brought the potential conflict between normative rational models and descriptive human models into sharp focus, but they had concluded that people were approximately or boundedly rational, within limits determined by their computational capacity. However, there was considerable evidence that the assumption of calibration was generally untenable, and some evidence from Cohen’s work that the axioms that required coherence were not consistent with intuitive judgments of probability. In this context, Kahneman and Tversky took a radical step: They proposed that the rules of probability, which define the rational “best guess” about outcomes, are not natural or intuitive methods of assessing degrees of belief or likelihood. Furthermore, they implied, simplifying the search set or restricting the number of computations was not enough to rescue the rationality assumptions. Instead, in many situations people naturally and spontaneously assess the likelihood of an outcome by processes that are qualitatively different from the rules of probability theory. In other words, “intuitive” judgment is not boundedly

rational, but not rational at all (at least in the classical “rational actor” sense).

Later critics have argued that the H&B program marked a sudden and arbitrary shift away from prior research on conservatism, which largely upheld the assumption of rationality (e.g., Gigerenzer & Murray, 1987; Lopes, 1991). This criticism is hard to support, for, as we explain later, the H&B model is consistent with conservatism as well as with the other anomalies listed earlier. The H&B program accounted for the previous findings and also predicted many specific laboratory-based anomalies presented and tested in Kahneman and Tversky’s early papers. We must emphasize that the laboratory-based demonstrations were never meant to be the phenomena to be explained—they were meant to illustrate and test the *processes* thought to underlie the real phenomena of interest and to illuminate specific tests that could sharply reject the behavioral applicability of the underlying axioms. The phenomena to be explained were judgments in the real world that seemed to be at odds with the dictates of probability theory.

Three Heuristics Explain Many Biases: The First Wave of Research

The Heuristics and Biases program began when Amos Tversky, a mathematical psychologist who had worked with Edwards and others on formal measurement models, described the current state of the Behavioral Decision Theory paradigm circa 1968 to Daniel Kahneman, his colleague in the Psychology Department at Hebrew University. Kahneman found the idea of tinkering with formal models such as SEU to make them fit the accumulating empirical evidence to be an unpromising approach to understanding the psychological processes involved in judgment and choice. Instead, he argued, based on his own research on visual attention and processing, the principles of cognition underlying judgment should follow the principles of perception (cf. Brunswik, 1956). Thus, instead of starting with formal models as the basis of descriptive accounts of judgment and decision making, Kahneman and Tversky started with principles of perception and psychophysics and extended them to the kind of processing necessary to evaluate probabilities and assess subjective values.

This approach immediately suggested a guiding paradigm for research on judgment and decision making: the study of visual illusions. The logic of studying perceptual illusions is that failures of a

system are often more diagnostic of the rules the system follows than are its successes. Consider, for example, the moon illusion: The full moon looks enormous as it sits on the horizon, but it appears more modestly sized when high in the sky. There is little to learn from the constancy of the perceived size of the moon along the long arc of the overhead sky, but its illusory magnification when it sits on the horizon provides insight about the way that the visual system uses contextual detail to compute perceived distance and hence perceived size. The visual illusion paradigm, like the cognitive illusion approach patterned on it, does not imply that judgments of size are typically wrong—in fact, it provides a map to those situations when intuitive perceptions are likely to be correct—but it highlights the processes by which perception or judgment is *constructed* from imperfect cues. We would not say that the visual system is “irrational” because it uses environmental cues in a heuristic way; rather, we can conclude that using environmental cues in a heuristic way gives rise—in well-specified, but not necessarily common circumstances—to systematic and diagnostic errors or biases.

Thus, the guiding logic of Kahneman and Tversky’s approach to the study of judgment was in practice the opposite of that championed by Simon, who had urged researchers to seek out and understand the environmental factors that maximized the success of simple processes. The cognitive illusion paradigm seeks out those environments or problem descriptions in which the judgment and choice processes people rely on lead to clear errors. The purpose was not to emphasize the predominance of bias over accuracy, but to find the clearest testing grounds for diagnosing the underlying simple processes or *judgmental heuristics* that people habitually employ. This is an important distinction that many subsequent critiques have failed to appreciate, and it is worth quoting Kahneman and Tversky’s original description of the logic of the H&B paradigm:

The subjective assessment of probability resembles the subjective assessment of physical quantities such as distance or size. These judgments are all based on data of limited validity, which are processed according to heuristic rules. For example, the apparent distance of an object is determined in part by its clarity. The more sharply the object is seen, the closer it appears to be. This rule has some validity, because in any given scene the more distant objects are seen less sharply than nearer objects. However, the

reliance on this rule leads to systematic errors in the estimation of distance. Specifically, distances are often over-estimated when visibility is poor because the contours of objects are blurred. On the other hand, distances are often underestimated when visibility is good because the objects are seen sharply. Thus the reliance on clarity as an indication of distance leads to common biases. Such biases are also found in intuitive judgments of probability. (Tversky & Kahneman, 1974, reprinted in Kahneman, Slovic, & Tversky, 1982, p. 3)

The heuristics that Kahneman and Tversky identified were also suggested by the principles of perceptual psychology, especially the organizing principles of Gestalt psychology (e.g., Koffka, 1935). Gestalt psychology emphasized how the perceptual system effortlessly and without awareness creates whole forms even when the information reaching the receptors is incomplete and indeterminate. According to the H&B approach, these underlying heuristics are not a simplified version of an ideal statistical analysis but something completely different. This constituted a key point of differentiation between the H&B account and others before it: “In his evaluation of evidence, man is apparently not a conservative Bayesian: he is not Bayesian at all” (Kahneman & Tversky, 1972, p. 450). Unfortunately, or so it seems to us, this statement was taken by some to imply that the H&B (hu)man was not simply un-Bayesian, but rather stupid.

In a later phase of their collaborative research, Kahneman and Tversky took the perceptual framework they had used to study probability judgment and used it to illuminate decision making under risk, leading to their most complete and formal model, Prospect Theory (Kahneman & Tversky, 1979), for which Kahneman received the Nobel Prize in Economics in 2002. In this model, fundamental perceptual principles such as comparison levels and adaptation (Helson, 1964), diminishing sensitivity, and the privileged status of pain served as the primitives of a model that once again used specific biases and errors as tools of diagnosis (see LeBoeuf & Shafir, Chapter 16).

It is illuminating to compare the evolutionary implications of Simon’s Bounded Rationality and the H&B approach. For Simon, the guiding evolutionary principle was computational realism (i.e., simplified approximation) that nonetheless was well adapted to fit the information environment. For Kahneman and Tversky, the guiding evolutionary

principle was that existing processes in perceptual analysis were coopted as tools for higher level cognitive processing. Although these tools might work well in many environments, they also lead to signature biases that are endemic to human intuition. In many cases, the biases that Kahneman and Tversky were signals of underlying heuristics were already well known. As noted earlier, Meehl and Rosen (1955) had warned clinicians of the danger of neglecting base rates in psychological diagnoses. In other cases, the biases were identified by informal observation, whether of psychologists who seemed to neglect power and underestimate sample sizes, army officers who neglected regression effects in determining the value of rewards versus punishment, or army selection personnel who maintained their belief in the efficacy of interviews despite statistical evidence to the contrary.

Negative and Positive Aspects of the Heuristics Program

From the first articles on heuristics and biases, Kahneman and Tversky noted that their program had two interrelated messages, one negative, about how intuitions *do not* work, and one positive, about how intuitions *do* work. In retrospect, it seems possible to identify two or three distinct stages of the program. In the first stage, the focus was on the surface structure of judgmental heuristics, and demonstrations were designed to show how case-specific information dominated intuitive judgment and led, at times, to the complete neglect of other normatively important information. The second stage (or as we describe it later, the “second wave”) attempted to describe the deep psychological structure of judgmental heuristics, and the accompanying demonstrations were more likely to show how the (often conflicting) multiple sources of information were weighted. Finally, the third stage organized a broader set of heuristic processes under the rubric of a dual-process model of reasoning and judgment.

In the first stage, which dates from the original collaboration in 1969 to the 1974 summary paper, Kahneman and Tversky focused primarily on defining three judgmental heuristics (representativeness, availability, and anchoring and adjustment) by means of analogies with the processes underlying perceptual illusions. In simple, between-subject scenario experiments, Kahneman and Tversky demonstrated that people neglect prior odds (“base rates”), sample size, evidence quality, and diagnosticity, and instead rely on their immediate evaluation of the

strength of the sample evidence to construct their subjective probability judgments. The experiments focused on everyday judgments and predictions about hospital births, school achievement, and professional membership, rather than abstract textbook probability questions about balls and urns, or dice and coins. Such a shift in context was neither irrelevant nor unplanned, as the authors noted that questions about chance devices were most likely to trigger the use of statistical rules rather than intuitive thinking. The authors acknowledged that almost any reasoning problem could be made “transparent” enough to allow participants to “see through” to its underlying statistical framework, but they argued that between-subject manipulations in nonchance settings were most informative about how people typically reasoned in everyday life.

The Positive Model: The Original Perceptual Metaphor

Along with the negative message that people do not intuitively follow Bayes’ rule, Kahneman and Tversky developed a positive descriptive model of statistical intuitions. When people infer the likelihood of a hypothesis from evidence, they asserted, people intuitively compute a feeling of certainty based on a small number of basic operations that are fundamentally different from Bayes’ rule. In particular, these basic heuristic processes include computing the similarity between a sample case and the category prototype or generating mechanism (representativeness), computing how easily instances of the relevant category come to mind (availability), and adjusting an already existing impression or number to take into account additional factors (anchoring and adjustment). Thus, representativeness measures the fit between a case and a possible cause, or between a sample and a possible distribution. Availability measures the ease with which specific examples come into consciousness: A highly unlikely event is one that seems literally “unimaginable.” Anchoring and adjustment is something quite different; it is not a measure, but a simplistic process of combination that fails to weight each component by its evidential value. These are heuristics because they are “shortcut” tools that bypass a more complicated and optimal algorithmic solution, where an algorithm is a step-by-step set of rules that guarantees a correct or optimal answer. Heuristics can be described in the language of “if then” procedural rules. *If* seeking the probability that a case is a member of a given category (or that

a sample was generated by a given population), *then* compute the similarity between the case/sample and the category/population prototype.” “*If seeking the probability that an event will occur, then compute the ease with which examples of that event come to mind.*” “*If a number is available for use and on the right scale, then adjust that number upward or downward according to knowledge that comes to mind.*” Whether such procedures were meant to be conscious or intentional strategies was not explicitly stated in the original papers.

Each of the operations described by Kahneman and Tversky yields an impression of certainty or uncertainty, but the heuristic operations themselves are unaffected by some of the required inputs to the Bayesian algorithm, such as prior odds ratio, separability of the hypotheses, validity of the evidence, or sample size. Instead, these “direct assessments” of probability are fundamentally *nonextensional* and *nonstatistical*, because they operate directly on the sample evidence without considering the relevant set-inclusion relations (the extensional rules), and without considering the degree of variability or uncertainty in the case information controlled by considerations of sample size and evidence quality (statistical rules).

In this approach, deviations from the normative model were not considered “failures of reasoning” but “cognitive illusions.” This term emphasizes that the outputs of the judgmental heuristics, like the processes involved in vision and hearing, lead to compelling impressions that do not disappear even in the presence of relevant rule-based knowledge. Furthermore, the heuristics do not represent a “strategy” chosen by the individual judge; again like perceptual processes, the heuristics produced their output without guidance or active awareness of their constructive nature. This general notion was not novel; it had been introduced by J. Cohen (1960) in his study of “psychological probability:”

Psychological probabilities which deviate from norms based on an abstract or “idealized” person are not errors, in a psychological sense, any more than optical “illusions” as such are errors. They can only be described as errors in terms of a non-psychological criterion. Knowledge of the objective lengths of the Muller-Lyler lines, for example, does not appreciably affect our subjective impressions of their magnitude. Precisely the same is true of the Monte Carlo fallacy [gambler’s fallacy] . . . ; even mathematicians who are perfectly convinced of the independence of

the outcomes of successive tosses of a coin are still inclined to predict a particular outcome just because it has not occurred for a relatively long time in a series of tosses. (Cohen, 1960, p. 29)

The heuristic approach helped to explain existing anomalies in statistical intuition as well as predict new phenomena. In particular, the gambler’s fallacy and probability matching can be seen as examples of representativeness at work. A long run is unrepresentative of a random chance process, and so we expect to see alternations to make the sequence seem more representative. In probability matching, the strategy of always predicting the most common outcome is completely unrepresentative of the kinds of patterns that seem likely to occur by chance, so predictions are made with the same kind of alternations that are representative of a random or chance process. Later, Gilovich, Vallone, and Tversky (1985) showed that people systematically misperceive random sequences because of the expectation that the sample sequence will “represent” the random nature of the causal distribution and contain many alternations and few long runs. When basketball fans were presented with a sequence of shots described as hits and misses, a majority perceived a sequence with a .5 probability of alternation as representing a “streak,” because it included more long runs than they expected. An even larger majority perceived a sequence with a .8 probability of alternation as representing a “chance” sequence, because there were few long runs, and so the observed pattern matched the defining characteristics of a “random” process. Not surprisingly, such fans perceived actual players to be streak shooters, even though none of the players studied had shooting patterns that deviated from a simple independence model based on the assumption that hits were no more likely to follow a hit than to follow a miss.

The often-observed difficulties people have in understanding and identifying regression artifacts (e.g., Campbell & Kenny, 1999) also follow from the application of representativeness: People expect an effect to be just as extreme as its cause, regardless of the strength of the predictive relationship. Thus, children are expected to be just as tall, short, or clever as their parents, and experienced psychologists expect their experimental replications to be just as significant as the original (significant) studies. Kahneman and Tversky (1973) coined the term “prediction by evaluation” to describe the process of matching the size of the effect with the size

of the cause: The extremity of the causal variable is *evaluated* and then an outcome is that is equally as extreme. However, when children are less clever than their parents or replications yield weaker results than their originals, people invariably seek out causal explanations—ignoring the statistical law of regression that operates whenever predictive relationships are not perfect. Such findings have profound implications beyond the rejection of an unrealistic model of rationality: If people see random sequences as systematic deviations from chance, and develop causal explanations for phenomena that represent simple regression artifacts, we can expect an intellectual culture that develops and maintains unfounded superstitions and useless home medical treatments, that sustains multiple competing explanations of social phenomena, and distrusts the quantitatively guided conservatism of science (Gilovich, 1991).

AVAILABILITY

Given that there are a lot of Canadian comedians, one can probably think of particular examples very readily. There is merit, then, in turning this around and concluding that if one has an easy time thinking of Canadian comedians, there probably are a lot of them. The logic is generally sound and it constitutes the essence of the *availability heuristic*, or the tendency to use the ease with which one can generate examples as a cue to category size or likelihood. But the “probably” in this inference is important. There can be other reasons why examples of a given category are easy or hard to generate and so availability is not always a reliable guide to actual frequency or probability (Kahneman & Tversky, 1973; Macleod & Campbell, 1992; Rothbart, Fulero, Jensen, Howard, & Birrell, 1978; Tversky & Kahneman, 1973).

Kahneman and Tversky (1973) first demonstrated this in a series of classic experiments. In one, participants were asked whether there are more words that begin with the letter “r” or that have “r” as the third letter. Because it’s easier to generate words that start with “r” (red, rabid, ratatouille...) than words that have an “r” in the third position (...Huron, herald, unreasonable), most participants thought there were more of the former than the latter. In reality, there are three times as many words with an “r” in the third position.

Ross and Sicoly (1979) explored the implications of the availability heuristic for everyday social life. They asked couples to specify their own percentage contribution to various tasks and outcomes

that come with living together—keeping the house clean, maintaining the social calendar, starting arguments, and so on. They predicted that each person’s own contributions would be more salient than their partner’s contributions and so both partners would overestimate their own role. When the estimates made by each member of a couple were summed, they tended to exceed the logical maximum of 100%. This was true, notably, for negative actions (e.g., starting fights) as well as positive actions—evidence that it is the availability heuristic and not self-enhancing motivations that is responsible for this effect.

Norbert Schwarz and his colleagues have shown how the availability heuristic can influence people’s self-assessments and, in so doing, also settled an important conceptual issue that lies at the core of the availability heuristic (Schwarz, Bless, et al., 1991; Schwarz & Vaughn, 2002; see also Gabrielcik & Fazio, 1984). Recall that people are assumed to use the *ease* with which they can generate instances of a given category when making judgments about the category. But note that if instances are easy to generate, one will probably come up with a lot of them. So how can we be sure that people are in fact influenced by the ease with which they generate instances (a metacognitive feature) rather than the *number* of instances they generate (a cognitive feature)? Typically, we can’t. What Schwarz and colleagues did was to disentangle these two, usually intertwined features. In one representative experiment, they asked half their participants to think of times they had been assertive and the other half to think of times they had been unassertive. Some of the participants in each group were asked to think of six examples and the others were asked to think of twelve examples. The required number of instances, six and twelve, were carefully chosen so that thinking of six examples would be easy but thinking of twelve would be a challenge.

This manipulation separates ease of generation (process) from the number of examples generated (content). Those asked to think of twelve examples of their assertiveness (or unassertiveness) will think of more examples than those asked to think of six, but they will have a harder time doing so. What Schwarz and colleagues found was that those asked to think of six examples of their past assertiveness later rated themselves as more assertive than those asked to think of twelve examples. The same pattern held for those asked to think of past examples of unassertiveness. Thus, it is the ease with which

people can recall examples, not the number of examples recalled, that dominates people's judgments. The effect was so strong, in fact, that those asked to come up with twelve examples of their own unassertiveness (and who thus had lots of examples of their failure to be assertive on the top of their heads) rated themselves as *more assertive* than those asked to come up with twelve examples of assertiveness (and who thus had lots of examples of their past assertiveness at the top of their heads.)

In a wry application of this paradigm, Fox (2006) had students list either two or ten ways a course could be improved as part of the standard end-of-the-term course evaluation process. Students asked to list ten possible improvements apparently had difficulty doing so, because they rated the course significantly more favorably than students asked to list two ways to improve.

REPRESENTATIVENESS

A university nutritionist informed readers of her column that a tomato "has four chambers and is red" and that eating tomatoes is good for the heart; a walnut "looks like a little brain" and "we now know that walnuts help develop more than three dozen neuron-transmitters (sic) for brain function;" and kidney beans assist with the healthy functioning of their organ namesake (Jones, 2008). This advice appears to be heavily influenced by a second heuristic identified by Kahneman and Tversky: representativeness.

Making judgments on the basis of representativeness reflects the mind's tendency to automatically assess the similarity between two entities under consideration and to use that assessment as input to a judgment about likelihood. Judgments about the likelihood of an object belonging to a category are powerfully influenced by how similar the object is to the category prototype (Kahneman & Tversky, 1972, 1973; Tversky & Kahneman, 1983). Judgments of the likelihood that an outcome stems from a particular cause are powerfully influenced by the similarity between putative cause and observed effect (Gilovich & Savitsky, 2002; Nisbett & Ross, 1980). Judgments about the likelihood of obtaining a given result are powerfully influenced by the similarity between the features of the imagined result and those of the processes thought to be at work (Kahneman & Tversky, 1972, 1973; Tversky & Kahneman, 1971).

The most compelling way to demonstrate that judgments are "powerfully" influenced by a hypothesized process is to show that they are excessively

influenced. Much of the research on representativeness has therefore sought to show that the heuristic leads people to make judgments that violate clear normative standards. Judging whether a sample is likely to have come from a particular generating process by assessing the similarity between the two, for example, has been shown to give rise to a "law of small numbers," or a tendency to believe, contrary to probability theory, that even small samples should be representative of the populations from which they are drawn (which is true of large samples and is captured in the law of large numbers). The belief in a law of small numbers has been established by studies showing that people (including expert statisticians and psychologists) are excessively confident about the replicability of research findings (Tversky & Kahneman, 1971), have difficulty recognizing or generating random sequences (Falk & Konold, 1997; Gilovich, Vallone, & Tversky, 1985; Wagenaar, 1972), and are overly influenced by the relative proportion of successes and failures, and insufficiently influenced by sample size, in assessments of how confident they can be in a particular hypothesis (Griffin & Tversky, 1992).

The work on representativeness that garnered the most attention and sparked the greatest controversy, however, involved experiments demonstrating that the allure of representativeness can prevent people from utilizing base rates or basic set-inclusion principles when making predictions. In one now-classic study (Kahneman & Tversky, 1973), participants were given the following description of an individual enrolled in graduate school:

Tom W. is of high intelligence, although lacking in true creativity. He has a need for order and clarity, and for neat and tidy systems in which every detail finds its appropriate place. His writing is rather dull and mechanical, occasionally enlivened by somewhat corny puns and by flashes of imagination of the sci-fi type. He has a strong drive for competence. He seems to have little feel and little sympathy for other people and does not enjoy interacting with others. Self-centered, he nonetheless has a deep moral sense.

One group of participants was asked to rank nine disciplines in terms of how closely Tom W. resembled the typical student in that field. A second group ranked them in terms of the likelihood that Tom was actually enrolled in each. A third group simply estimated the percentage of all graduate students in the United States who were enrolled in each discipline.

There were two critical findings. First, the rankings of the likelihood that Tom W. actually studied each of the disciplines were virtually identical to the rankings of how similar he seemed to the typical student in each field. Participants' assessments of likelihood, in other words, were powerfully influenced by representativeness. Second, the rankings of likelihood did not correspond at all with what the participants knew about the popularity of the different disciplines. Information about the base rate, or the *a priori* likelihood of Tom being a student in each of different fields, was simply ignored.

Experiments like this sparked a long-running controversy about whether and when people are likely to ignore or underutilize base rates (Cosmides & Tooby, 1996; Gavanski & Hui, 1992; Gigerenzer, 1991; Griffin & Buehler, 1999; Koehler, 1996). The controversy was productive, especially of publications, because it yielded such findings as: people are more likely to utilize base-rate information if it is presented after the information about the individual (Krosnick, Li, & Lehman, 1990), if the base rate is physically instantiated in a sampling paradigm (Gigerenzer, Hell, & Blank, 1988, but see Poulton, 1994, p. 153), and if the base rate is causally related to the to-be-predicted event (Ajzen, 1977; Tversky & Kahneman, 1982). But in an important respect the controversy was misguided because the essential idea being put forward was that people's judgments are powerfully influenced by representativeness, not that people never use, or even typically don't use, base rates. Instead, the Tom W. studies and others like it were existence proofs of the power of representativeness to overwhelm all other considerations in at least some circumstances.

ANCHORING

Suppose someone asks you how long it takes Venus to orbit the sun. You reply that you don't know (few people do), but your interrogator then asks for an estimate. How do you respond? You might think to yourself that Venus is closer than Earth to the sun and so it probably takes fewer than the 365 days it takes the earth to make its orbit. You might then move down from that value of 365 days and estimate that a year on Venus consists of, say, 275 days. (The correct answer is 224.7.)

To respond in this way is to use what Tversky and Kahneman called the anchoring and adjustment heuristic (Tversky & Kahneman, 1974). One starts with a salient or convenient value and adjusts to an estimate that seems right. The most notable

feature of such adjustments is that they tend to be insufficient. In most investigations of such "anchoring effects," the investigators take care to ensure that the respondents know that the anchor value is entirely arbitrary and therefore carries no implication whatsoever about what the right value might be. In the initial demonstration, Tversky and Kahneman (1974) spun a "wheel of fortune" device and then asked participants whether the percentage of African countries in the United Nations is higher or lower than the number that came up. After participants indicated whether they thought it was higher or lower, they were asked to estimate the actual percentage of African countries in the United Nations. What they found was that the transparently arbitrary anchor value significantly influenced participants' responses. Those who confronted larger numbers from the wheel of fortune gave significantly higher estimates than those who confronted lower numbers. Anchoring effects using paradigms like this have been observed in people's evaluation of gambles (Carlson, 1990; Chapman & Johnson, 1999), estimates of risk and uncertainty (Plous, 1989; Wright & Anderson, 1989), perceptions of self-efficacy (Cervone & Peake, 1986), anticipations of future performance (Switzer & Sniezak, 1991), answers to general knowledge questions (e.g., Jacobowitz & Kahneman, 1995), and willingness to pay for consumer items (Ariely, Loewenstein, & Prelec, 2003).

As the research on anchoring evolved, comparable effects using all sorts of other paradigms have been observed and it appears that such effects are not always the result of insufficient adjustment. Indeed, probably the fairest reading of the anchoring literature is that there is not one anchoring effect produced by insufficient adjustment, but a family of anchoring effects produced by at least three distinct types of psychological processes (Epley, 2004). Epley and Gilovich (2001, 2004, 2005, 2006) have provided evidence that people do indeed adjust insufficiently from at least some anchor values, particularly those that people generate themselves (like the earlier question about Venus). They have found, for example, that people articulate a process of adjusting from self-generated anchors, and that manipulations that should influence adjustment, but not other potential causes of anchoring, have a significant effect on people's judgments. In particular, people who are incidentally nodding their heads while answering, are cognitively busy, or lack incentives for accurate responding tend to be more influenced by *self-generated* anchor values than those

who are incidentally shaking their heads, are not busy, or are given incentives for accuracy.

Manipulations such as these, however, have generally been shown to have no effect on participants' responses in the standard (experimenter-generated) anchoring paradigm pioneered by Tversky and Kahneman (Chapman & Johnson, 1999; Epley & Gilovich, 2001, 2005; Tversky & Kahneman, 1974; see Simmons, Leboeuf, & Nelson, 2010 for an exception). At first glance, this is a bit of a puzzle because it raises the question of why, without insufficient adjustment, anchoring effects would occur. This question has been addressed most extensively by Thomas Mussweiler and Fritz Strack (Mussweiler, 2002; Mussweiler & Strack, 1999, 2000; Strack & Mussweiler, 1997). They maintain that most anchoring effects are the result of the enhanced accessibility of anchor-consistent information. The attempt to answer the initial question posed by the investigator—"Is the Nile longer or shorter than 5,000 [800] miles?"—leads the individual to first test whether the given value is correct—is the Nile 5,000 [or 800] miles long? Because people evaluate hypotheses by attempting to confirm them (Evans, 2007; Snyder & Swann, 1978; Skov & Sherman, 1986), such a search generates evidence disproportionately consistent with the anchor. Mussweiler and Strack (2000) provide support for their analysis by showing that information consistent with the anchor value presented to participants is indeed disproportionately accessible. For example, participants who were asked whether the price of an average German car is higher or lower than a high value were subsequently quick to recognize words associated with expensive cars (Mercedes, BMW); those asked whether the price of an average German car is higher or lower than a modest value were subsequently quick to recognize words associated with inexpensive cars (Volkswagen, Golf).

Oppenheimer, LeBoeuf, and Brewer (2008) have recently shown that the semantic activation elicited by different anchors can be quite general. They asked one group of participants whether the Mississippi River was longer or shorter than 4,800 miles, and another group whether it was longer or shorter than 15 miles. They then asked their participants to draw a line equal to the length of a standard toothpick. Those exposed to the high initial anchor drew longer toothpicks than those exposed to the low initial anchor. This suggests that exposure to the initial anchor activated the general concept of "long" or "short," which influenced their representation (and

production) of a standard toothpick. To test this idea, Oppenheimer and colleagues had participants in a follow-up experiment perform a word completion task after being exposed to high or low anchor values. Participants exposed to the high anchors were more likely to form words connoting bigness (BIG for B_G, LONG for _ONG) than those exposed to the low anchors.

Recent research suggests that there is likely a third source of anchoring effects: pure numeric priming. That is, an anchor activates its own numeric value and those close to it, which are then highly accessible and influential when the person tries to fashion a response. In one notable experiment, participants were asked whether the runway at Hong Kong International Airport was longer or shorter than 7.3 kilometers or 7,300 meters and were then asked to estimate the cost of an unrelated project. Those asked the question in terms of meters gave higher estimates on the second, unrelated task than those asked the question in terms of kilometers—presumably because the latter primed smaller absolute numbers (Wong & Kwong, 2000). Although some have argued otherwise, this does not appear to be the result of the differential accessibility of semantic information consistent with the initial anchor because 7.3 kilometers and 7,300 meters represent the same value, just in different units. More recent research casts further doubt on the possibility that the differential accessibility of anchor-consistent semantic information is responsible for such effects. Critcher and Gilovich (2008) asked participants what percentage of the sales of a P-97 (or P-17) cell phone would be in the European market. Participants estimated a higher percentage of European sales for the P-97 than the P-17. Note that the process that would give rise to the heightened accessibility anchor-consistent semantic information (testing whether the anchor value might be the correct value) is not applicable here. It seems far-fetched to maintain that participants asked themselves whether part of the model label (97 or 17) might be the European market share.

The Negative Model: Normative Neglect and Its Discontents

The "negative" conclusion from this program of research—that intuitive judgments typically reflect only case-specific evidence; that people neglect base rates, evidence diagnosticity, sample size, and other features about the broader distribution—is enough to explain many of the anomalies in probability

judgment listed earlier. If people focus only on the sample-specific evidence, then conservatism should be prevalent when base rates, sample sizes, evidence, and diagnosticity are high, and radical or overconfident judgments should prevail when they are low. This “psychology of evidential neglect” was implicit in the defining papers in the H&B program, and it was later made explicit by Griffin and Tversky’s (1991) “strength-weight” theory and then modeled by Brenner’s (1995, 2003) random support theory. Koehler, Brenner, and Griffin (2002) found substantial support for the basic neglect model in the everyday probabilistic judgments of physicians, economists, and lawyers working in real-world settings. Even weather forecasters, aided by computer projections and immediate outcome feedback, showed substantial neglect of base rate and validity considerations until they received specific feedback about their biases.

As noted earlier in the discussion of the base-rate fallacy and the Tom W. study in particular, criticisms of the “neglect” message began soon after the early laboratory studies were published. One prominent critic claimed that he had “disproved the representativeness heuristic almost before it was published; and therewith...also disproved the base rate fallacy” (Anderson, 1996, p. 17). In particular, Anderson had shown that base rates and case-specific information received about equal weight when manipulated across scenarios in a within-subject design. Tversky and Kahneman (1982) accepted that within-subject designs revealed the *capacity* for rule-based thinking, whereas between-subject designs revealed the *actual application* of rules in practice.

Many economists, whose theories would suffer most if the H&B challenge to classical rationality was widely accepted, wondered about whether the various neglect biases would disappear with appropriate incentives or market conditions. In a series of studies, an economist (Grether, 1992) found that judgments consistent with the Bayesian model did increase very slightly, but significantly, with incentives for accuracy. More important, even in a chance setup (balls sampled from bingo cages), with both sample evidence and base rates determined by drawing balls from a cage, a context that should make the sampling mechanism salient and “transparent,” there was still considerable evidence of heuristic thinking. Similarly, studies of business students in market games involving repeated plays and real incentives also revealed biased judgments in accord with the H&B account (Camerer, 1987), but the biases

seemed to decline with repeated playing of the game (see Camerer & Smith, Chapter 18). It is important to note, however, that studies of judgment in which people actively discovered the base rate for themselves (instead of deciding which of the experimenter’s numbers was relevant to the task) also support a strong form of base-rate neglect (e.g., Dawes, Mirels, Gold, & Donahue, 1993; Griffin & Buehler, 1999; Yates & Estin, 1996; Yates et al., 1998).

We next turn to two critiques that have attracted considerable research attention and raise questions about the fundamental underpinnings of the first wave of the H&B research. The first claim is that findings of the program are merely artifacts of the conversational rules between subject and experimenter; the second is that H&B researchers have confused different definitions of probability.

Some commentators have claimed that many of the apparently “irrational” judgments observed in various studies were actually caused by rules of conversational implicature. There are two versions of this claim: The first is that people actively make sense of their environment, actively search for the appropriate meaning of questions, statements, conversations, and questionnaires, and that the same objective information can mean something different in different social or conversational contexts. This perspective is part of a *constructivist* approach to judgment (Griffin & Ross, 1991) that is consistent with the second wave of H&B research discussed later (e.g., Kahneman & Miller, 1986). Kahneman and Tversky (1982b) themselves discussed the problems with using what they called the “conversational paradigm” and noted that participants were actively involved in figuring out what the experimenters wanted to convey, just as if they were engaged in a face-to-face conversation. In that same chapter, they further noted the relevance of Grice’s maxims of communication to their problems (see Grice, 1975; Hilton & Slugoski, 2000) and later explicitly attempted to develop judgment tasks that avoided the common-language ambiguity of terms such as “and” and “or” (Tversky & Kahneman, 1983).

However, this acknowledgment did not prevent a second and more critical version of the conversational interpretation. The claim is that results of the scenario studies lacked external validity because changes in wording and context could reduce the rate of biased responses to questionnaire scenarios. For example, Macchi (1995) argued that base-rate neglect may arise from textual ambiguity such that the verbal expression of $P(D|H_1)$ is interpreted as

$P(H1|D)$. Thus, the text “The percentage of deaths by suicide is three times higher among single individuals . . .” may be interpreted to mean “within the suicide group the percentage of single individuals who died by suicide is three times higher” (p. 198). To test this hypothesis, Macchi changed the key phrase to read “1% of married individuals and 3% of single individuals commit suicide” and found that this dramatically increased the number of participants who used both the base rate and the specific information provided. Of course, it is possible to reapply a conversational analysis to the revised question, and it is difficult to know when the cycle should end. That is why it is so useful to have a real-world phenomenon to guide the evaluation of laboratory studies that otherwise can get lost in a perpetual cycle of “experiments about experiments.”

The conversational perspective has also focused on the lawyer-engineer paradigm. Some follow-up studies challenged the explanation that the base-rate neglect observed in the original paradigm was due to judgment by representativeness, and they have been widely cited as evidence that heuristic thinking is eliminated in familiar, real-world social settings (e.g., Barone, Maddux, & Snyder, 1997). For example, Zukier and Pepitone (1984) found greater attention to base-rate information when participants were instructed to think like scientists than when participants were instructed to understand the person’s personality. A related study (Schwarz, Strack, Hilton, & Naderer, 1991) reported greater attention to base-rate information when participants were told that the personality sketch was randomly sampled by a computer than when they were told it was written by a psychologist. Thus, one might be tempted (despite the many other demonstrations of representativeness in the laboratory and the real world) to conclude that the proper use of statistical logic depends largely on social roles and contextual implications. However, a closer look at these studies leads to an interpretation more in line with a “constructive” sense-making interpretation that does not undercut the H&B position. In both studies participants were presented only with a low base rate of engineers; inferences about base-rate use were based on changes in judgment in a paradigm that did not manipulate base rate. Thus, these studies suggest not that judgment by representativeness is an artifact of a contrived experimental situation, but rather that heuristics operate upon information that is actively constructed by the perceiver. As noted, one of the first examinations of the role of conversational

implicature (Grice, 1975) in the H&B paradigm was by Kahneman and Tversky in the final chapter of the Kahneman, Slovic, and Tversky (1982) book (Kahneman & Tversky, 1982b, p. 502), which marks the boundary between the first and second waves of the H&B research tradition.

The second major critique is the claim that the H&B program is built solely (and narrowly) on questions about probability judgments for unique events. Some defenders of the “objective” or “frequentist” school of probability have denied any role for the rules of probability in describing events that cannot be replicated in an infinite series. Nonetheless, it is undeniable that physicians, judges, and stockbrokers, along with virtually everyone else, use terms such as “probability” and “chance” to describe their beliefs about unique events. One of the greatest statisticians of the 20th century has described the logical foundation of the subjective probability viewpoint as follows: “the formal rules normally used in probability calculations are also valid, as conditions of consistency for subjective probabilities. You must obey them, not because of any logical, empirical or metaphysical meaning of probability, but simply to avoid throwing money away” (De Finetti, 1970). We note that this point can also be made with respect to throwing away lives, or even throwing away happiness.

The frequentist critics of the H&B approach claim that when the classic demonstrations of heuristics are reframed in terms of aggregate frequency, the biases decline substantially or even disappear (e.g., Cosmides & Tooby, 1996; Gigerenzer, 1994; 1998; Jones, Jones, & Frisch, 1995). However, proponents of the H&B approach have explored this possibility for some time, in what we term the “second wave” of heuristics research. For example, Kahneman and Tversky (1982b) proposed that when making aggregate frequency judgments, people were more likely to recruit statistical rules of reasoning, especially rules of set-inclusion relationships, than when making individual probability judgments; Tversky and Kahneman (1983) proposed that set-inclusion relations were more compelling arguments when framed in frequentistic “counting” contexts; Griffin and Tversky (1992) proposed that aggregate frequency judgments led to greater attention to “background” information such as past performance (including base rates); and Tversky and Koehler (1994) proposed that the violations of set-inclusion relations observed when compound hypotheses were explicitly “unpacked” into elementary

hypotheses would be smaller for frequency than probability judgments. Thus, the dispute between critics and proponents of the H&B tradition is not about whether probability and frequency judgments are psychologically distinct, or that frequency presentations are intrinsically simpler than probability interpretations, or even that the magnitude of biases are typically smaller in frequentistic formulations—the dispute is about the causes of the discrepancy and its implications for understanding the classic demonstrations of judgmental heuristics and heuristic thinking in real-world applications.

According to the H&B approach, the discrepancy between single-event probability and aggregate frequency judgments occurs because aggregate frequency judgments are less amenable to heuristic assessments that operate “holistically” on unique cases and are more sensitive to statistical or logical rules because the application of such rules is more transparent. Furthermore, comparisons of the two tasks involve irrelevant confounds because the two scales of judgment are rarely psychologically parallel (Griffin & Buehler, 1999). According to H&B’s frequentist critics, a “frequency format” is consistent with the evolved software of the mind, and single-event “subjective” probability judgments are inherently unnatural (Gigerenzer, 1998, 1994). Supporting this perspective is evidence that people are extremely efficient, and seemingly unbiased, at encoding and storing the frequencies of letters and words to which they have been exposed. On the other hand, this perspective cannot account for the observation that virtually all uses of the concept “chance” (meaning likelihood) in early English literature are consistent with a subjective, single-event judgment (Bellhouse & Franklin, 1997), nor that people untutored in Bayesian or frequentist statistics regularly use expressions of subjective probability to describe their beliefs about the world. A series of studies by Sloman and his colleagues has provided convincing evidence that frequentistic representations improve probability judgments when and if they lead to more concrete representations of set-inclusion relations (e.g., Barbey & Sloman, 2007; Sloman, Over, Slovak, & Stiebel, 2003).

Heuristics Unbound: Beyond Three Heuristics

As with any initial statement of a theory, the first wave of H&B demonstrations left some empirical anomalies to be explained. One prominent issue was the problem of “causal base rates” (Ajzen, 1977):

When base rates could be given a causal interpretation (e.g., a high proportion of failures on an exam implied that a difficult exam *caused* the failure rate), they received substantial weight in judgment. This led Tversky and Kahneman (1982) to include the computation or assessment of causality or causal propensity (see Cheng & Buehner, Chapter 12) as a basic heuristic operation, and to acknowledge that the distinction between case-specific and population-based information was less sharp than originally proposed. This latter conclusion was reinforced by the finding that people were sometimes most responsive to the size of a sample *relative* to the size of a population (Bar-Hillel, 1982). Such a “matching” approach to sample size implied a broader kind of representativeness calculation, or as Bar-Hillel termed it, a second-order representativeness. The sharp distinction between heuristics that operated on cases, and rules that operated on abstract statistical quantities, it appeared, was not always clear and seemed better captured by a more flexible distinction between “holistic” and “analytic” thinking. Furthermore, the initial statements of the H&B approach contained some ambiguity with regard to whether judgmental heuristics were deliberate strategies to avoid mental effort or were largely automatic processes that were uncontrolled and uncontrollable. These issues were addressed by a second generation of papers on judgmental heuristics by Kahneman and Tversky.

The second wave of heuristics research began with an analysis of the “planning fallacy,” the tendency for people to make optimistic predictions even when aware that similar projects have run well over schedule (Kahneman & Tversky, 1979). This paper introduced a new perceptual metaphor, based on prediction by evaluation, that contrasted an “inside” and an “outside” perspective on a prediction problem. Using an inside or internal perspective, a judge focuses on the specific details of the current case; using an outside perspective, a judge “sees” the specific case as one instance of a broader set of instances. Shortly afterward, a paper on causal reasoning (Tversky & Kahneman, 1982) demonstrated how intuitive or heuristic processes could be applied to both case-specific and distributional information as long as both types of information were in a form amenable to “natural assessments.” For example, base rates that have causal implications (e.g., a sports team that has won 9 of its last 10 games) may induce a computation of a “causal disposition” connected to that team (Kahneman & Varey, 1990a). These two

approaches blurred the distinction between case-specific and statistical information, and instead distinguished between information that can be directly evaluated by natural assessments in a holistic manner (“associationist” computations) and information that requires logical inference (rule-based computations) before it can be used.

A key paper in this second wave of research included the exploration of the *conjunction fallacy* (Tversky & Kahneman, 1983). Although cited primarily for the memorable “Linda problem,” the 1983 paper on the conjunction fallacy further developed the perceptual model of judgmental heuristics and clarified the role of abstract rules in intuitive statistical judgment. In this and related papers (e.g., Kahneman & Miller, 1986; Kahneman & Tversky, 1982a), Kahneman, Tversky, and colleagues distinguished low-level “natural” or routine or basic cognitive assessments that are relatively automatic and spontaneously evoked by the environment, from explicit, higher level judgmental heuristics, which are typically evoked by an attempt to answer a question. Clear candidates for natural assessments include computations of similarity, causal potency, and counterfactual surprise.

Tversky and Kahneman (1983) chose the conjunction rule of probability as a case study in the conflict between heuristic thinking and rule-based reasoning. They argued that the conjunction rule of probability (no conjunction of events can be more probable than either constituent event alone) is one of the most basic and compelling rule of probability and is understood, in some form, by virtually every adult. Thus, in a wide variety of contexts, they examined when the *conjunction rule* would overcome the “conjunction fallacy,” the tendency to judge a conjunction as more probable than its least likely constituent.

For example, participants in one study were given the following description of an individual:

Bill is 34 years old. He is intelligent but unimaginative, compulsive, and generally lifeless. In school, he was strong in mathematics but weak in social studies and humanities.

They were then asked to rank the likelihood of eight possible life outcomes for Bill, including (1) Bill is an accountant, (2) Bill plays jazz for a hobby, and (3) Bill is an accountant who plays jazz for a hobby. Ninety-two percent of the respondents assigned a higher rank to (3) than to (2), even though any state of the world that satisfies (3) automatically satisfies (2) and so (3) cannot be more likely than (2).

Because the conjunction fallacy violates one of the most basic rules of probability theory, Kahneman and Tversky (1983) anticipated controversy and provided a wide-ranging discussion of alternative interpretations. They included additional controls for the possibility that respondents misunderstood the words “and” or “or;” they made sure that the same effects occurred with frequencies as well as probabilities and that the effect applied when reasoning about heart attacks as well as when reasoning about personality descriptions; and they made sure that the same effects obtained with expert and seasoned political forecasters as with college students. Nonetheless, the anticipated controversy ensued, centering around participants’ interpretation of the conjunction (e.g., Mellers, Hertwig, & Kahneman, 2001), the effects of frequency versus probability response formats (Hertwig & Gigerenzer, 1999), and the limits of laboratory research.

Kahneman and Tversky created conjunctions that “seemed” or “felt” more likely than their constituents by using representativeness (combined events or descriptions were more similar to the target than one or both of the constituents, as in the Bill and Linda examples), availability (the combination of events or descriptions were better search cues than one or both of the constituents), and causal relatedness (the combination of events created a causal link that seemed plausible, easy to imagine, and therefore more likely than one or both of the constituent events). The real-world phenomenon that is reflected in the findings from the conjunction fallacy studies is that as predictive scenarios become more detailed, they become objectively more unlikely yet “feel” more likely. The authors noted that many participants reported being simultaneously aware of the relevance of the conjunction rule and the feeling that the conjunction was more likely than the constituent categories. Conjunction fallacies were extremely common in between-subject designs, quite common in nontransparent within-subject designs, and only substantially reduced by a combination of a within-subject design and a frequentistic design in which participants could “see” that the number of people with A *and* B must be less than the number of people with A. Except in special circumstances, then, intuitive judgments do not conform to the rules of probability, even when those rules are known and endorsed by the intuitive judges.

Note how this notion is fundamentally different from the “cognitive miser” model of social cognition. Heuristic judgments are not explained as the

result of too little thought due to cognitive laziness or inadequate motivation, but as the result of uncontrolled “thinking too much” in quick and natural ways. This model of spendthrift automatic processes was termed “mental contamination” by Kahneman and Varey (1990b), who related the basic processes of heuristic thinking to a wide range of perceptual, cognitive, and social examples, including the Stroop effect and motor effects on persuasion.

Whereas the original H&B program focused on situations in which only heuristics were evoked, and the conjunction fallacy paper examined how heuristics and statistical rules might compete, Griffin and Tversky (1991) described how the strength of impression and the weight of statistical evidence might combine. Using the anchoring and adjustment process as the “master heuristic,” they suggested that people typically anchor on the strength of their impressions and then adjust (insufficiently) according to rule-based arguments about sample sizes or evidential validity. In “support theory,” Tversky and his students developed a formal treatment of how perceptions of evidential support are translated into judgments of probability.

Support theory (Rottenstreich & Tversky, 1997; Tversky & Koehler, 1994) was founded, in particular, on earlier observations of systematic violations of extensionality such as the conjunction fallacy and findings from the fault-tree paradigm (Fischhoff, Slovic, & Lichtenstein, 1978). In contrast to probability theory, in which probabilities are assigned to events that obey the laws of set inclusion, in support theory probabilities are assigned to descriptions of events, referred to as *hypotheses*. Support theory thereby allows two different descriptions of the same event to receive different probability judgments, in much the same way that prospect theory accommodated the possibility that different choices might be made to an identical decision depending on how that decision is “framed” or described (Kahneman & Tversky, 1979).

Support theory represents judged probability in terms of the balance of perceived evidential support for a focal hypothesis A and an alternative hypothesis B, such that $P(A,B) = s(A) / [s(A) + s(B)]$. For instance, A might represent the hypothesis that Jack is a lawyer and B the hypothesis that Jack is an engineer. A key feature of support theory is the assumption that hypotheses described at a greater level of detail will tend to have greater perceived support than a hypothesis describing the same event in less detail. For instance, “unpacking” the hypothesis

that Jack is a lawyer into the hypothesis that Jack is either a corporate lawyer, a criminal lawyer, a divorce lawyer, or a tax lawyer tends to increase support and hence, in the earlier example, the judged probability that Jack is a lawyer rather than an engineer. Unpacking the engineer hypothesis, by contrast, is expected to decrease the judged probability that Jack is a lawyer rather than an engineer. Such unpacking effects are particularly likely when the unpacked components are plausible but unlikely to come to mind in evaluating the packed version of the hypothesis; by contrast, unpacking implausible components can actually have the opposite effect, making the unpacked hypothesis seem less likely than its packed counterpart (Sloman, Rottenstreich, Wisniewski, Hadjichristidis, & Fox, 2004).

Support theory offered an overarching account of intuitive probability judgment that could accommodate a variety of heuristic and other reasoning processes by which the judge might evaluate the extent to which a hypothesis is supported by the available evidence. For instance, given a personality sketch of Jack, support for the lawyer hypothesis might be evaluated based on representativeness (i.e., his similarity to a prototypical lawyer). Or, in the absence of personality information, support might be based on the availability of male lawyers in memory. Support for the lawyer hypothesis might even be based on overall frequency or base-rate information. It is notable that the means by which such statistical information is incorporated in the assessment of support need not necessarily follow the specific combination formula of Bayes rule, but it simply serves as an additional argument that may be considered as part of the support assessment process.

In short, support theory continued the development of incorporating a broader set of assessment processes that went beyond basic heuristics and also characterized the role that heuristics play in intuitive probability judgment as a means by which people evaluate how much a body of evidence supports a particular hypothesis. Indeed, many studies using support theory have shown that eliciting ratings of heuristic attributes such as perceived similarity or causal strength and using them as a proxy measure of support in the earlier support theory equation can reproduce intuitive probability judgments quite closely (e.g., Fox, 1999; Koehler, 1996; Tversky & Koehler, 1994). More generally, in terms of the distinction made by Griffin and Tversky, such research has revealed that perceived support typically is highly sensitive to the strength of the available

evidence and largely insensitive to its weight or credence (e.g., Brenner, Griffin, & Koehler, 2012). This suggests that support is often evaluated in a heuristic manner, though the support theory framework itself can accommodate other, or additional, considerations as well.

Along with these developments, led by Kahneman and Tversky, the second wave of research on judgmental heuristics saw substantial contributions from other cognitive and social psychologists. Two notable extensions included the development of the “affect heuristic” by Paul Slovic and colleagues, and the splitting off of perceptual fluency from the availability heuristic and treating it as an additional metacognitive “natural assessment” along with ease of generation. The affect heuristic uses one’s immediate good/bad affective reactions to stimuli as an input to various judgments and decisions such as valuation, agreement, and more generally, approach and avoidance (Slovic, Finucane, Peters, & MacGregor, 2002).

AVAILABILITY’S CLOSE COUSIN: FLUENCY

The mere act of imagining an outcome can make it seem more likely to occur. Imagining one candidate winning an election makes it seem more likely that that candidate will triumph (Carroll, 1978) and imagining what it would be like to have a disease makes it seem that one is more at risk of getting it (Sherman, Cialdini, Schwartzman, & Reynolds, 1985). This effect was originally interpreted as the result of availability: Imagining the event made it more cognitively available and hence it was judged more likely. But what exactly are the “relevant instances” that easily (or not) come to mind when one is asked to estimate the likelihood of having an ulcer?

Another interpretation of these findings centers around the concept of fluency: Thinking of a target event is likely to have a different feel if one had, in fact, mentally tried it on earlier. It is likely to feel more “fluent.” Fluency refers to the experience of ease or difficulty associated with perception or information processing and is somewhat distinct from the ease of generating instances. A clear image is easy to process and fluent. A phonemically irregular word is hard to process and disfluent. People use the metacognitive experience of fluency as a cue when making inferences about all sorts of judgments (Jacoby & Dallas, 1981; Oppenheimer, 2008). People judge fluent names to be more famous (Jacoby, Woloshyn, & Kelley, 1989), fluent objects to be better category members (Whittlesea & Leboe, 2000), and adages

that rhyme to be more valid than those that don’t (McGlone & Tofaghbakhsh, 2000).

In addition to these direct effects on judgment, fluency appears to influence how people process relevant information. A feeling of disfluency while processing information appears to undermine people’s confidence in what they are doing, leading to something of a “go slow, be careful” approach to judgment and decision making. Thus, people are more likely to choose a default option when choosing between consumer products that are made disfluent (Novemsky, Dhar, Schwarz, & Simonson, 2007). Fluency also appears to influence the level of abstraction at which information is encoded. Given that blurry (disfluent) objects tend to appear to be farther away than distinct objects (Tversky & Kahneman, 1974), one might expect disfluent entities more generally to appear relatively far away. Indeed, Alter and Oppenheimer (2008) found that cities are judged to be farther away when their names are presented in a difficult-to-read font.

A Third Wave: Dual-Process and Two-System Accounts of Judgment Heuristics

As Neisser (1963) noted in an early review of dual modes of cognition, “The psychology of thinking seems to breed dichotomies.” Consistent with this observation, social and cognitive psychologists have recognized that people appear to approach various cognitive tasks in two very different ways (Chaiken & Trope, 1999; Evans, 2004; Kahneman, 2011; Sloman, 1996; Strack & Deutsch, 2004). One involves mental processes that are fast, associationist, and often automatic and uncontrolled. The other involves processes that are slower, rule based, and more deliberate. Scholars in both disciplines have devoted a lot of energy trying to specify the nature of these two types of processes, or “systems” of thought, and to delineate when each is operative and how they interact when people make a judgment or choose a course of action. The two systems have been given many names and, following Stanovich (1999), we refer to them simply as “System 1” and “System 2” for ease of exposition (see Evans, Chapter 8; Stanovich, Chapter 22). (To our knowledge, the term “dual processes” first appeared in Wason & Evans, 1975.)

Given Daniel Kahneman’s long-standing interest in visual attention—instantiated in his classic 1973 book *Attention and Effort*—it is not surprising that the H&B program came to incorporate

both controlled and automatic processes. (In the preface to his 1973 book, Kahneman wrote: “While the allocation of attention is flexible and highly responsive to the intentions of the moment, there are pre-attentive mechanisms that operate automatically, outside voluntary control...it is easy to notice several aspects or attributes of an object, but it is difficult or impossible to prevent the perceptual analysis of irrelevant attributes” [p. 7].) The 1983 paper on the conjunction fallacy implicitly provided a dual-system analysis of the competition between automatic intuitive processes and effortful rule-based processes, and this analysis was formalized by Sloman (1996) who also drew upon social psychological models of the conflict between a “gut feeling” and a more considered analysis (Denes-Raj & Epstein, 1994; Epstein, 1991).

Perhaps the most striking evidence of two mental systems that guide judgment and behavior is Epstein’s work on the “ratio bias” phenomenon (Denes-Raj & Epstein, 1994; Epstein, 1991). Epstein told participants that they could win a prize by blindly selecting a jellybean of a given color from one of two urns. One urn had 1 winning jellybean and nine of another, losing color. The second urn had 9 winning jellybeans and 91 of the losing color. What Epstein found was that many participants chose to select from the larger urn that offered lower odds of winning because they couldn’t resist the thought that the larger urn had more winning beans. They did so despite the fact that the chances of winning with each of the urns was explicitly provided for them. When the choice was between a 10% chance in the small urn and a 9% chance in the large urn, 61% of the participants chose the large urn. When it was a contest between 10% in the small urn and 5% in the large urn—odds only half as good in the latter—23% of the participants still chose the large urn.

Epstein attributes this decidedly irrational result to an “experiential” system of reasoning that operates on concrete representations, and hence finds the greater number of winning jellybeans in the large urn to be more promising. This experiential or intuitive impulse, however, usually conflicts with the rational realization that the actual odds are better in the small urn. Some participants explicitly stated that they knew they should pick the smaller urn, but they nonetheless were going with a gut feeling that they were more likely to pick a winner from the large one. This experience of being pulled in two different directions suggests that there are two things—two mental systems—doing the pulling.

This was emphasized by Sloman (1996), who described a possible cognitive architecture consisting of two relatively independent systems to explain the diverse findings implicating dual processes in reasoning, choice, and judgment.

Kahneman and Frederick (2002, 2005; Kahneman, 2011) highlighted these relations between System 1 and System 2 in their influential “third wave” restatement of the H&B program of research. In their “attribute substitution” account, System 1 automatically computes an assessment with some connection to the task at hand—an emotional reaction, a sense of fluency, the similarity between examples or between an example and a category. Both the perceived relevance of the assessment and its immediacy often give rise to the sense that the task is done and that the assessment produced by System 1 *is* the answer being sought. For example, one cause of death is judged to be more common than another because it is easier to think of examples of the former (Slovic, Fischhoff, & Lichtenstein, 1982). One attribute (ease of retrieval) *substitutes* for another, desired attribute (likelihood).

In many circumstances, however, and for a variety of different reasons, System 2 intervenes and deems the automatic assessment inadequate for the task at hand. A more deliberate, rule-based response is given. For example, one might consciously realize, especially if one has received training in statistics and recognizes threats to validity, that a given cause of death is highly available because it is frequently discussed in the media. “In the context of a dual-system view, errors of intuitive judgment raise two questions: ‘What features of system 1 created the error?’ and ‘Why was the error not detected and corrected by system 2?’” (Kahneman & Frederick, 2005, p. 268). The attribute substitution model has captured a great deal of attention because it offered a unified account of a diverse set of judgmental phenomena, such as the role of heuristics and logical rules on probability judgment, happiness assessments, duration neglect in remembered pain, and on contingent valuation methods used to assess people’s willingness to pay (WTP) for such things as environmental remediation. As Kahneman and Frederick (2005, p. 287) summarized:

The original goal of the heuristics and biases program was to understand intuitive judgment under uncertainty. Heuristics were described as a collection of disparate cognitive procedures, related only by their common function in a particular judgmental

domain... It now appears, however, that judgment heuristics are applied in a wide variety of domains and share a common process of *attribute substitution* in which difficult judgments are made by substituting conceptually or semantically related assessments that are simpler and more readily accessible.

The current treatment explicitly addresses the conditions under which intuitive judgments are modified or overridden. Although attribute substitution provides an initial input into many judgments, it need not be the sole basis for them. Initial impressions are often supplemented, moderated or overridden by other considerations, including the recognition of relevant logical rules and the deliberate execution of learned algorithms. The role of these supplemental or alternative inputs depends on characteristics of the judge and the judgment task.

Although the dual-system account of judgmental heuristics is not without its skeptics (e.g., Keren & Schul, 2009), in its very general form it has received broad acceptance. A number of questions, remain, however, about the best way to characterize the operations and interactions of the two systems. Evans (e.g., 2008; see Evans, Chapter 8), for instance, distinguishes default-interventionist dual-process models from parallel-competitive dual-process models. It has been suggested, furthermore, that System 2 should be split into two components reflecting cognitive ability and thinking dispositions, respectively, yielding a triprocess model (Stanovich, 2009). In short, the dual-system approach to judgment under uncertainty has been very influential, but many details will need to be filled in before it can be developed into a comprehensive process-based account of how heuristics operate.

Conclusions

We provided a historical overview of the H&B tradition, its intellectual forebearers, and its evolution through three waves of conceptualization and reconceptualization, but this should not be taken to imply that the program is frozen in the past. In addition to the hearty oak tree of classic H&B research, the program still continues to send out new green shoots of intellectual offspring. One “second-wave” example is a new model of counterfactual reasoning based on a model of semantic evidence that follows from the H&B approach (Miyamoto, Gonzalez, & Tu, 1995). The dual-processing perspective has motivated neuropsychological studies attempting to isolate and locate the brain networks associated with

the “dueling” heuristic and rule-based processes underlying classic H&B demonstrations (e.g., De Neys & Goel, 2011); the impact of experienced versus presented statistical information continues to be an active area of research (e.g., Brenner, Griffin, & Koehler, 2005; Brenner, Griffin, & Koehler, 2012; Fox & Hadar, 2006; Hertwig, Barron, Weber, & Erev, 2004); and the applied impact of the H&B tradition on understanding expert judgment in such fields as finance, political science, law, medicine, and organizational behavior continues to grow (e.g., Koehler, Brenner, & Griffin, 2002; Tetlock, 2005).

Future Directions

Questions to guide future development:

What is the relation between general cognitive ability and susceptibility to heuristic-based judgmental bias?

Are there fundamental individual differences in the tendency to make heuristic-based judgments?

What circumstances facilitate detection and correction of conflict between heuristic and rule-based evaluations?

Are the processes underlying System 2 operations that support “override” of initial, heuristic responses related to more basic inhibitory operations that guide attention in, for example, Stroop, flanker, and go/no-go tasks?

Under what conditions does extended experience in carrying out a particular judgment task reduce susceptibility to base-rate neglect, conjunction errors, and other systematic biases?

Do organizational practices or market interaction consistently attenuate biases associated with use of judgmental heuristics?

Can anchoring and/or adjustment usefully be viewed as the “master heuristic?”

How useful is the distinction between positive versus negative contributions in theory development to psychology more generally?

Acknowledgments

Cognitive Hierarchies and Emotions in Behavioral Game Theory

Colin F. Camerer and Alec Smith

Abstract

Until recently, game theory was not focused on cognitively plausible models of choices in human strategic interactions. This chapter describes two new approaches that do so. The first approach, cognitive hierarchy modeling, assumes that players have different levels of partially accurate representations of what others are likely to do, which vary from heuristic and naïve to highly sophisticated and accurate. There is reasonable evidence that this approach explains choices (better than traditional equilibrium analysis) in dozens of experimental games and some naturally occurring games (e.g., a Swedish lottery, auctions, and consumer reactions to undisclosed quality information about movies). Measurement of eye tracking and functional magnetic resonance imaging (fMRI) activity during games is also suggestive of a cognitive hierarchy. The second approach, psychological games, allows value to depend upon choice consequences *and* on beliefs about what will happen. This modeling framework can link cognition and emotion, and express social emotions such as “guilt.” In a psychological game, guilt is modeled as the negative emotion of knowing that another person is unpleasantly surprised that your choice did not benefit her (as she had expected). Our hope is that these new developments in a traditionally cognitive field (game theory) will engage interest of psychologists and others interested in thinking and social cognition.

Key Words: bounded rationality, cognitive hierarchy, emotions, game theory, psychological games, strategic neuroscience

Introduction

This chapter is about cognitive processes in strategic thinking. The theory of games provides the most comprehensive framework for thinking about the valued outcomes that result from strategic interactions. The theory specifies how “players” (that’s game theory jargon) might choose high-value strategies to guess likely choices of other players. Traditionally, game theory has been focused on finding “solutions” to games based on highly mathematical conceptions of rational forecasting and choice. More recently (starting with Camerer, 1990), behavioral game theory models have extended the rational theories to include stochastic response; limits on inferring

correctly what other players will do; social emotions and considerations such as guilt, anger, reciprocity, or social image; and modulating factors, including inferences about others’ intentions. Two general behavioral models that might interest cognitive psychologists are the focus of this chapter¹: cognitive hierarchy modeling and psychological game theory.

Conventional game theory is typically abstract, mathematically intimidating, computationally implausible, and algorithmically incomplete. It is therefore not surprising that conventional tools have not gained traction in cognitive psychology. Our hope is that the more psychologically plausible behavioral variants could interest cognitive

psychologists. Once limited strategic thinking is the focus, questions of cognitive representation, categorization of different strategic structures, and the nature of social cognition and how cooperation is achieved all become more interesting researchable questions. The question of whether people are using the decision-making algorithms proposed by these behavioral models can also be addressed with observables (such as response times and eye tracking of visual attention) familiar in cognitive psychology. Numerical measures of value and belief derived in these theories can also be used as parametric regressors to identify candidate brain circuits that appear to encode those measures. This general approach has been quite successful in studying simpler nonstrategic choice decisions (Glimcher, Camerer, Fehr, & Poldrack, 2008) but has been applied infrequently to games (see Bhatt & Camerer, 2011).

What Is a Game?

Game theory is the mathematical analysis of strategic interaction. It has become a standard tool in economics and theoretical biology, and it is increasingly used in political science, sociology, and computer science. A game is mathematically defined as a set of players, descriptions of their information, a fixed order of the sequence of choices by different players, and a function mapping players' choices and information to outcomes. Outcomes may include tangibles like corporate profits or poker winnings, as well as intangibles like political gain, status, or reproductive opportunities (in biological and evolutionary psychology models). The specification of a game is completed by a payoff function that attaches a numerical value or "utility" to each outcome.

The standard approach to the analysis of games is to compute an equilibrium point, a set of strategies for each player which are simultaneously best responses to one another. This approach is due originally to John Nash (1950), building on earlier work by Von Neumann and Morgenstern (1944). Solving for equilibrium mathematically requires solving simultaneous equations in which each player's strategy is an input to the other player's calculation of expected payoff. The solution is a collection of strategies, one for each player, where each player's strategy maximizes his expected payoff given the strategies of the other players.

From the beginning of game theory, how equilibrium might arise has been the subject of ongoing discussion. Nash himself suggested that equilibrium beliefs might resolve from changes in "mass action"

as populations learn about what others do and adjust their strategies toward optimization.²

More recently game theorists have considered the epistemic requirements for Nash equilibrium by treating games as interactive decision problems (cf. Brandenburger, 1992). It turns out that Nash equilibrium for n -player games requires very strong assumptions about the players' *mutual* knowledge: that all players share a common prior belief about chance events, know that all players are rational, and know that their beliefs are common knowledge (Aumann & Brandenburger, 1995).³ The latter requirement implies that rational players be able to compute beliefs about the strategies of coplayers and all states of the world, beliefs about beliefs, and so on, ad infinitum.

Two Behavioral Approaches: Cognitive Hierarchy and Psychological Games

Cognitive hierarchy (CH) and psychological games (PG) models both modify assumptions from game theory to capture behavior more realistically.

The CH approach assumes that boundedly rational players are limited in the number of interpersonal iterations of strategic reasoning they can (or choose) to do. There are five elements to any CH predictive model:

1. A distribution of the frequency of level types $f(k)$
2. Actions of level-0 players
3. Beliefs of level- k players (for $k = 1, 2, \dots$) about other players
4. Assessing expected payoffs based on beliefs in (3)
5. A stochastic choice response function based on the expected payoffs in (4)

The typical approach is to make precise assumptions about elements (1–5) and see how well that specific model fits experimental data from different games. Just as in testing a cooking recipe, if the model fails badly then it can be extended and improved.

In Camerer, Ho, and Chong (2004), the distribution of level- k types is assumed to follow a Poisson distribution with a mean value τ . Once the value of τ is chosen, the complete distribution is known. The Poisson distribution has the sensible property that the frequencies of very high-level types k drop off quickly for higher values of k . (For example, if the average number of thinking steps $\tau = 1.5$, then less than 2% of players are expected to do five or more steps of thinking.)

To further specify the model, level-0 types are usually assumed to choose each strategy equally often.⁴ In the CH approach, level- k players know the correct proportions of lower-level players, but they do not realize there are other even higher-level players (perhaps reflecting overconfidence in relative ability). An alternative assumption (called “level- k ” modeling) is that a level- k player thinks *all* other players are at level $k - 1$.

Under these assumptions, each level of player in a hierarchy can then compute the expected payoffs to different strategies: Level 1’s compute their expected payoff (knowing what level 0’s will do); level 2’s compute the expected payoff given their guess about what level 1’s and 0’s do, and how frequent those level types are; and so forth. In the simplest form of the model, players choose the strategy with the highest expected payoff (the “best response”); but it is also easy to use a logistic or power stochastic “better response” function (e.g., Luce, 1959). Because the theory is hierarchical, it is easy to program and solve numerically using a “loop.”

Psychological games models assume that players are rational in the sense that they maximize their expected utility given beliefs and the utility functions of the other players. However, in psychological games models, payoffs are allowed to depend directly upon players’ beliefs, their beliefs about their coplayers’ beliefs, and so on, a dependence that is ruled out in standard game theory. The incorporation of belief-dependent motivations makes it possible to capture concerns about intentions, social image, or even emotions in a game-theoretic framework. For example, in psychological games one person, Conor(C) might be delighted to be surprised by the action of another player, Lexie (L). This is modeled mathematically as C liking when L’s strategy is different than what he (C) expected L to do. Some of these motivations are naturally construed as social emotions, such as guilt (e.g., a person feels bad choosing a strategy which harmed another person P who did not expect it, and she feels less bad if P did expect it).

Of the two approaches, CH and level- k modeling are easy to use and apply to empirical settings. Psychological games are more general, applying to a broader class of games, but are more difficult to adapt to empirical work.

The CH Model

The next section gives some motivating empirical examples of the wide scope of games to which the theory has been applied with some success

(including two kinds of field data), and consistency with data on visual fixation and fMRI. The CH approach is appealing as a potential cognitive algorithm for four reasons:

1. It appears to fit a lot of experimental data from many different games better than equilibrium predictions do (e.g., Camerer et al., 2004; Crawford, Costa-Gomes, & Iribarri, 2010).
2. The specification of how thinking works and creates choices invites measurement of the thinking process with response times, visual fixations on certain payoffs, and transitions between particular payoffs.
3. The CH approach introduces a concept of skill into behavioral game theory. In the CH model, the players with the highest thinking levels (higher k) and most responsive choices (higher λ) are implicitly more skilled. (In equilibrium models, all players are perfectly and equally skilled.)

Next we will describe several empirical games that illustrate how CH reasoning works.

Example 1: p-beauty contest

A simple game that illustrates apparent CH thinking has come to be called the “p-beauty contest game” (or PBC). The name comes from a famous passage in John Maynard Keynes’s book *The General Theory of Employment, Interest and Money*. Keynes wrote:

Professional investment may be likened to those newspaper competitions in which the competitors have to pick out the six prettiest faces from a hundred photographs, the prize being awarded to the competitor whose choice most nearly corresponds to the average preferences of the competitors as a whole; so that each competitor has to pick, not those faces which he himself finds prettiest, but those which he thinks likeliest to catch the fancy of the other competitors, all of whom are looking at the problem from the same point of view. It is not a case of choosing those which, to the best of one’s judgment, are really the prettiest, nor even those which average opinion genuinely thinks the prettiest. We have reached the third degree where we devote our intelligences to anticipating what average opinion expects the average opinion to be. And there are some, I believe, who practice the fourth, fifth and higher degrees. (p. 156)

In the experimental PBC game, people choose numbers from 0 to 100 simultaneously without talking.⁵ The person whose number is closest to p times the average wins a fixed price.

A typical interesting value of p is $2/3$. Then the winner wants to be two-thirds of the way between the average and zero. But, of course, the players all know the other players want to pick $2/3$ of the average. In a Nash equilibrium, everyone accurately forecasts that the average will be X and also chooses a number which is $(2/3)X$. This implies $X = (2/3)X$ or $X^* = 0$.

Intuitively, suppose you had no idea what other people would do, so you chose $2/3$ of $50 = 33$. This is a reasonable choice but is not an equilibrium, since choosing 33 while anticipating 50 leaves a gap between expected behavior of others and likely behavior by oneself. So a person who thinks, “Hey! I’ll pick 33” should then think (to adhere to the equilibrium math), “Hey! *They’ll* pick 33” and then pick 22. This process of imagining, choosing, and revising does not stop until everyone expects 0 to be chosen and also picks 0.

Figure 18.1 shows some data from this game played with experimental subjects and in newspaper and magazine contests (where large groups play for a single large prize). There is some evidence of “spikes” in numbers corresponding to $50p$, $50p^2$ and so on.

Example 2: Betting on selfish rationality of others

Another simple illustration of the CH theory is shown in Table 18.1. In this game a row and column player choose from one of two strategies, T or B (for row) or L or R (for column). The column player always gets 20 for choosing L and 18 for choosing R. The row player gets either 30 or 10 from T, and a sure 20 from B.

If the column player is trying to get the largest payoff, she should always choose L (it guarantees 20 instead of 18). The strategy L is called a “strictly dominant strategy” because it has the highest payoff for every possible choice by the row player.

The row player’s choice is a little trickier. She can get 20 for sure by choosing B. Choosing T is taking a social gamble. If she is confident the column player will try to get 20 and choose L, she should *infer* that $P(L)$ is high. Then the expected value of T is high and she should choose T. However, this inference is essentially a bet on the selfish rationality of the other player. The row player might think the column player will make a mistake or is spiteful (and prefers the (10,18) cell because she gets less absolute payoff but a higher relative payoff compared to the row player). There is a crucial cognitive difference in playing L—which is the right strategy if you want the most money—and playing T—which is the right strategy if you are willing to bet that other players are very likely to choose L because they want to earn the most money.

What does the CH approach predict here? Suppose level-0 players randomize between the two strategies. If $\tau = 1.5$, then $f(0|\tau = 1.5) = .22$. Then half of the level-0 players will choose column R and row B, which is .11% of the whole group.

Level-1 players always choose weakly dominant strategies, so they pick column L (in fact, all higher level column players do, too). Since level-1 row players think L and R choices are equally likely, their expected payoff from T is $30(.5) + 10(.5) = 20$, which is the same as the B payoff; so we assume they randomize equally between T and B. Since $f(1|\tau = 1.5) = .33$, this means the unconditional total frequency of B play for the first two levels is $.11 + .33/2 = .27$.

Level-2 row players think the relative proportions of lower types are $g_2(0) = .22/(.22 + .33) = .40$ and

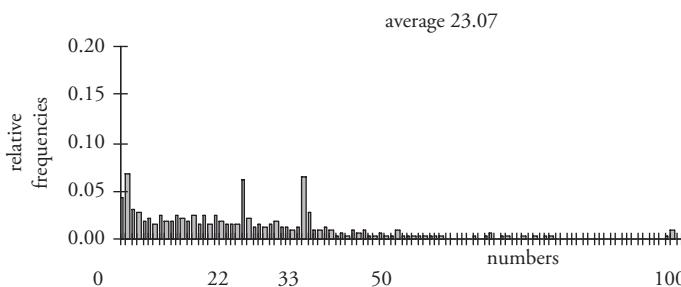

Fig. 18.1 Choices in “ $2/3$ of the average” game (Bosch-Domenech, Garcia-Montalvo, Nagel, & Satorra, 2002).

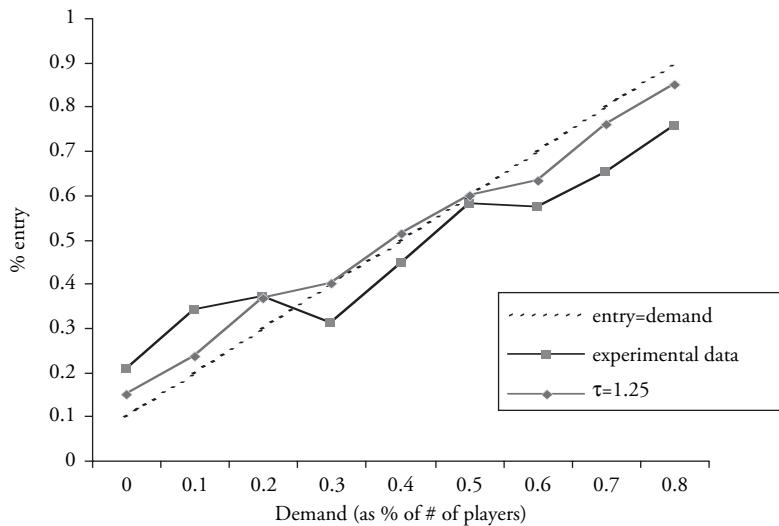

Fig. 18.2 Predicted and observed behavior in entry games (Camerer, Ho, & Chong, 2004). See color figure.

$g_2(1) = .33/(.22 + .33) = .60$. They also think the level 0's play either L or R, but the level 1's choose L for sure. Together, this implies that they believe there is a .20 chance the other person will choose R ($= .5(.40) + 0(.60)$) and an .80 chance they will choose L. With these odds, they prefer to choose T. That is, they are sufficiently confident the other player will “figure it out” and choose the self-serving L that T becomes a good bet to yield the higher payoff of 30.

Putting together all the frequencies $f(k)$ and choice percentages, the overall expected proportion of column R play is .11 and row B play is .27. Note that these proportions go in the direction of the Nash prediction (which is zero for both), but they account more precisely for the chance of mistakes

and misperceptions. Importantly, choices of R should be less common than choices of B. R choices are just careless, while B choices might be careless *or* might be sensible responses to thinking there are a lot of careless players.

Table 18.1 shows that some (unpublished) data from Caltech undergraduate classroom games (for money) over 3 years are generally close to the CH prediction. The R and B choice frequencies are small (as both Nash and CH predict), but B is more common than R.

One potential advantage of CH modeling is that the same general process could apply to games with different economic structures. In both of the two examples, a Nash equilibrium choice can be derived

Table 18.1. Payoffs in Betting Game, Predictions (Nash and CH), and Results From Classroom Demonstrations in 2006–2008

	L	R	Predictions		Data	
			Nash	CH	2006 + 07 + 08	Average
T	30, 20	10, 18	1.00	.73	.81 + .86 + .78	.82
B	20, 20	20, 18	.00	.27	.19 + .14 + .22	.18
Nash	1.00	0				
CH	.89	.11				
2006 + 07 + 08	.95 + .95 + .75	.05 + .05 + .25				
Average	.88	.12				

Note. Upper left is the unique Nash equilibrium.

Table 18.2. Payoffs From Hand T Choice in a “Matching Pennies” Game, Predictions, and Data

		Predictions						
		H	T	Nash	CH	Levels 1–2	Levels 3–4	Data
H		2,0	0,1	.50	.68	1	0	.72
T		0,1	1,0	.50	.32	0	1	.28
Nash		.33	.67					
CH		.26	.74					
Data		.33	.67					

by repeated application of the principle of eliminating “weakly dominated” strategies (i.e., strategies that are never better than another dominating strategy, for all choices by other people, and is actually worse for some choices by others). Hence, these are called “dominance solvable” games. Indeed, the beauty-contest example is among those that motivated CH modeling in the first place, since each step of reasoning corresponds to one more step in deletion of dominated strategies.

Table 18.2 shows predictions and results for an entirely different type of game, called “asymmetric matching pennies.” In this game the row player earns points if the choices match (H,H) or (T,T). The column player wins if they mismatch. There is no pair of strategies that are best responses to each other, so the equilibrium requires choosing a probabilistic “mixture” of strategies. Here, equilibrium analysis makes a bizarre prediction: The row player should choose H and T equally often, while the column player should shy away from H (as if preventing Row from getting the bigger payoff of 2) and choose T 2/3 of the time. (Even more strangely: If the 2 payoff is $x > 1$ in general, then the mixture is always 50–50 for the row player, and is $x/(x+1)$ on T for the column player! That is, in theory changing the payoff of 2 *only* affects the column player, and it does not affect the row player who might earn that payoff.)

The CH approach works differently.⁶ The lower level row players (1–2) are attracted to the possible payoff of 2, and choose H. However, the low-level column players switch to T, and higher level row players (levels 3–4) figure this out and switch to T. The predicted mixture (for $\tau = 1.5$) is actually rather close to the Nash prediction for the column player ($P(T) = .74$ compared to Nash .67), since the

higher-level types choose T more and not H. And indeed, data from column player choices in experiments are close to both predictions. The CH mixture of row play, averaged across type frequencies, is $P(H) = .68$, close to the data average of .72. Thus, the reasonable part of the Nash prediction, which is lopsided play of T and H by column players, is reproduced by CH and is consistent with the data. The unreasonable part of the Nash prediction, that row players choose H and T equally often, is not reproduced and the differing CH prediction is more empirically accurate.

Entry Games

In simple “entry” games, N players simultaneously choose whether to enter a market with demand C. If they stay out, they earn a fixed payoff (\$.50). If they enter, then all the entrants earn \$1 if there are C or fewer entrants, and they earn 0 if there are more than C entrants. It is easy to see that the equilibrium pattern of play is for *exactly* C people to enter; then they each earn \$1 and those who stay out earn \$.50. If one of the stayer-outers switched and entered, she would tip the market and cause the C + 1 entrants to earn 0. Since this would lower her own payoff, she will stay put. So the pattern is an equilibrium.

However, there is a problem remaining (it’s a common one in game theory): How does the group collectively decide, without talking, *which* of the C people enter and earn \$1? Everybody would like to be in the select group of C entrants if they can; but if too many enter they all suffer.⁷ This is a familiar problem of “coordinating” to reach one of many different equilibria.

The first experiments on this type of entry game were done by a team of economists (James Brander and Richard Thaler) and a psychologist, Daniel Kahneman. They were never fully published but were described in a chapter by Kahneman (1988). Kahneman says they were amazed how close the number of total entrants was to the announced demand C (which varied over trials). “To a psychologist,” he wrote, “it looked like magic.” Since then, a couple of dozen studies have explored variants of these games and reported similar degrees of coordination (e.g., Duffy & Hopkins, 2005).

Let’s see if cognitive hierarchy can produce the magic. Suppose level-0 players enter and stay out equally often, and ignore C. If level-1 players anticipate this, they will think there are too many entrants for $C < (N/2)$ and too few if $C > (N/2) - 1$. Level-1 players will therefore enter at high values

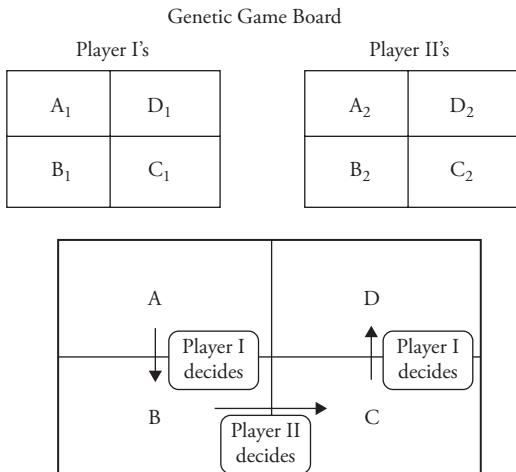

Fig. 18.3 The game board from Hedden and Zhang (2002). Generic game structure with arrows indicating direction of play.

of C. Notice that level-1 players are helping the group move toward the equilibrium. Level 1's undo the damage done by the level 0's, whoever enter at low C, by staying out, which reduces the overall entry rate for low C. They also exploit the opportunity that remains for high C, by entering, which increases the overall entry rate. Combining the two levels, there will be less entry at low C and more entry at high C (it will look like a step function; see Camerer et al., 2004).

Furthermore, it turns out that adding higher-level thinkers continues to push the population profile toward an overall entry level that is close to C. The theory makes three sharp predictions: (1) Plotting entry rates (as a % of N) against C/N should yield a regressive line which crosses at (.5, .5). (2) Entry rates should be too high for C/N < .5 and too low for C/N > .5. (3) Entry should be increasing in C, and relatively close, even without any learning at all (e.g., in the first period of the game).

Figure 18.2 illustrates a CH model prediction with $\tau = 1.25$, single-period data with no feedback from Camerer et al. (2004), and the equilibrium (a 45-degree line). Except for some nonmonotonic dips in the experimental data (easily accounted for by sampling error), the predictions are roughly accurate.

The point of this example is that approximate equilibration can be produced, as if by “magic,” purely from cognitive hierarchy thinking without any learning or communication needed. These data are not solid proof that cognitive hierarchy reasoning is occurring in this game, but it does show how, in principle, the cognitive hierarchy approach can

explain both deviations from Nash equilibrium (in the beauty contest, betting, and matching pennies games that were described earlier), and also surprising conformity to Nash equilibrium (in this entry game).

Private Information

The trickiest class of games we will discuss, briefly, involve “private information.” The standard modeling approach is to assume there is a hidden variable, X , which has a possible distribution $p(X)$ that is commonly known to both players (Harsanyi, 1967).⁸ The informed player I knows the exact value X from the distribution, and both players know that only I knows the value. For example, in card games like poker, players know the possible set of cards their opponent might have, and they know that the opponent knows exactly what the cards are.

The cognitive challenge that is special to private information games is to infer what a player’s actions, whether they are actually taken or hypothetical, might reveal about his information. Various experimental and field data indicate that some players are not very good at inferring hidden information from observed action (or anticipating the inferable information).

A simple and powerful example is the “acquire-a-company” problem introduced in economics by Akerlof (1970) and studied empirically by Bazerman and Samuelson (1983). In this game, a privately held company has a value which is perceived by outsiders to be uniformly distributed from 0 to 100 (i.e., all values in that range are equally likely). The company knows its exact value, and outsiders know that the company knows (due to the common prior assumption).

A bidder can operate the company much better, so that whatever the hidden value V is, it is worth $1.5V$ to them. They make a take-it-or-leave-it (Boulwarean) offer of a price P . The bargaining could hardly be simpler: The company sells if the price P is above “hidden” value V —which the bidder knows that the company knows—and keeps the company otherwise. The bidder wants to maximize the expected “surplus” gain between the average of the values $1.5V$ he is likely to receive and the price.

What would you bid? The optimal bid is surprising, though the algebra behind the answer is not too hard. The chance of getting the company is the chance that V is less than P , which is $P/100$ (e.g., if $P = 60$ then 60% of the time the value is below P and the company changes hands). If the

company is sold, then the value must be below P , so the expected value to the seller is the average of the values in the interval $[0, P]$, which is $P/2$. The net expected value is therefore $(P/100)$ times expected profit *if sold*, which is $1.5*(P/2) - P = -1/4P$. There is no way to make a profit on average. The optimal bid is zero!

However, typical distributions of bids are between 50 and 75. This results in a “winner’s curse” in which bidders “win” the company but fail to account for the fact that they only won because the company had a low value. This phenomenon was first observed in field studies of oil-lease bidding (Capen et al., 1971) and has been shown in many lab and field data sets since then. The general principle that people have a hard time guessing the implications of private information for actions others will take shows up in many economic settings (a kind of strategic naivete; e.g., Brocas et al., 2009).

The CH approach can easily explain strategic naivete as a consequence of level-1 behavior. If level-1 players think that level-0 players’ choices do not depend on private information, then they will ignore the link between choices and information.

Eye-Tracking Evidence

A potential advantage of cognitive hierarchy approaches is that cognitive measures associated with the algorithmic steps players are assumed to use, in theory, could be collected along with choices. For psychologists this is obvious, but, amazingly, it is a rather radical position in economics and most areas of game theory!

The easiest and cheapest method is to record what information people are looking at as they play games. Eye-tracking measures visual fixations using video-based eye tracking, typically every 5–50 msec. Cameras look into the eye and adjust for head motion to guess where the eyes are looking (usually with excellent precision). Most eye trackers record pupil dilation as well, which is useful as a measure of cognitive difficulty or arousal.

Since game theory is about interactions among two or more people, it is especially useful to have a recording technology that scales up to enable recording of several people at the same time. One widely used method is called “Mouselab.” In Mouselab, information that is used in strategic computations, in theory, is hidden in labeled boxes, which “open up” when a mouse is moved into them.⁹

Several studies have shown that lookup patterns often correspond roughly, and sometimes quite closely,

to different numbers of steps of thinking. We’ll present one example (see also Crawford et al., 2010).

Example 1: Alternating-offer bargaining

A popular approach to modeling bargaining is to assume that players bargain over a known sum of joint gain (sometimes called “surplus,” like the valuable gap between the highest price a buyer will pay and the lowest price a seller will accept). However, as time passes, the amount of joint gain “shrinks” due to impatience or other costs. Players alternate, making offers back and forth (Rubinstein, 1982).

A three-period version of this game has been studied in many experiments. The amount divided in the first round is \$5, which then shrinks to \$2.50, \$1.25, and 0 in later rounds (the last round is an “ultimatum game”). If players are selfish and maximize their own payoffs, and believe that others are too, the “subgame perfect” equilibrium (SPE) offer by the first person who offers (player 1), to player 2, should be \$1.25. However, deriving this offer either requires some process of learning or communication, or an analysis using “backward induction” to deduce what offers would be made and accepted in all future rounds, then working back to the first round. Early experiments showed conflicting results in this game. Neelin et al. (1988) found that average offers were around \$2, and many were equal splits of \$2.50 each. Earlier, Binmore et al. (1985) found similar results in the first round of choices but also found that a small amount of experience with “role reversal” (player 2’s switching to the player 1 first-offer position) moved offers sharply toward the SPE offer of \$1.25. Other evidence from simpler ultimatum games showed that people seem to care about fairness and are willing to reject a \$2 offer out of \$10 about half the time, to punish a bargaining partner they think has been unfair and greedy (Camerer, 2003).

So are the offers around \$2 due to correct anticipation of fairness-influenced behavior or to limited understanding of how the future rounds of bargaining might shape reactions in the first round? To find out, Camerer et al. (1993) and Johnson et al. (2002) did the same type of experiment but hid the amounts being bargained over in each round in boxes that could be opened, or “looked up,” by moving a mouse into those boxes (an impoverished experimenter’s version of video-based eye tracking).

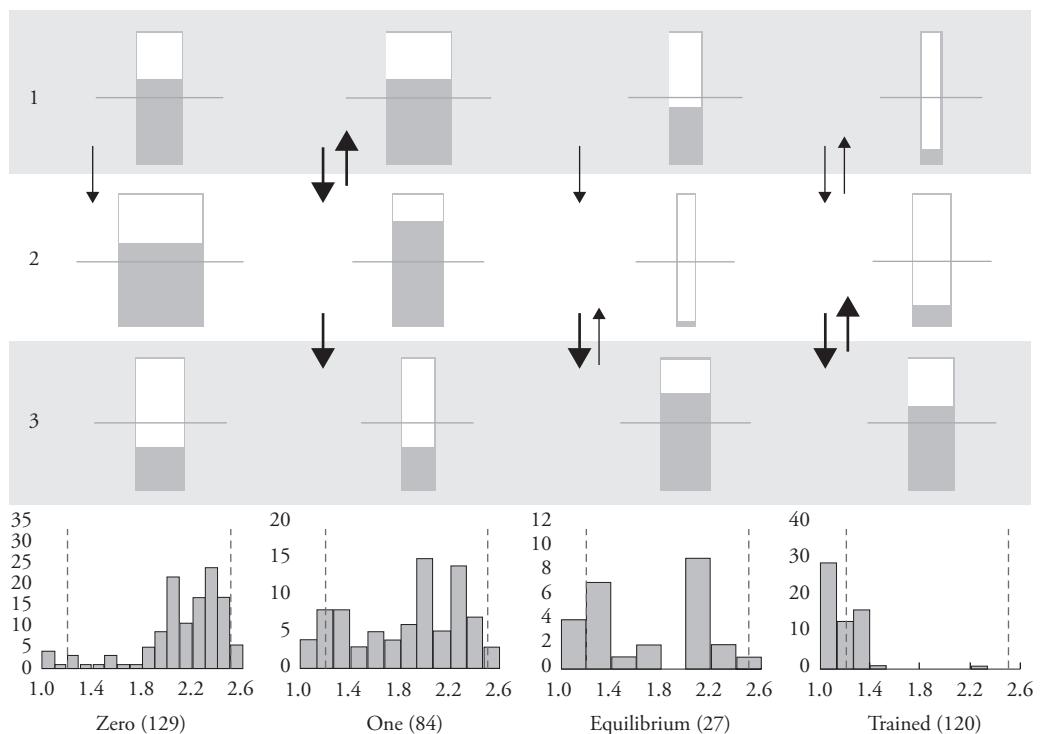

Fig. 18.4 An icon graph of visual attention in three rounds of bargaining (1, 2, and 3) and corresponding distributions of offers. Each column represents a different “type” of person-trial classified by visual attention. See color figure.

They found that most people who offered amounts between the equal split of \$2.50 and the SPE of \$1.25 were not looking ahead at possible future payoffs as backward induction requires. In fact, in 10%–20% of the trials the round 2 and round 3 boxes were not opened at all!

Figure 18.4 illustrates the basic results. The top rectangular “icon graphs” visually represent the relative amounts of time bargainers spent looking at each payoff box (the shaded area) and numbers of different lookups (rectangle width). The bold arrows indicate the relative number of transitions from one box to the next (with averages of less than one transition omitted).

Each column represents a group of trials that are preclassified by lookup patterns. The first column ($N = 129$ trials) averages people who looked more often at the period 1 box than at the future period boxes (indicating “level-0” planning). The second column ($N = 84$) indicates people who looked longer at the second box than the first and third (indicating “level One” planning with substantial focus one step ahead). The third column ($N = 27$) indicates the smaller number of “equilibrium” trials

in which the third box is looked at the most. Note that in the level-1 and Equilibrium trials, there are also many transitions between boxes one and two, and boxes two and three, respectively. Finally, the fourth and last column shows people who were briefly trained in backward induction, then played a computerized opponent that (they were told) planned ahead, acted selfishly, and expected the same from its opponents.

The main pattern to notice is that offer distributions (shown at the bottom of each column) shift from right (fairer, indicated by the right dotted line) to left (closer to selfish SPE, the left dotted line) as players literally look ahead more. The link between lookups and higher-than-predicted offers clearly shows that offers above the SPE, in the direction of equal splits of the first round amount, are partly due to limits on attention and computation about future values. Even in the few equilibrium trials, offers are bimodal, clustered around \$1.25 and \$2.00. However, offers are rather tightly clustered around the SPE prediction of \$1.25 in the “trained” condition. This result indicates, importantly, that backward induction is not actually that cognitively challenging to execute (after instruction, they can

easily do it), but instead it is an unnatural heuristic that does not readily spring to the minds of even analytical college students.

fMRI Evidence

Several neural studies have explored which brain regions are most active in different types of strategic thinking. The earliest studies showed differential activation when playing a game against a computer compared to a randomized opponent (e.g., Coricelli & Nagel, 2009; Gallagher et al., 2002; McCabe et al., 2001).

One of the cleanest results, and an exemplar of the composite picture emerging from other studies, is from Coricelli and Nagel's (2009) study of the beauty contest game. Their subjects played 13 different games with different target multipliers p (e.g., $p = 2/3, 1, 3/2$, etc.). On each trial, subjects chose numbers in the interval [0,100] playing against either human subjects or against a random computer opponent. Using behavioral choices, most subjects can be classified into either level 1 ($n = 10$; choosing p times 50) or level 2 ($n = 7$; choosing p times p times 50, as if anticipating the play of level-1 opponents).

Figure 18.7 shows brain areas that were differentially active when playing human opponents compared to computer opponents, and in which that human-computer differential is larger in level-2 players compared to level-1 players. The crucial areas are bilateral temporoparietal junction (TPJ), MPFC/paracingulate, and VMPFC.¹⁰ These regions are thought to be part of a general mentalizing circuit, along with posterior cingulate regions (Amodio & Frith, 2006).

In recent studies, at least four areas are reliably activated in higher-level strategic thinking: dorsomedial prefrontal cortex (DMPFC), precuneus/posterior cingulate, insula, and dorsolateral prefrontal cortex (DLPFC). Next we summarize some of the simplest results.

DMPFC activity is evident in Figure 18.7. It is also active in response to nonequilibrium choices (where subjects' guesses about what others will do are wrong; Bhatt & Camerer, 2005) and uncertainty about strategic sophistication of an opponent (Yoshida et al., 2009). In addition, DMPFC activity is related to the "influence value" of current choices on future rewards, filtered through the effect of a person's future choices on an opponent's future choices (Hampton, Bossaerts, & O'Doherty, 2008; aka "strategic teaching"; Camerer, Ho, & Chong, 2002; Chong, Camerer, & Ho, 2006). Amodio and

Frith (2006) suggest an intriguing hypothesis: that mentalizing-value activation for simpler to more complex action value computations is differentially located along a posterior-to-anterior (back-to-front) gradient in DMPFC. Indeed, the latter three studies show activation roughly in a posterior-to-anterior gradient (Tailarach $y = 36, 48, 63$; and $y = 48$ in Coricelli & Nagel, 2009) that corresponds to increasing complexity.

Activity in the precuneus (adjacent to posterior cingulate) is associated with economic performance in games ("strategic IQ;" Bhatt & Camerer, 2005) and difficulty of strategic calculations (Kuo et al., 2009). Precuneus is a busy region, with reciprocal connections to MPFC, cingulate, and DLPFC (Cavanna & Trimble, 2006). It is also activated by a wide variety of higher-order cognitions, including perspective-taking and attentional control (as well as the "default network" active at rest; see Bhatt & Camerer, 2011). It is likely that precuneus is not activated in strategic thinking, per se, but only in special types of thinking that require taking unusual perspectives (e.g., thinking about what other people will do) and shifting mental attention back and forth.

The insula is known to be involved in interoceptive integration of bodily signals and cognition. Disgust, physical pain, empathy for others in pain, and pain from social rejection activate insula (Eisenberger et al., 2003; Kross et al., 2011). Financial uncertainty (Preuschoff, Quartz, & Bossaerts, 2008), interpersonal unfairness (Hsu et al., 2008; Sanfey et al., 2003), avoidance of guilt in trust games (Chang et al., 2011), and "coaxing" or second-try signals in trust games also activate insula. In strategic studies, Bhatt and Camerer (2005) found that higher insula activity is associated with lower strategic IQ (performance).

The DLPFC is involved in working memory, goal maintenance, and inhibition of automatic prepotent responses. Differential activity there is also associated with the level of strategic thinking (Yoshida et al., 2009) with stronger response to human opponents in higher-level strategic thinkers (Coricelli & Nagel, 2009), and with maintaining level-2 deception in bargaining games (Bhatt et al., 2010)¹¹

Do Thinking Steps Vary With People or Games?

To what extent do steps of thinking vary systematically across people or game structures? From a cognitive point of view, it is likely that there is *some* intrapersonal stability because of differences in working memory, strategic savvy, exposure to game

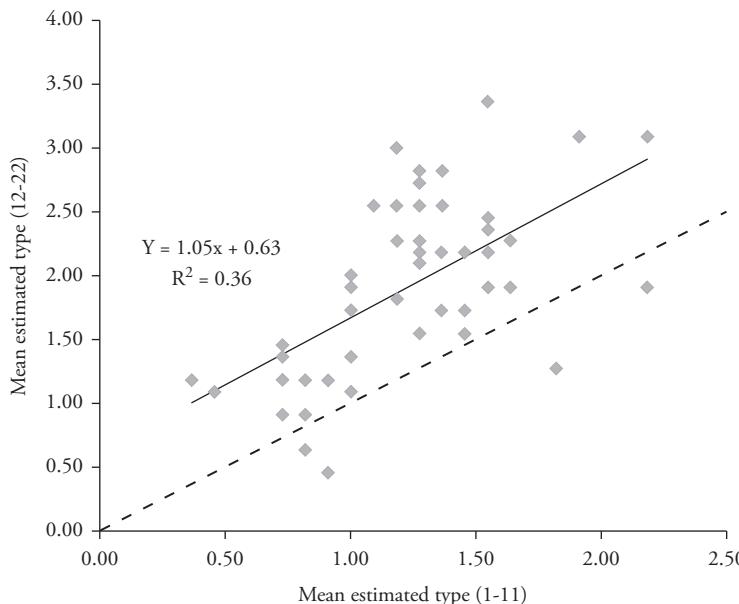

Fig. 18.5 Estimated strategic level types for each individual in two sets of 11 different games (Chong, Camerer, and Ho, 2005). Estimated types are correlated in two sets ($r = .61$).

theory, experience in sports betting or poker, task motivation, and so on. However, it is also likely that there are differences in the degree of sophistication (measured by τ) across games because of an interaction between game complexity and working memory, or how well the surface game structure maps onto evolutionarily familiar games.¹²

To date, these sources of level differences have not been explored very much. Chong, Ho, and Camerer (2005) note some educational differences (Caltech students are estimated to do .5 steps of thinking more than subjects from a nearby community college) and an absence of a gender effect. Other studies have showed modest associations ($r = .3$) between strategic levels and working memory (digit span; Devetag & Warglien, 2003) and the “eyes of the mind” test of emotion detection (Georganas, Healy, & Weber, 2010).

Many papers have reported some degree of cross-game type stability in level classification. Studies that compare a choice in one game with one different game report low stability (Burchardi & Penczynski, 2010; Georganas et al., 2010). However, as is well known in personality psychology and psychometrics, intrapersonal reliability typically increases with the number of items used to construct a scale. Other studies using more game choices to classify report much higher correlations (comparable to Big 5 personality measures) (Bhui & Camerer, research in progress).

As one illustration of potential type stability, Figure 18.5 below shows estimated types for individuals

using the first 11 games in a 22-game series (x-axis) and types for the same individuals using the last 11 games. The correlation is quite high ($r = .61$). There is also a slight upward drift across the games (the average level is higher in the last 11 games compared to the first), consistent with a transfer or practice effect, even though there is no feedback during the 22 games (see also Weber, 2003).

Field Data

Since controlled experimentation came late to economics (c. 1960) compared to psychology, there is a long-standing skepticism about whether theories that work in simple lab settings generalize to naturally occurring economic activity. Five studies have applied CH or level-k modeling to auctions (Gillen, 2009), strategic thinking in managerial choices (Goldfarb & Yang, 2009; Goldfarb & Xiao, in-press), and box office reaction when movies are not shown to critics before release (Brown, Camerer, & Lovallo, in press).

One study is described here as an example (Östling et al., 2011). In 2007 the Swedish Lottery created a game in which people pay 1 euro to enter a lottery. Each paying entrant chooses an integer 1–99,999. The *lowest unique positive integer* (hence, the acronym LUPI) wins a large prize.

The symmetric equilibrium is a probabilistic profile of how often different numbers are chosen (a “mixed” equilibrium). The lowest numbers are always chosen more often (e.g., 1 is chosen most often); the rate of decline in the frequency of choice is accelerating up

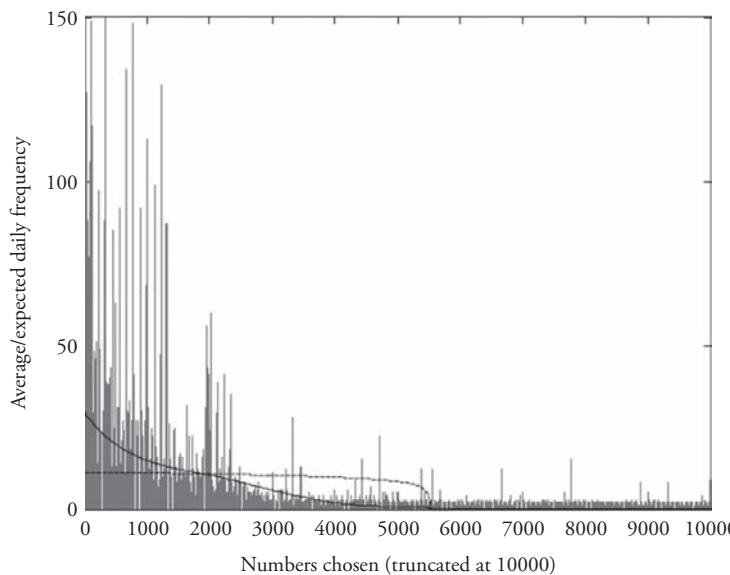

Fig. 18.6 Numbers chosen in week 1 of Swedish LUPI lottery ($N = \text{approximately } 350,000$). Dotted line indicates mixed Nash equilibrium. Solid line indicate stochastic cognitive hierarchy (CH) model with two free parameters. Best-fitting average steps of thinking is $\tau = 1.80$ and $\lambda = .0043$ (logit response).

to a sharp inflection point (number 5,513); and the rate of decline slows down after 5,513.

Figure 18.6 shows the data from only the lowest 10% of the number range, from 1–10,000 (higher number choices are rare, as the theory predicts). The predicted Nash equilibrium is shown by a dotted line—a flat “shelf” of choice probability from 1 to 5,513, then a sharp drop. A fitted version of the CH model is indicated by the solid line. CH can explain the large frequency of low number choices (below 1,500), since these correspond to low levels of strategic thinking (i.e., people don’t realize everyone else is choosing low numbers, too). Since level-0 types randomize, their behavior produces too many high numbers (above 5,000). Since the lowest and highest numbers are chosen too often according to CH, compared to the equilibrium mixture, CH also

implies a gap between predicted and actual choices in the range 2,500–5,000. This basic pattern was replicated in a lab experiment with a similar structure. While there are clear deviations from Nash equilibrium, consistent with evidence of limited strategic thinking, in our view the Nash theory prediction is not bad considering that it uses no free parameters and comes from an equation which is elegant in structure but difficult to derive and solve.

The LUPI game was played in Sweden for 49 days in a row, and results were broadcast on a nightly TV show. Analysis indicates an imitate-the-winner fictive learning process, since choices on one day move in the direction of 600-number range around the previous day’s winner. The result of this imitation is that every statistical feature of the numbers chosen moves toward the equilibrium across the 7 weeks.

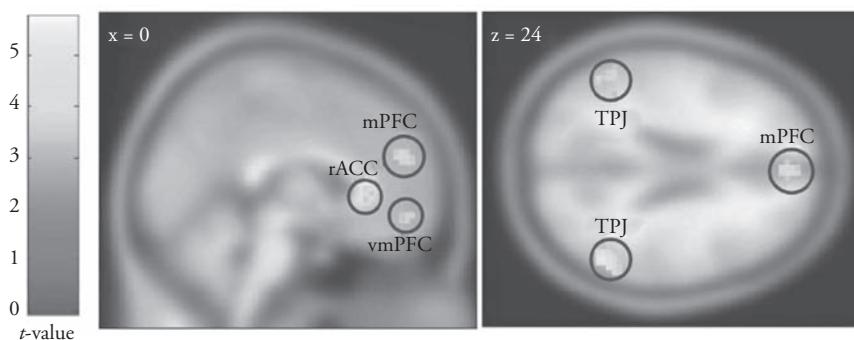

Fig. 18.7 Brain regions more active in level-2 reasoners compared to level-1 reasoners (classified by choices), differentially in playing human compared to computer opponents. mPFC, medial prefrontal cortex; rACC, rostral anterior cingulate cortex; TPJ, temporoparietal junction; vmPFC, ventromedial prefrontal cortex. (From Coricelli & Nagel, 2009, Fig. S2a.) See color figure.

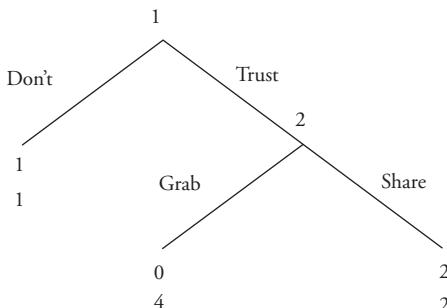

Fig. 18.8 A simple trust game (Dufwenberg & Gneezy, 2000).

For example, in the last week the average number is 2,484, within 4% of the predicted value of 2,595.

Psychological Games

In many strategic interactions, our own beliefs or beliefs of other people seem to influence how we value consequences. For example, surprising a person with a wonderful gift that is perfect for her is more fun for everyone than if the person had asked for it. Some of that pleasure comes from the surprise itself.

This type of pattern can be modeled as a “psychological game” (Geanakoplos, Pearce, & Stacchetti, 1989; Battigalli & Dufwenberg, 2009). PGs are an extension of standard games in which the utility evaluations of outcomes can depend on beliefs about what was thought to be likely to happen (as well as typical material consequences). This approach requires thinking and reasoning since the belief is derived from analysis of the other person’s motives. Together these papers provide tools for incorporating motivations such as intentions, social norms, and emotions into game-theoretic models.

Emotions are an important belief-dependent motivation. Anxiety, disappointment, elation, frustration, guilt, joy, regret, and shame, among other emotions, can all be conceived of as belief-dependent incentives or motivations and incorporated into models of behavior using tools from psychological game theory.

One example is guilt: Baumeister, Stillwell, and Heatherton (1994) write: “If people feel guilty for hurting their partners...and for failing to live up to their expectations, they will alter their behavior (to avoid guilt).” Battigalli and Dufwenberg (2007) operationalize the notion that people will anticipate and avoid guilt in their model of guilt aversion. In their model, players derive positive utility from both material payoffs and negative utility from

guilt. Players feel guilty if their behavior disappoints a coplayer relative to his expectations.¹³

Consider Figure 18.8, which illustrates a simple trust game from Dufwenberg (2002). Player 1 may choose either “Trust” or “Don’t.” In the first case player 1 gets the move, while after a choice of “Don’t” the game ends and each player gets payoff 1. If player 2 gets the move, she chooses between “Grab” and “Share.” The payoffs to Grab are 0 for player 1 and 4 for player 2.

The subgame perfect equilibrium of this game for selfish players is for Player 2 to choose Grab if she gets the move since it results in a higher payoff for her than choosing Share. Player 1 anticipates this behavior and chooses Don’t to avoid receiving 0. Both players receive a payoff of 1, which is inefficient.

Now suppose that Player 2 is guilt averse. Then her utility depends not only on her material payoff but also on how much she “lets down” player 1 relative to his expectations. Let p be the probability that player 1 assigns to “Share.” Let p' represent Player 2’s (point) belief regarding p , and suppose that 2’s payoff from Grab is then $4 - \theta p$, where theta represents player 2’s sensitivity to guilt. If player 1 chooses Trust it must be that p is greater than $\frac{1}{2}$; otherwise player 1 would choose Don’t. Then if $\theta \geq 2$, player 2 will choose Share to avoid the guilt from letting down Player 1. Knowing this, player 1 will choose Trust. In this outcome both players receive 2 (instead of 1 in the selfish subgame perfect equilibrium), illustrating how guilt aversion can foster trust and cooperation where selfish behavior leads to inefficiency.

A number of experiments have studied guilt aversion in the context of trust games, including Dufwenberg and Gneezy (2000), Charness and Dufwenberg (2006, 2011), and Reuben et al. (2009). All of these papers find evidence that a desire to avoid guilt motivates players to behave unselfishly by reciprocating trust (for a contrary opinion see Ellingsen et al., 2010). Recent fMRI evidence (Chang et al., 2011) suggests that avoiding guilt in trust games is associated with increased activity in the anterior insula.

Psychological game theory also may be employed to model other social emotions such as shame (Tadelis, 2011) or anger (Smith, 2009) or to import existing models of emotions such as disappointment, elation, regret, and rejoicing (Bell, 1982, 1985; Loomes & Sugden, 1982, 1986) into games.¹⁴ Battigalli and Dufwenberg (2009) provide some examples of these applications. These models are just a glimpse of the potential applications of

psychological game theory to the interaction of emotion and cognition in social interactions.

Another important application of psychological game theory is sociological concerns, such as reciprocity (which may be driven by emotions). In an important work, Rabin (1993) models reciprocity via functions that capture a player's "kindness" to his coplayer and the other player's kindness to him. These kindness functions depend on the players' beliefs regarding each other's actions and their beliefs about each other's beliefs. Dufwenberg and Kirchsteiger (2004) and Falk and Fischbacher (2006) extend Rabin's model to sequential games.

Psychological game theory provides a useful toolkit for incorporating psychological, social, and cultural factors into formal models of decision making and social interactions. Many applications remain to be discovered and tested via experiment.

Conclusions

Compared to its impact on other disciplines, game theory has had less impact in cognitive psychology so far. This is likely because many of the analytical concepts used to derive predictions about human behavior do not seem to correspond closely to cognitive mechanisms. Some game theorists have also complained about this unrealism. Eric Van Damme (1999) wrote:

Without having a broad set of facts on which to theorize, there is a certain danger of spending too much time on models that are mathematically elegant, yet have little connection to actual behavior. At present our empirical knowledge is inadequate and it is an interesting question why game theorists have not turned more frequently to psychologists for information about the learning and information processes used by humans (p. 204).

But recently an approach called behavioral game theory has been developed that uses psychological ideas to explain both choices in many different games, and associated cognitive and biological (Bhatt & Camerer, 2011; Camerer, 2003).

This chapter discussed two elements of behavioral game theory that might be of most interest to cognitive psychologists: the cognitive hierarchy approach; and psychological games in which outcome values can depend on beliefs, often accompanied by emotions (e.g., a low bargaining offer could create anger if you expected more, or joy if you expected less).

The cognitive hierarchy approach assumes that some players choose rapidly and heuristically

("level 0") and higher-level players correctly anticipate what lower-level players do. The theory has been used to explain behavior in lab games which is both far from and close to equilibrium in different games, is supported by evidence from visual eye tracking and Mouselab, is evident in "theory of mind" circuitry during fMRI, and also can explain some patterns in field data (such as the Swedish LUPI lottery).

Research on psychological games is less well developed empirically but has much promise for understanding phenomena like "social image," norm enforcement, how emotions are created by surprises, and the relationship between emotion, cognition, and strategic behavior.

Future Directions

There are a lot of open research questions in which combining cognitive science and game theory would be useful. Here are a few:

1. Can the distribution of level types be derived endogenously from more basic principles of cognitive difficulty and perceived benefit, or perhaps from evolutionary constraint on working memory and theory of mind (e.g., Stahl, 1993)?
2. CH models have the potential to describe differences in skill or experience. Skill arises in everyday discussions about even simple games like rock, paper, and scissors; in games with private information such as poker; and games that tax working memory such as chess. Are skill differences general or domain-specific? Can skill be taught? How does skill development change cognition and neural activity?
3. The computational approach to strategic thinking in behavioral game theory could be useful for understanding the symptoms, etiology, and treatment of some psychiatric disorders. Disorders could be conceptualized as failures to correctly anticipate what other people do and feel in social interactions or to make good choices given sensible beliefs. For example, in repeated trust games King-Casas et al. (2008) found that patients with borderline personality disorder did not have typical activity in insula cortex in response to being mistrusted and earned less money because of the inability to maintain steady reciprocal trust behaviorally. Chiu et al. (2008) found that autism patients had less activity in a region of anterior cingulate that typically encodes signals of valuation during one's own strategic choices (compared to choices of others).

4. A small emerging approach in the study of literature focuses on the number of mental states that readers can track and their effect (e.g., Zunshine, 2006). One theory is that three mental states are a socially important reasonable number (e.g., love triangles) and are therefore narratively engaging. Work on cognitive schemas, social categorization, computational linguistics, and game theory could therefore be of interest in the study of literature.
5. Formal models connecting emotions with beliefs, actions, and payoffs can illuminate the relationships between affective states and behavior. The utility function approach to modeling emotions makes clear that emotions influence behavior only when the hedonic benefits of emotional behavior outweigh the costs. This approach, which considers even emotion-driven behavior as the outcome of an optimization problem (perhaps sculpted by human evolution rather than conscious cost-benefit, of course), promises to open up new avenues of research studying the relationship between emotion and strategic choices. These theories could also help organize interesting findings about neural correlates and biological bases of social emotions (e.g., Crockett, Clark, Tabibnia, Lieberman, & Robbins, 2008; Izuma, Saito, & Sadato, 2010; Takahashi, Kato, Matsuura, Mobbs, Suhara, & Okubo, 2009).

Notes

1. Another important component of behavioral game theory is learning from repeated play (perhaps using reinforcement rules as well as model-based “fictive learning” (Camerer & Ho, 1999). Learning models are widely studied but lie beyond the scope of this chapter (see e.g., Fudenberg & Levine, 1998; Camerer, 2003, chapter 6).

2. Other mechanisms that could produce equilibration include learning from observation, introspection, calculation (such as firms hiring consultants to advise on how to bid on auctions), imitation of attention-getting or successful strategies or people, or a process of preplay talking about future choices. The learning literature is well developed (e.g., Camerer, 2003, chapter 6), but the study of imitation and preplay talking could certainly use more collaboration between game theorists and psychologists.

3. Common knowledge requires, for two players, that A knows that B knows that A knows . . . ad infinitum.

4. A more general view is that level 0’s choose intuitively or “heuristically” (perhaps based on visually salient strategies or payoffs, or “lucky numbers”), but that topic has not been explored very much.

5. Restricting communication is not meant to be realistic and certainly is not. Instead, communication is restricted because choosing what to say is itself a “strategy” choice which complicates analysis of the game—it opens a Pandora’s box of possible

effects that lie outside the scope of standard game theory. However, game theorists are well aware of the possible powerful effects of communication and have begun to study it in simple ways. In her thesis Nagel (1995) reports some subject debriefing that is illustrative of CH thinking, and Sbriglia (2008) reports some protocols, too. Burchardi and Penczynski (2010) also used chat messaging and team choice to study communication and report evidence largely consistent with CH reasoning.

6. This analysis assumes $\tau = 1.5$, but the general point holds more widely.

7. Note that this is a close relative of a “threshold public goods” game. In that game, a public good is created, which benefits everyone, if T people contribute, but if even one person does not, the public good is not produced. In that case, everyone would like to be in the N-T group of people who benefit without paying.

8. $p(X)$ is a “common prior.” An example is a game of cards, in which everyone knows the contents of the card deck, do not know what face-down cards other players are holding but also know that the other players do know their own face-down cards.

9. There are several subtle variants. In the original Mouselab, boxes open and close automatically when the mouse enters and exits. Costa-Gomes, Crawford and Broseta (2001) wanted more deliberate attention, so they created a version in which a click is required to open a box. Brocas et al. (2009) created a version that requires the mouse button to be held down to view box contents (if the button press is halted the information disappears).

10. The rostral ACC, labeled rACC, is more active in level-1 than in level-2 players in the human-computer contrast.

11. DLPFC is also involved in cognitive regulation of emotions (e.g., Ochsner et al., 2009).

12. What we have in mind here is similar to Cheng and Holyoak (1985) and Fiddick, Cosmides, and Tooby’s (2000) arguments about the difference between abstract logic performance and contextualized performance. For example, games that resemble hiding food and guarding hidden locations might map roughly onto something like poker, whereas a lot of games constructed for challenge and entertainment, such as chess, do not have clear counterparts in ancestral adaptive environments.

13. Other models of belief-dependent utility can be placed in the general framework of Battigalli and Dufwenberg (2009). For example, Caplin and Leahy (2004) model doctor–patient interactions where uncertainty may cause patient anxiety. The doctor is concerned about the patient’s well-being and must decide whether to provide (potentially) anxiety-causing diagnostic information. Bernheim (1994) proposes a model of conformity where players care about the beliefs their coplayers have regarding their preferences. The model can produce fads and adherence to social norms. Related work by Benabou and Tirole (2006) models players who are altruistic and also care about other’s inferences about how altruistic they are. Gill and Stone (2010) model players who care about what they feel they deserve in two-player tournaments. The players’ perceived entitlements depend upon their own effort level and the efforts of others.

14. A (single person) decision problem involving any of these emotions may be modeled as a psychological game with one player and moves by nature.

Abstract

The past decade has seen a renewed interest in moral psychology. A unique feature of the present endeavor is its unprecedented interdisciplinarity. For the first time, cognitive, social, and developmental psychologists, neuroscientists, experimental philosophers, evolutionary biologists, and anthropologists collaborate to study the same or overlapping phenomena. This review focuses on moral judgments and is written from the perspective of cognitive psychologists interested in theories of the cognitive and affective processes underlying judgments in moral domains. The review will first present and discuss a variety of different theoretical and empirical approaches, including both behavioral and neuroscientific studies. We will then show how these theories can be applied to a selected number of specific research topics that have attracted particular interest in recent years, including the distinction between moral and conventional rules, moral dilemmas, the role of intention, and sacred/protected values. One overarching question we will address throughout the chapter is whether moral cognitions are distinct and special, or whether they can be subsumed under more domain-general mechanisms.

Key Words: moral psychology, moral judgment, norms, moral domains, intention, folk psychology, emotion, reasoning, cross-cultural psychology, neuroscience, trolley problem, convention, protected and sacred values, heuristics and biases, dual-process theory, moral grammar, side-effect effect

Introduction

The past decade has seen a renewed interest in moral psychology. Empirical research on morality is not new, of course. There has been a long tradition in different fields, such as social and developmental psychology. Nevertheless, a unique feature of the present endeavor is its unprecedented interdisciplinarity. For the first time, cognitive, social, and developmental psychologists, neuroscientists, experimental philosophers, evolutionary biologists, and anthropologists collaborate to study the same or overlapping phenomena.

In this review, we will focus on research trying to elucidate the cognitive and affective foundations of *moral judgment*. As a first approximation

one can say that moral judgments refer to the rightness or wrongness of specific acts or policies. A central question that will be repeatedly brought up in this review is whether we need a separate field of moral psychology to study this specific class of judgments. Do moral judgments possess characteristics that make them qualitatively distinct from other judgments? This question can be divided into two subquestions: (1) Are there moral rules people universally invoke when making moral judgments, and (2) Are moral cognitions a natural kind with specialized cognitive machinery, or are moral judgments just a special case of judgments in general? We will try to answer these two questions by reviewing recent studies investigating whether moral rules

are universal and whether there is evidence for an innate module devoted to moral cognitions.

The answer to the first question seems to be no. Cross-cultural research has made it clear that although a variety of moral rules, such as “do no harm,” are strongly endorsed in Western cultures, at least by liberals, they are not universally endorsed (see Rai & Fiske, 2011). For example, whereas in some societies hitting and fighting is impermissible, in other cultures certain forms of violence are praised. Some cultures allow violence only to outgroup members; others also encourage violence within their ingroup and find it acceptable that children, women, or animals are harmed in some circumstances. Other moral domains, such as concerns about sexuality, fairness, health, or food, are also highly variable (see Prinz, 2007; Rai & Fiske, 2011; Sripada & Stich, 2006). Thus, the contents of moral rules vary widely across cultures.

One possibility to address the second question is to look at evidence showing that moral cognitions are innate. The evidence about lack of universality already indicates that it is unlikely that specific moral rules (e.g., “do no harm”) are innate. Although some researchers argue that some moral rules may be components of a universal moral grammar (Hauser, 2006; Mikhail, 2011), the evidence for this claim is weak (see Prinz, 2007; also see section on “Moral Grammar Theory”). Some researchers have therefore proposed that moral cognitions are nothing special: Moral reasoning is just domain-general reasoning with moral contents. Bucciarelli, Khemlani, and Johnson-Laird (2008) have, for example, claimed that moral reasoning can be modeled as deontic reasoning with the contents of the rules determined by cultural norms. Similarly, Gigerenzer (2010) claims that there is no special class of moral heuristics. Instead the same domain-general social heuristics guide moral and nonmoral behavior (e.g., “If there is a default, do nothing about it”). Although there can be no doubt that domain-general processes influence moral reasoning (see section on “Domain-General Cognitive Theories”), it also seems implausible to fully reduce moral rules to deontic rules. Deontic rules do not differentiate between moral rules and mere, arbitrary conventions, which seem psychologically distinct (see section on “The Moral/Conventional Distinction”).

Currently there is a debate about whether the evidence favors the theory that we are innately disposed to acquire *moral rules*, which share a core content that may be variably instantiated in different

cultures (Hauser, 2006; Joyce, 2006), or whether we are simply disposed to acquire *norms* whatever their content may be. Sripada and Stich (2006) differentiate norms from both moral rules and mere conventions. Like moral rules, norms typically transcend mere conventions and are considered independent of what an authority says. People believe that the norms they follow should be honored as ends, not as means to achieve a goal. Moreover, norm violations often lead to punitive emotions, such as anger or guilt. However, people who endorse norms do not necessarily claim universality for them, a feature typically associated with moral rules (see section on “The Moral/Conventional Distinction”). Sripada and Stich (2006) have suggested a domain-general norm acquisition mechanism that is capable of acquiring norms, including moral ones, the specific contents of which are culture-dependent.

This dispute is hard to settle because it depends on how moral norms are distinguished from norms in general. The review by Machery and Mallon (2010) concludes that currently the most parsimonious account is that people are universally disposed to acquire norms in general. Moral norms are then a special case; their contents are specified by the culture in which a person is born.

The question whether there is a cognitive module devoted to moral cognitions is also complicated by the fact that moral concerns may be subdivided into different domains. Extending Shweder, Much, Mahapatra, and Park’s (1997) theory, Haidt and Joseph (2007) propose five moral domains that are characterized by unique adaptive challenges, contents, triggering stimuli, virtues, and emotions. In Western cultures concerns with Harm/Care and with Fairness/Reciprocity dominate. Harm/Care concerns are triggered by suffering and distress, especially by one’s kin, and are accompanied by the emotion of compassion. The Fairness/Reciprocity domain deals with cheating, cooperation, and deception and is accompanied by the emotions anger, gratitude, and guilt. However, there are further domains. Ingroup/Loyalty norms regulate group cooperation through pride and anger, whereas Authority/Respect norms control hierarchies by recruiting the emotions respect and fear. Finally, many cultures are concerned with Purity/Sanctity, which consists of norms referring to food, health, and sexuality (thus conceiving the body as sacred), often enforced through feelings of disgust. These moral values are not only needed to understand other cultures, but there are also differences within the Western culture. For example,

conservatives are more likely than liberals to embrace all these values. In contrast, Western liberals mainly emphasize Harm and Fairness/Justice-based concerns (Graham, Haidt, & Nosek, 2009; see also Wright & Baril, 2011).

Whereas Haidt and Joseph (2007) believe that these five domains correspond to adaptations that led to innately specified dispositions to acquire domain-specific moral norms, Rai and Fiske (2011) present an alternative theory that views norms as mechanisms to regulate specific types of social relations. Unity is the motive to care for and support the integrity of ingroups, Hierarchy is the motive to respect rank in social groups, Equality is the motive for balanced in-kind reciprocity, and Proportionality is the motive for rewards and punishments to be proportionate to merit and judgments to be based on a utilitarian calculus of costs and benefits (i.e., market pricing). People are simultaneously parts of several social relations so that moral norms may vary in different contexts. For example, harm may be prohibited within ingroups that rely on the implicit assumption of Equality, whereas it may be obligatory when it is proposed in the context of Hierarchy (e.g., war) or Proportionality (e.g., punishment). This theory is consistent with the assumption that some moral norms are innate, but innateness claims here are not made about the norms but rather about the universality of specific types of social relations, where moral cognition is still part of broader social-relational cognition.

Our review of research on moral judgment will start with a critical discussion of competing theories of moral judgment. We will present these theories along with selected experimental behavioral and neuroscientific studies supporting the respective theory. We will then discuss these theories in the context of a selected number of specific research topics that have attracted particular interest in recent years.

Critical Review of Global Theories

In this section we will review and discuss global theories of moral judgment. Although these theories typically are presented as general frameworks, it will turn out that the focus of the theories differs.

Kohlberg's Rationalist Theory

Kohlberg's (1981) important theory of moral development, which was inspired by Piaget's (1932) view is discussed in many current accounts as an example of a theory that views conscious moral reasoning as a central component of morality (Haidt, 2001; Hauser, 2006). Kohlberg's (1981) famous

method to study moral competencies was simple. He presented subjects (mainly children and adolescents) with dilemmas in which different moral factors conflicted. For example, in the famous *Heinz dilemma*, Heinz's dying wife can only be saved by taking a new drug that a pharmacist has developed. The production of the drug costs \$200, but the pharmacist charges \$2,000, double of what Heinz can pay. The pharmacist refuses to sell the drug cheaper so that Heinz eventually decides to break into the pharmacy and steal the drug. Kohlberg asked his subjects whether Heinz should have done this. He was primarily interested in the justifications for the answers, which he coded to reconstruct the level of moral reasoning.

Kohlberg found that children from many cultures typically move through a sequence of levels and sub-stages, although not everyone reaches the higher levels of reasoning (see also Crain, 1985). Level 1 represents *preconventional* morality. This level is characterized by an orientation toward the likely punishment or obedience toward fixed rules ("do not steal"). In Level 2, the level of *conventional morality*, typically reached in adolescence, values of family and society come into play. Here the children think that people should live up to the expectations of family and society, and be good persons. For example, Heinz's behavior might be defended as good, whereas the pharmacist might be described as greedy. Later within Level 2, subjects become more concerned with society as a whole with an emphasis on laws, respecting authorities, and performing duties to maintain social order. In Level 3, *postconventional* morality, the justifications transcend the level of norms and laws and focus on the legitimacy of the norms regulating society. In this stage violations of individual rights, such as liberty and life, may be invoked to justify behavior that breaks the law.

Kohlberg did not believe in innate factors driving moral development but rather viewed the transition between levels as driven by the opportunities afforded in everyday social interactions. Change may occur as a result of everyday role taking and perspective change fostering empathy, or it may be driven by reflections about moral situations.

DISCUSSION

Kohlberg was a rationalist. He believed that our moral judgments are driven by reasoning processes, and that progress in moral development is driven by reflections and discussions. Many current theories criticize this rationalist assumption. For

example, Haidt (2001) argues that moral intuitions are primarily based on unconscious intuitions, with justifications being post hoc rationalizations (see section on “Haidt’s Social Intuitionist Model”). Thus, it can be questioned whether the justifications Kohlberg elicited really caused the intuitions in the moral dilemmas. Other researchers acknowledge that occasionally moral intuitions may be based on reasoning processes, but they argue there are also important cases in which we do not have conscious access to the factors driving our intuitions (see Cushman, Young, & Hauser, 2006). A related critique is that Kohlberg’s focus on levels and stages underestimates the context dependency and variability of moral reasoning. Moral intuitions in different cases may be driven by different context factors so that the reduction to a general level may be an oversimplification.

Kohlberg’s theory has also been criticized as culturally biased (see also Gilligan, 1982, for the claim that Kohlberg’s higher levels are biased toward the reasoning of males). Kohlberg argues that people in all cultures go through the same levels, but there may be differences in the rates of development and the end state. For example, he found that in urban contexts people typically reach Level 2 and some lower stages of Level 3, whereas in tribal communities and small villages, Level 1 is rarely surpassed. Simpson (1974) argues that Kohlberg has developed a stage model based on the Western philosophical tradition and has then imposed it on non-Western cultures. Kohlberg’s response was that his theory is not about the specific values different cultures endorse but about general modes of reasoning, but this position has become increasingly questionable in light of the diminished role of justifications as evidence for morality in current theories.

Emotion-based Theories

Kohlberg’s (1981) theory can be traced back to rationalist philosophy. Moral reasoning is described as conscious deliberation; the sequence of moral stages seems to lead toward ethical positions that have been elaborated in Kant’s (1959) and Rawls’ (1971) philosophy. Many current theories are instead influenced by Hume’s (1960) philosophy of morality. Hume held the view that moral distinctions are not results of reasoning processes but can be derived, analogous to aesthetic judgments, from affectively laden moral sentiments: feelings of approval and disapproval felt by spectators who contemplate a character’s trait or action.

HAIDT’S SOCIAL INTUITIONIST MODEL

Inspired by Hume, Haidt (2001) defines moral judgments as “evaluations (good vs. bad) of the actions or character of a person that are made with respect to a set of virtues held to be obligatory by a culture or subculture” (p. 817). In his model an important distinction is between reasoning, a conscious activity in which conclusions are derived through several steps, and intuition, also a cognitive process that is characterized “as the sudden appearance in consciousness of a moral judgment, including an affective valence (good-bad, like-dislike), without any conscious awareness of having gone through steps of searching, weighing evidence, or inferring a conclusion” (p. 818). Thus, whereas reasoning is largely conscious, intuition is based on automatic, unconscious processes.

In his social intuitionist model, the primary link underwriting moral judgments is the link between the eliciting situations and moral intuitions. Reasoning processes may modify judgments, but in the model they are optional and start after initial intuitions have been formed. The role of reasoning is often to provide post hoc rationalizations of the already formed moral intuitions. Occasionally, private reasoning may override the initial intuitions, but this is relatively rare. Apart from these processes that occur within the individual, the model also contains links to other members of the social group. Other people may be influenced by moral judgments, or they may change their minds on the basis of discussions. Moreover, the intuitions and reasoning of others may influence the moral intuitions of the individual. Thus, individuals are embedded in social contexts and their norms.

Evidence for the existence of a direct intuitive link comes from a number of studies (see Haidt, 2001, 2007; Haidt & Kesebir, 2010). In several studies about harmless taboo violations (e.g., eating a pet dog; a consensual incestuous relation with birth control), many subjects judged that the acts were morally wrong but were unable to provide reasons for their judgments (i.e., moral dumbfounding; see Haidt & Hersh, 2001; Haidt, Koller, & Dias, 1993). Moral dumbfounding can be viewed as evidence for the unconscious elicitation of moral intuitions.

The automaticity of moral judgments may lead to misattributions of consciously accessible affects. For example, Wheatley and Haidt (2005) selected highly hypnotizable subjects who were given a post-hypnotic suggestion to feel a flash of disgust when

they read an arbitrary word. Moral vignettes were presented that did or did not contain the word. The results showed that moral judgments can be made more severe by the presence of the hypnotically triggered disgust. In a related study, Schnall, Haidt, Clore, and Jordan (2008) manipulated the context in which subjects made moral judgments about a character in a story. Subjects who scored high on a *private body consciousness* scale made harsher judgments in the presence of a bad smell (“fart spray”) than in its absence. Similarly, Eskine, Kacinik, and Prinz (2011) showed that the taste of a beverage influences moral judgments about other people.

Although our focus in the present chapter is on theories of moral reasoning, it should be noted that Haidt is a social psychologist who is mainly interested in processes that go beyond individual reasoning (see Haidt, 2007; Haidt & Kesebir, 2010). Individuals are embedded in large social contexts in which they influence others, as they are influenced by others. Thus, whereas many researchers have used the model of a lonely “intuitive scientist” to study moral reasoning, Haidt prefers the metaphor of an “intuitive politician.” The focus on larger social contexts also highlights the important role of group norms, cooperation, and methods of the society to punish defectors, which are often neglected in research centered on judgment and decision making (see also Haidt’s theory of moral domains in the “Introduction” to this chapter).

Discussion

Although Haidt’s primary interest is social and culture psychology, we will focus here on his ideas about moral judgment. His approach proved a valuable contrast to the rationalist approaches of Kohlberg (1981). Numerous findings show that moral judgments can be intuitive and automatic. However, from the viewpoint of cognitive psychology, the contrast between reasoning and intuition excludes important possibilities in the middle. In modern theories of reasoning, it is rarely assumed that the steps undertaken by the reasoner are fully accessible to consciousness (see Harman, Mason, & Sinnott-Armstrong, 2010). Mental model theory, Bayesian theories, and even mental logic theory postulate various processes that work below the threshold of conscious awareness.

A further problem is that the step between eliciting situation and intuition remains largely opaque in Haidt’s (2001) theory. Although Haidt acknowledges that intuitions are based on cognitive processes,

and Haidt and Kesebir (2010) even mention that heuristics may play an important role, there is no worked-out theory of how specific situations lead to particular moral intuitions. A cognitive-affective theory of moral intuitions needs to specify how moral scenarios are perceived and categorized, and how these initial appraisals are further processed. Of course, the information processing steps and representations leading to moral intuitions may well be unconscious or only partly conscious.

Finally, the claim that moral intuition is primary and that reasoning is secondary has led to critiques. Although it seems plausible that this relation often holds given that intuitions are based on faster processes than reasoning, there are certainly also cases in which people do not have clear initial intuitions and arrive at their judgments after careful deliberation (see Haidt & Kesebir, 2010; Paxton & Greene, 2010).

THE PLACE OF EMOTIONS

IN MORAL JUDGMENTS

In Haidt’s (2001) theory, affective evaluations play an important role in moral intuitions, but the exact role of them is left open. In fact, virtually every theory of moral reasoning acknowledges that emotions are an important part of our moral judgments. Even Kant (1959), in his rationalist philosophy of morals, claims that moral judgments are typically accompanied by moral feelings. What is debated is the exact place of emotions in moral judgments.

Different positions can be distinguished (see Hauser, 2006; Huebner, Dwyer, & Hauser, 2009; Prinz & Nichols, 2010). The Kantian approach, which postulates that deliberate conscious reasoning processes generally precede emotions, is refuted by the findings discussed in the section on “Haidt’s Social Intuitionist Model.” Numerous studies have shown that moral judgments are often immediately triggered without extensive reflections.

A second possibility, in the tradition of Hume’s ideas, views moral judgments as caused by distinct prior emotions. The problem with this approach is that it is unclear which emotions trigger distinctly moral judgments and how these emotions are caused. For example, feelings of disgust may alter moral evaluations (Schnall et al., 2008; Wheatley & Haidt, 2005), but not all feelings of disgust lead to moral judgments. Also there is no clear unambiguous relation between affects and judgments. Feelings of pity and compassion may occur when we observe immoral torture but also when we watch a lifesaving amputation of a leg. Thus, it seems more likely that

affects, such as disgust, moderate moral evaluations that are already independently triggered by signaling the degree of aversiveness or disutility.

These problems have led Nichols (2004) to his “sentimental rules” theory. Nichols argues that moral judgments are fed by two components: a normative theory and a system of emotions. The normative theory specifies the content of moral rules that are acquired in a specific sociocultural environment; the emotions alter their character, which includes being considered serious and authority independent (see section on “The Moral/Conventional Distinction”). Due to the presence of emotions, moral rules acquire their force and impact (i.e., emotion-backed rules). Moral judgments in the absence of emotions are possible but rare in healthy subjects. Such judgments would also not have the same force and strength as judgments based on emotion-backed rules. Prinz (2007) proposes a related theory but questions the possibility of separating emotions from moral judgments. In his view, moral concepts, such as “moral” or “immoral,” contain emotions as essential components (as in Hume’s account).

The present research does not allow us to empirically decide between these positions (see Huebner et al., 2009). Studies in which affect was manipulated prior to or simultaneous with the scenarios (e.g., Valdesolo & DeSteno, 2006; Wheatley & Haidt, 2005) show that affect influences judgments; they do not demonstrate that emotions are necessary for moral judgments. They might instead affect the interpretation of the scenario, the evaluation of the outcomes, or the interpretation of the test question.

The results of neuroimaging and neuropsychological studies are also ambiguous. Neuroimaging studies have shown that emotional responses are integral components of moral reasoning. For example, an increased activity in the frontal polar cortex (FPC) and medial frontal gyrus was seen in moral judgments compared to judgments of nonmoral claims (Moll et al., 2002; Moll, de Oliveira-Souza, & Eslinger, 2003; see also Greene, Sommerville, Nystrom, Darley, & Cohen, 2001). Similarly, neuropsychological studies provide strong evidence for the role of emotions in morality. For example, frontotemporal dementia patients, who suffer from the deterioration of their prefrontal and anterior temporal cortex, show blunted emotions, disregard for others, and a willingness to engage in moral transgressions (Damasio, 1994; Mendez, Anderson, & Shapira, 2005). However, the exact functional role of emotion remains unclear.

The most interesting evidence comes from a study by Koenigs et al. (2007; see also Ciaramelli, Muccioli, Lådavas, & di Pellegrino, 2007). Damage to the ventromedial prefrontal cortex (VMPC) leads to an emotional flattening and to a decreased ability to anticipate rewards and punishments (Damasio, 1994). Koenigs and colleagues showed that VMPC patients were generally able to evaluate moral dilemmas in which a victim needs to be sacrificed to save others like healthy subjects, but they differed in high-conflict dilemmas, which cause strong emotional responses in healthy subjects. Whereas these healthy subjects were primarily led by their affective responses, the VMPC patients opted for a consequentialist resolution, which simply compared numbers of victims (see also sections on “Dual-Process Theory,” “Moral Grammar Theory,” and “Moral Dilemmas”). Recently, Bartels and Pizarro (2011) extended these findings by showing that healthy participants who had higher scores on measures of Machiavellianism, psychopathy, and life meaninglessness indicated greater endorsement of utilitarian solutions. Again these studies show that in healthy subjects emotions influence judgments, but it is unclear how. Huebner and colleagues (2009) suggest that emotions in these cases may influence the interpretation of the scenario. Emotionally salient outcomes may be downplayed by the VMPC patients, and this in turn affects the moral evaluations.

Another strategy to elucidate the role of emotions in moral judgments is to take a closer look at the emotions that accompany judgments (see also Prinz & Nichols, 2010). The philosopher Williams (1985) has distinguished “thin” (e.g., good, bad) from “thick” moral concepts that are loaded with content (e.g., cruelty, courage). Similarly, in emotion research one can study thin affects (e.g., positive, negative) that may occur in the absence of awareness of the triggering conditions, or emotions can be described as thick relational concepts that have moral content and trigger specific moral behavior. This position views emotions as cognitively entrenched (Lazarus, 1991), and it is consistent with the views that moral emotions are constitutive of moral judgments (Prinz, 2007) or are strongly attached to moral rules (Nichols, 2004). Examples of moral emotions are anger and guilt. According to Prinz and Nichols (2010), anger is typically elicited by a violation of somebody’s autonomy and often motivates retaliatory acts. In contrast, guilt is elicited by the feeling of direct or indirect responsibility for somebody’s harm, especially when the harmed

person belongs to the ingroup so that there is a threat of separation or exclusion. Both emotions not only express affects but are constitutive for the expression of specific moral values.

Dual-Process Theory

All theories we have discussed so far acknowledge that both conscious reasoning and emotion-based intuitions play an important role in moral judgments. They differ, however, in what process they consider primary. A further theory, the dual-process model proposed by Greene and colleagues, claims that our brains contain multiple systems driving moral intuitions, one devoted to rational, the other to emotional processes. The system underlying rational deliberations is slow, effortful, and controlled, whereas the affective system consists of automatic, largely unconscious, intuition-based processes (see Cushman, Young, & Greene, 2010, for an overview).

Initial evidence for the dual-process theory comes from a neuroimaging study by Greene et al. (2001). This study investigated moral dilemmas, such as the trolley dilemma (Foot, 1967; Thomson, 1985), which will be more extensively discussed in the section on "Moral Dilemmas." The basic scenario in trolley dilemmas describes a runaway trolley threatening to kill five people on the track. Many people find it permissible to flip a switch that redirects the train onto a side track where only one person would be killed (bystander version), whereas it is generally considered impermissible to shove a person onto the tracks to stop the train (footbridge version), despite the fact that in both scenarios one person would be killed instead of five (Hauser, Cushman, Young, Jin, & Mikhail, 2007; see also Fig. 19.1). Greene and colleagues argued that the footbridge case is more *personal* and therefore triggers a negative affective response, consistent with deontological philosophy, whereas the bystander version is more *impersonal*, which therefore leads to a consequentialist weighing of lives harmed. Thus, the theory is that there are two separate systems in the brain, one triggering affect-based, and the other rational, consequentialist responses. The nature of the moral dilemma decides which system predominates. Supporting this theory, the results of Greene et al. (2001) indeed showed that brain regions associated with emotions, such as the medial prefrontal cortex, were more active with personal dilemmas, whereas brain regions associated with controlled cognitive processes such as working memory and abstract reasoning were more

active with impersonal dilemmas. Greene et al. (2001) also reported reaction time data favoring their theory, but a reanalysis by McGuire, Langdon, Coltheart, and Mackenzie (2009) shows that outliers that needed to be removed are mainly responsible for the observed pattern.

In follow-up studies, Greene and colleagues presented particularly difficult "high-conflict" dilemmas (see also "The Place of Emotions in Moral Judgments"). For example, in one example a situation is presented in which the father of a crying baby can only save his other children from enemy soldiers if he smothers his crying child to death; otherwise all children including the crying one would be killed. Greene, Nystrom, Engell, Darley, and Cohen (2004) have shown that in such cases the anterior cingulate cortex (ACC) is active, which is involved when incompatible responses are activated. Moreover, consistent with the dual-process theory, the dorsolateral prefrontal cortex was more active when what Greene et al. viewed as the "consequentialist" response (i.e., killing the baby) was given. In a related study, Greene, Morelli, Lowenberg, Nystrom, and Cohen (2008) presented subjects with such hard moral dilemmas while at the same time exposing them to a cognitively demanding secondary task. The results showed that only the "consequentialist" responses were slowed down by this procedure, which had no effect on the affect-based (according to Greene et al. "deontological") responses. Similarly Suter and Hertwig (2011) manipulated how much time they granted their subjects to render a judgment in order to constrain controlled processes. They found more "deontological" responses under strict time constraints than in the contrasting condition in which subjects had more time to respond.

Whereas these findings showed selective interference with the assumed consequentialist brain area, the studies with patients with VMPC lesions discussed in "The Place of Emotions in Moral Judgments" are evidence for interference with the emotional areas. These patients tended to give the "consequentialist" answer in high-conflict dilemmas, while the emotion-based response was blunted (Koenigs et al., 2007; Mendez et al., 2005).

DISCUSSION

Multisystem theories are attractive in many areas because they integrate a large body of different findings compared to single-system theories, which are less flexible. However, the particular version of a

dual-system theory by Greene and colleagues has drawn a number of critiques. Prinz (2008) argues that the results of Greene et al.'s (2001) study are consistent with the view that the dilemmas trigger a strong negative emotional response to harming an innocent bystander and a weaker positive emotional response to saving five potential victims. Differences in salience of the harming versus the saving options may explain the observed patterns. Moll and De Oliveira-Souza (2007) suggest that differential activations of brain areas underlie different prosocial emotions, which integrate emotional and cognitive processes rather than putting them in conflict.

A further possible critique concerns the interpretation of the contents of the two postulated brain areas. Although the exact characterization shifts across publications (see Cushman et al., 2010), the brain areas identified as underlying moral judgments were often characterized using labels describing philosophical positions, such as deontological and consequentialist (see Greene, 2008). However, it is questionable whether different brain areas embody complex contentful moral philosophies rather than more domain-general processes, such as affective reactions versus rational deliberations. Moreover, Kahane et al. (in press) have pointed out a confounding: In the experimental scenarios used by Greene and colleagues (2001, 2004) the deontological option is always also the more intuitive one. Thus, the discovered asymmetries between responses corresponding to deontological vs. consequentialist rules might in fact be due to differences in intuitiveness. Using additional scenarios in which the consequentialist response is more intuitive than the deontological one (e.g., lying in order to prevent serious harm), Kahane and colleagues demonstrated that characteristic differences in neural activation are more closely related to the intuitiveness of the response options than to their deontological versus consequentialist content.

Furthermore, the characterization of responses based on numbers of saved lives as consequentialist overstates the finding. For example, the people who judge killing the baby to be acceptable in the crying baby dilemma outlined earlier need not have applied a consequentialist moral philosophy; the same conclusion could have been reached by application of a deontological rule (Kamm, 2007) or without reference to any formal moral theory (see also Kahane & Shackel, 2008). So far, there is no evidence that a version of an intuitive consequentialist theory is coded anywhere in the brains of naïve subjects. It

would be more parsimonious to say that in different conditions different aspects of the scenarios (for example, acts versus number of victims) are highlighted (cf. Bartels, 2008). This interpretation would also have the advantage that VMPC patients and psychopaths would not have to be viewed as particularly rationalist, consequentialist reasoners (see also Bartels & Pizarro, 2011).

Finally, there are different versions of dual-process theories, which seem equally consistent with the data (see Evans, 2007; Evans, Chapter 8). One possibility is the theory endorsed by Greene and colleagues, which assumes there are two dissociable systems that operate independently, acquire different knowledge, and compete in the control of behavior. However, another possibility is that there is only a single database (e.g., trolley dilemmas with various features, such as acts and outcomes) and sequential processes operating on these representations. The initial fast processes may lead to heuristic or emotion-based judgments, whereas in some circumstances the output of the initial pass is further processed by more effortful, controlled processes (Evans, 2007; Kahneman & Frederick, 2005). This theory would also explain the findings without the need to postulate multiple brain areas embodying different moral philosophies.

Moral Grammar Theory

The theories we have discussed so far largely focus on whether moral reasoning is driven by intuitive affective processes or by conscious reasoning. None of the theories specifies a precise computational mechanism that translates situational input into moral judgments. It is the contribution of Mikhail (2007, 2011) to rise to the challenge and present a sketch of such a computational theory (see also Hauser, 2006). Like the other modern theorists, Mikhail accepts that moral judgments are typically not based on conscious deliberate reasoning. However, this does not mean that the underlying processes cannot be reconstructed as steps of computational information processing. Most cognitive theories, in both higher and lower order cognition, assume the operation of unconscious processes underlying the mental products that rise to consciousness.

Mikhail's theory of universal moral grammar is inspired by Chomsky's (1957) linguistic grammar theory. We have intuitions about the grammaticality of sentences, which can be explained as the output of the operation of a complex unconscious system of syntactic rules. Similarly, Mikhail argues that our judgments of moral permissibility may be driven by

an unconscious moral grammar that contains moral rules. The moral grammar theory holds that individuals are intuitive lawyers who possess unconscious knowledge of a rich set of legal rules along with a natural readiness to compute mental representations of human acts and omissions in legally cognizable terms. Following Chomsky, Mikhail claims that the moral grammar is innate and universal. The innateness claim is defended by a variant of the *poverty of stimulus argument*, according to which the learning input of children would not sufficiently constrain the moral rules they seamlessly acquire. A further argument is that people often have clear moral intuitions without being able to verbally explicate or justify them (Cushman et al., 2006). Empirical support for the theory mainly comes from a large Internet study in which thousands of subjects from various countries were confronted with variations of the trolley and other dilemmas (see section on “Moral Dilemmas”).

Moral grammar theory specifies a series of computational steps transforming the observed stimuli into morally relevant internal representations. Initially a set of conversion rules encodes the temporal structure of the presented stimulus (e.g., a trolley dilemma) and transforms it into a representation of the underlying causal structure. For example, in the bystander dilemma (see sections on “Dual-Process Theory” and “Moral Dilemmas”; see also Fig. 19.1), the temporally ordered events “throwing a switch,” “turning the train,” and “killing one man” are integrated into a causal chain representation. This way knowledge is acquired about morally relevant causal features, such as whether death is a side effect or a means of the proposed act or omission. Next, other conversion rules translate the causal representation into a moral representation by assigning evaluations to the effects (good vs. bad). This representation is further converted into a representation of the underlying intentional structure. In a scenario with both good and bad effects, it is by default assumed that the good outcome is the intended outcome, whereas the bad effect is a merely foreseen side effect. However, if the bad effect is a means to a good outcome, it necessarily is intended, because it constitutes the only route to the good effect. Further morally relevant information is filled in, such as whether the act is a case of intentional battery or whether the victim is harmed without having given consent. Finally, a set of deontic rules is applied to the final representation of the stimulus, yielding a judgment of obligation, permissibility or prohibition of the encoded action.

So far Mikhail (2011) has focused on two deontic rules, which are particularly relevant for trolley dilemmas. The “prohibition of battery and homicide” forbids an agent to purposely cause harm to a non-consenting victim. A second rule, the *doctrine of double effect* (DDE), can be traced back to Aquinas and to Roman Catholic theology from the 19th century. The correct interpretation of this doctrine is under dispute (see Woodward, 2001). Double effect refers to the two effects an action might have, the intended goal and a foreseen but unintended side effect. According to Mikhail’s (2009) reading of the DDE, an otherwise prohibited act, such as battery or homicide, with good and bad effects may be permissible if the prohibited act itself is not directly intended, only the good outcomes are intended, the bad ones merely foreseen, the good effects outweigh the bad one, and there are no better alternatives. This rule is consistent with the finding that people typically consider it acceptable to redirect the trolley in the bystander version but oppose the act in the footbridge version. In the bystander version the act generates a bad effect as a side effect, which is not intended but only foreseen, whereas in the footbridge version a person is directly killed as a means to a greater good. Thus, this is a case of intentional battery.

DISCUSSION

Although to date the computational theory underlying moral grammar theory is only a sketch of a model, its precision and detail vastly surpass what other moral theories currently offer. The focus on processing details may also be the reason why the scope of the model is thus far limited. It is clearly developed to account for trolley dilemma intuitions, whereas it is less clear how other moral cases will be handled.

The focus on a restricted class of harm-based dilemmas and on deontic rules that are taken from Western moral philosophy (e.g., DDE) cast doubt on the claim that the theory is universally valid as claimed. Although the Internet study has collected data in numerous cultures, we will show in the section on “Moral Dilemmas” that alternative explanations of the effects are plausible. It seems questionable that a principle, such as the DDE, is universally valid. Even an initially plausible deontic principle, such as the prohibition of intentional battery, does not seem to hold universally (see “Introduction”).

In some versions of the moral grammar theory, the analogy to Chomsky’s (1957) grammar theory is carried even further to accommodate findings of intercultural differences. In his principles and parameter

theories, Chomsky claimed that we are born with a universal innate grammar that contains fixed principles but also parameters that are set by the linguistic environment of the person. This model explains why people are able to quickly learn very different languages with differences in the syntax. Analogously, it has been argued that moral grammar may contain principles, such as the doctrine of double effect, and parameters that are set by the culture (Dwyer, 2006; Hauser, 2006; Roedder & Harman, 2010). However, no formal version of a moral grammar of this kind has been worked out yet, so this proposal remains untestable. Moreover, moral principles, such as the doctrine of double effect, combine domain-specific rules with domain-general processes (e.g., intentional and causal analyses) so that it is unclear how both types of processes are organized within an innate module (see also Cushman & Young, 2011).

There are further critiques casting doubts on the analogy between moral grammar and Chomsky's (1957) syntax theory (see also Dupoux & Jacob, 2007). First, it seems questionable to compare grammaticality judgments with permissibility judgments. Whereas with sufficient training about the meaning of the concept of syntax we know whether a sentence like "colorless green ideas sleep furiously" is grammatical, our moral intuitions, even with professional training, are extremely context sensitive and hardly ever clear cut. It seems unlikely that the factors influencing moral judgments are encapsulated in a way that warrants the modularity assumption. Moral intuitions seem to be closer to semantics and pragmatics than syntax. Moreover, the fact that people do not have conscious knowledge about moral rules does not entail innateness. There is a large literature on artificial grammar learning, for example, which similarly demonstrates judgments in the absence of valid verbal justifications (see Litman & Reber, 2005, for an overview).

These critiques do not diminish the contribution of Mikhail (2011). It is possible to work on a theory of moral rules without accepting the innateness or universality claims. In fact, the hypothesis that moral judgments are driven by moral principles, such as the doctrine of double effect, can easily be isolated from other claims (see Cushman et al., 2010) and can be tested independently (see section on "Moral Dilemmas").

Moral Heuristics

A further approach to studying moral judgments is motivated by the *heuristics and biases* paradigm,

which comes in several, often competing variants (see Sinnott-Armstrong, Young, & Cushman, 2010). A general assumption underlying research on heuristics is that people use mental shortcuts or rules of thumb that generally work well but also lead to systematic errors in specific circumstances (see Sunstein, 2005). Heuristics may operate consciously or unconsciously. We will restrict our discussion here to contentful heuristics; a discussion of the role of affect, which has also sometimes been described in terms of heuristics, will not be repeated here (see section on "The Place of Emotions in Moral Judgments").

One specific characterization of the concept of heuristics describes their use as *attribute substitution* (Kahneman & Frederick, 2005). Often target attributes T of an object X are not easily accessible so that a person instead uses an attribute H, the heuristic attribute, which is correlated with X and is more accessible. The user of the heuristic tends to believe in T when H is present. This simple model applies to many cases within the heuristics and biases program. For example, it has been shown that availability (H) is used to infer probability (T) of an event (X) (Kahneman, Slovic, & Tversky, 1982). Or in a competing theory context it has been shown that recognition (H) is often used as the basis of decisions about the size (T) of cities (X) (Gigerenzer, Todd, & the ABC Research Group, 1999).

This general framework has also been applied to moral reasoning. Baron (1994, 1998) has argued that consequentialism or utilitarianism provides normatively correct answers in questions of morality. But people who are not philosophically trained do not think along the lines of these normative theories, but rather use simple heuristics that often mislead them because they lead to overgeneralizations beyond the contexts in which they provide useful advice. Baron and his colleagues have tried to show that people are not thinking according to the normative consequentialist guidelines but instead use simple heuristics.

An example of such a heuristic is the "do no harm" heuristic, which may underlie the common intuition that it is worse for a physician to kill a patient with a deadly disease than let him die by refraining from any kind of medical intervention. Consequentialist philosophers argue that these cases should be treated equivalently (Singer, 1979). Baron and colleagues have shown in a number of well-controlled experiments that people consider harmful acts worse than harmful omissions with otherwise identical, predictable outcomes (i.e., omission bias).

For example, Spranca, Minsk, and Baron (1991) found that people find it worse when somebody who wants to harm a person offers this person a food item with an allergenic ingredient than when she passively watches the person who does not know about the ingredient taking this item himself.

A related research view has been suggested by Sunstein (2005), who subscribes to a weak non-utilitarian form of consequentialism that also might count types of acts or violations of rights as relevant consequences that need to be weighed. Otherwise the general approach is similar to Baron's. Sunstein has developed a catalog of heuristics, for example, "do no harm," "people should not engage in wrongdoing for a fee," "punish and do not reward betrayals of trust," or "do not tamper with nature" (see also Baron, 1998). This list of heuristics seems to come straight from Western deontological philosophy.

DISCUSSION

Many of the previously discussed moral theories have left the aspect of cognitive appraisal of the situation unspecified. Theories of moral heuristics represent an important step in the direction of specifying the rules that may underlie moral evaluations. However, it can be questioned whether the normative foundation of the heuristics approach holds in moral reasoning. In nonmoral tasks, such as the estimation of city sizes, the target attributes can be clearly measured and compared with the output of the heuristics. In moral domains it is far less clear what the target attributes are (see Sinnott-Armstrong et al., 2010). To evaluate a heuristic, it would be necessary to use a normative theory, and in ethics, even more than in other fields, there is no agreement about the proper normative theory. For various reasons, in psychology, consequentialism has been proposed as the yardstick for ethical judgments (Baron, 1994; Greene, 2008; Sunstein, 2005), but once we delve into the philosophical literature it becomes clear that there are various versions of consequentialist and nonconsequentialist ethics that are defensible (see Kamm, 2007; Parfit, 2011; Scanlon, 1999). For example, it is far from clear whether killing should really be viewed as equivalent to letting die (Kamm, 2007). Moreover, it can be argued that although a utilitarian cost-benefit analysis may be appropriate in small worlds with limited options, in realistic scenarios relevant information about possible outcomes, probabilities, and costs and benefits is simply not available to make such a complex strategy

reliably applicable (Bennis, Medin, & Bartels, 2010; Binmore, 2008; Gigerenzer, 2010).

Once we abandon the commitment to a specific normative ethical position, the distinction between heuristic and target attribute breaks down. A heuristic, such as "do no harm," may then be better framed as part of a deontological target theory that people happen to endorse (Sinnott-Armstrong et al., 2010). Instead of classifying simple moral rules as heuristics for a target attribute, it may be more productive to empirically study them as building blocks underlying moral judgments. It will probably turn out that one-sentence rules are too simple to explain the many subtle context effects that are known. For example, the research on the trolley dilemma shows that people do not generally invoke a "do no harm" rule; and even a more complex rule, such as the doctrine of double effect, does not provide a complete theory (see section on "Moral Dilemmas"). The research shows that far more complex intuitive theories underlie appraisal processes than the heuristics approach suggests. Moreover, complex intuitive systems of rules may only be one possible way to represent moral knowledge. Other possibilities include memory for exemplars (e.g., of moral transgressions) or prototype representations (see Harman et al., 2010; Sripada & Stich, 2006).

Domain-General Cognitive Theories

We have discussed several theoretical approaches that model the cognitive and emotional factors underlying moral judgments. However, another possible research strategy is to treat moral judgments simply as a special case of domain-general cognitive processes. For example, various researchers have shown that principles found in behavioral economics and psychological judgment and decision theory (JDM) also affect intuitions about moral scenarios (Rai & Holyoak, 2010; Reyna & Casillas, 2009). Examples include framing effects (Bartels & Medin, 2007; Kern & Chugh, 2009; Petrinovich & O'Neill, 1996; Sinnott-Armstrong, 2008), outcome bias (Gino, Shu, & Bazerman, 2010), or effects of joint versus separate evaluation (Bartels, 2008; Lombrozo, 2009; Paharia, Kassam, Greene, & Bazerman, 2009).

Another promising class of theories applicable to moral reasoning is causal model theory. Moral judgments are generally concerned with the evaluation of acts that lead to direct and indirect effects. It has been shown that the locus of intervention, the intentions causing the acts, and the causal structure leading

from acts to good and bad effects affect judgments (Cushman & Young, 2011; Sloman, Fernbach, & Ewing, 2009; Waldmann & Dieterich, 2007).

Others have pointed out the impact of attentional processes in moral judgment. As Bartels and Medin (2007; Bartels, 2008; Sachdeva & Medin, 2008) have demonstrated, moral scenarios may be evaluated very differently depending on where subjects' attention is directed (see also section on "Sacred/Protected Values"). In a related vein, Waldmann and Wiegmann (2010) argued that aspects of the causal structure of moral dilemmas may affect moral judgment by influencing people's attentional focus on alternative counterfactual contrasts (see section on "Moral Dilemmas").

The list of domain-general factors influencing moral judgment is much longer still. Abstract, high-level construal of actions leads to amplified ascriptions of both blame and praise to agents compared to more low-level, concrete representations of the same actions (Eyal, Liberman, & Trope, 2008). Metacognitive experiences like processing fluency are also used as input for moral judgment (Laham, Alter, & Goodwin, 2009; Rai & Holyoak, 2010). Approach- and avoidance-based motivational systems seem to have similar effects on judgments about moral issues as they do in other domains (Janoff-Bulman, Sheikh, & Hepp, 2009). Extensive mental simulation, induced by closed eyes during the judgment process, makes moral judgments more extreme (Caruso & Gino, 2011). And recently, more and more researchers have pointed out the importance of individual differences in moral judgment, including need for cognition (Bartels, 2008; Bartels & Pizarro, 2011), working memory capacity (Moore, Clark, & Kane, 2008), sensitivity to reward and punishment (Moore, Stevens, & Conway, 2011), and personality traits such as extraversion (Feltz & Cokely, 2009).

Specific Research Topics

After having outlined the main theoretical approaches to the study of moral judgment, along with relevant empirical evidence taken as support of them, we now turn to four selected empirical research areas that have attracted much attention in the recent years. The aim of this section is to demonstrate the complexity of explaining moral judgments in specific tasks.

The Moral/Conventional Distinction

One of the central controversies in the field of moral psychology concerns the question of whether

morality constitutes an independent domain with specific norms. Do humans reason qualitatively differently about moral rules as opposed to mere social conventions? This question has motivated various studies and led to controversial discussions.

The moral/conventional distinction was introduced to psychology by Turiel (1983). According to him, the purpose of conventional rules is to coordinate behavior in social systems. They gain their binding status by consensus within a given society, and they are arbitrary in that different agreements could have led to alternative conventions which would be just as feasible or appropriate. This implies that it is impossible to know whether a given action is in accordance with present social conventions by looking at the *action itself*. To know that it is appropriate to address your teacher by her last name, for example, you need to know that your society agreed that this is the proper way to behave since there is nothing intrinsically bad about addressing your teacher by her first name.

By contrast, the main distinguishing feature of moral rules, according to Turiel (1983), is that they are *not* arbitrary in the way conventions are. The reason for this is that they are concerned with certain *contents*: They regulate actions that have intrinsic consequences related to harm, fairness, or justice. A prototypical example of a moral transgression is that of a child pushing another child off a swing just because she wants to use it instead. According to Turiel, this act can be directly classified as harmful by any human observer familiar with pain regardless of the cultural context in which the act occurs.

Turiel (1983) argued that the moral and the conventional are separate domains of social knowledge, which are acquired and processed independently. In his view, moral rules can be empirically distinguished from conventional rules based on what Kelly, Stich, Haley, Eng, and Fessler (2007) called *signature moral pattern*. This term refers to a characteristic set of reactions people usually exhibit when they judge transgressions of prototypical moral rules: People supposedly consider moral rules, in contrast to conventional rules, to be valid even if they are not enforced by an authority (authority independence). Furthermore, moral rules are considered to be universally valid for all agents in similar circumstances across all times, places, and cultures (universality). Finally, people are expected to judge transgressions of moral rules as particularly serious and to justify their wrongness with reference to principles of harm, fairness, or justice.

An empirical paradigm to assess these signature patterns is the “moral/conventional task,” in which participants are presented with someone violating a prototypical moral rule (as in the swing example) or a social convention (as in the teacher example). If Turiel (1983) is right, then cases of moral transgression should reliably elicit the signature moral response pattern, while cases of conventional transgression should elicit the *signature conventional pattern* (i.e., judgments of authority dependence, lack of universality, decreased seriousness, and justification not related to harm, fairness, or justice; see Kelly et al., 2007). This pattern of response characteristics has been confirmed in a large number of empirical studies in diverse populations, including young children and people from different cultures (see Turiel, 2006, for an overview).

Despite its doubtless merit in advancing empirical research on moral psychology, the Turiel (1983) theory faces a number of conceptual and empirical problems. On the conceptual side, Turiel’s definition of morality seems to be at least in part a *petitio principii*: How people manage to recognize matters of fairness and justice seems to be just as much in need of explanation as how they recognize matters of morality. Intuitively, only the harm component seems to be a more basic concept, and more recent work trying to defend a content-based distinction mainly concentrates on harm (e.g., Royzman, Leeman, & Baron, 2009; Sousa, Holbrook, & Piazza, 2009).

The Turiel (1983) theory can also be contested on empirical grounds. In Turiel’s content-based approach to defining the moral domain, harm avoidance, fairness, and justice are tacitly assumed to be universal ends. We have already pointed out in the Introduction that cross-cultural research casts doubt on this universalist assumption.

Another empirical problem has been raised by Blair (1995). He questioned the assumption that only general cognitive capacities are needed to recognize moral transgressions. He showed that incarcerated psychopaths do not respond to moral transgressions with the signature moral pattern, even though they possess all the experiential and inferential capacities that according to Turiel (1983) are sufficient to distinguish the moral from the conventional. Blair’s (1995) proposal is that the human mind contains a specific module that is indispensable for this task, and which is selectively impaired in psychopathic individuals. He posits the existence of a violence inhibition mechanism (VIM) that is activated by perceptual key stimuli, mainly nonverbal

facial distress cues of suffering individuals. Once activated, the VIM triggers a withdrawal response in the observer, which he or she interprets as a moral emotion. According to Blair (1995), conventional transgressions lack these VIM specific distress cues. They therefore fail to activate the VIM and lead to a different response pattern.

It is notable that on Blair’s (1995) account, the main criterion for distinguishing between the moral and the conventional is shifted from a property of the *rules* (i.e., their content) to the activation of a cognitive structure in the *observer*. This focus has been adopted by other theorists, but there is considerable disagreement about the nature of this assumed cognitive structure. Nichols (2002), for example, doubts that a modular VIM as proposed by Blair (1995) would by itself be able to distinguish wrong from merely bad. Consider the example of a patient expressing agony while a nurse is changing the bandage of his wound (see Royzman et al., 2009). Although we instantly realize the patient’s suffering and even that the nurse is its proximal cause, we are not inclined to morally condemn her. It is not clear, however, why the observer’s VIM should not be activated in this example. It seems that we use some additional information when we make the moral/conventional distinction.

As already discussed in the section on “The Place of Emotions in Moral Judgments,” Nichols (2002, 2004) argues that this additional information is contained in a person’s “normative theory,” which is acquired in a cultural learning process. The normative theory contains all social rules, moral as well as conventional. Whether a given transgression elicits the signature moral pattern depends on whether the violated rule is backed by the activation of an emotion. This emotion need not be related to harm. For example, Nichols (2002) demonstrated that prototypically conventional transgressions can elicit the signature moral pattern if they are associated with disgust. His participants judged snorting loudly and spitting into cups at dinner tables to be universally and authority-independently wrong, especially those who scored high on a measure of disgust sensitivity (but see Royzman et al., 2009, for an alternative interpretation of the data).

Turiel’s (1983) distinction of two distinct social domains that can be empirically identified through unique signature patterns has also been questioned. Kelly et al. (2007) argue that the elements of the signature moral pattern on the one hand, and those of the signature conventional pattern on the other,

do not co-occur as monolithically as assumed by Turiel. For example, they point to the results of Haidt et al. (1993) and Nichols (2002) showing that people sometimes judge transgressions as universally wrong without justifying this assessment with notions of harm, fairness, or justice (see section on “Intuitionist Theories”). Thus, harm-related concerns do not seem *necessary* to elicit aspects of the signature moral pattern. Conversely, as Kelly et al. (2007) show, neither are they *sufficient* to do so. Instead of employing simple schoolyard transgressions of the kind Turiel (1983) and most of his followers used, Kelly and colleagues presented their participants with more complex harm-related cases from the adult world. For example, they asked their subjects whether it was okay for the captain of a modern U.S. cargo ship to whip one of his sailors as punishment for being drunk at work. Most participants responded that it was not. The researchers then went on to tell the same story, with the only difference that it was now supposed to have taken place several hundred years ago. The percentage of subjects considering the captain’s whipping behavior as wrong decreased significantly in this scenario. Similar changes were obtained when norm violations were fictitiously placed in faraway countries. Similarly, Kelly et al. (2007) showed that whether harmful actions are judged as wrong often depends on whether these actions were approved or forbidden by an authority. Taken together, these findings indicate that intrinsically harmful actions are not necessarily seen as universally or authority-independently wrong, contrary to what was assumed by Turiel (1983) and other harm-based approaches (Royzman et al., 2009; Sousa et al., 2009).

In light of this evidence, Sripada and Stich (2006) argue that the distinction between conventional and moral rules is not psychologically meaningful. At the same time, however, they share the intuition that not all social rules are treated identically. Rather than contrasting moral rules with conventional ones, they argue that there is a psychologically important subclass of rules that they call “norms.” Norms are not characterized by abstract philosophical principles or by specific contents, but mainly by the fact that people are *intrinsically motivated* to follow them.

In the Sripada and Stich (2006) model, people across all ages and cultures share the tendency to acquire and execute norms. The content of these norms, however, is assumed to be entirely determined by the social environment, and it need not (contrary to what Western philosophers have

assumed) be held to be universally valid. This view has the advantage that it simultaneously explains the difference between norms and conventions, while making no assumptions about the contents of the norms a specific culture selects. However, to date the mechanisms implementing this assumed norm acquisition device have only been sketched, so it is hard to see how it can be empirically tested against theories that assume an innate preparedness for the acquisition of specific moral rules. Also, it is not clear how the content-free norm view can predict which of the culturally endorsed rules will be assigned the status of norms as opposed to conventions. Moreover, given the lack of constraints on content a larger diversity of norms might be predicted than is actually observed. If, however, commonalities are explained as solutions to similar adaptive challenges all social groups face, which would be a plausible claim, then it may be implausible to exclude evolutionary processes from creating some of these commonalities (see Haidt & Joseph, 2007; Joyce, 2006).

Moral Dilemmas

The currently most discussed and studied moral dilemma in both philosophy and psychology is the trolley dilemma, which we already have encountered in previous sections. Trolley dilemmas have become the *Drosophila* for testing alternative philosophical and psychological theories of moral judgments in harm-based moral dilemmas. This dilemma is theoretically interesting for philosophers because it can be shown that people seem to reason according to consequentialist principles in some versions of the dilemma, but according to deontological rules in other versions (Foot, 1967; Kamm, 2007; Thomson, 1985; Unger, 1996). In the past decade a large number of psychological studies have been performed to pinpoint the factors underlying the different moral intuitions.

An influential study based on 5,000 subjects in 120 countries was performed by Hauser et al. (2007). This study is the primary evidence for moral grammar theory (see section on “Moral Grammar Theory”). Figure 19.1 illustrates two basic trolley cases used by Hauser and colleagues. In their variant of the *bystander* dilemma, the driver of a train heading toward five people on the track faints. Denise, a passenger, has the option to redirect the train toward a side track with one person. Eighty-five percent of the subjects responded “yes” to the test question that asked whether it is permissible

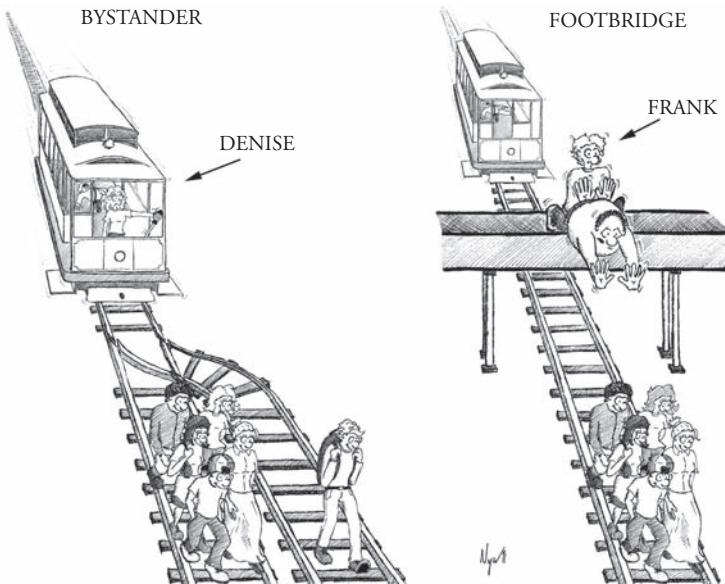

Fig. 19.1 Illustration of bystander and footbridge conditions as described by Hauser et al. (2007).

for Denise to turn the train. In the *footbridge* version of the dilemma, a runaway train is also heading toward five people. Here Frank stands on a bridge going over the tracks, realizing that he can stop the train with a heavy weight. The only available heavy weight is a large man standing next to him. Just twelve percent respond "yes" to the test question of whether it is permissible for Frank to shove the man. The effect was reliably observed in the studied countries, although subjects generally had difficulties justifying their intuitions (see also Cushman et al., 2006). The authors interpret the effect as evidence for the unconscious use of the *doctrine of double effect* (DDE, see section on "Moral Grammar Theory"), which allows harming a person as a side effect, but not as a means of saving more people.

However, the two conditions differ in a number of potentially relevant features, giving rise to various alternative explanations. First, in one condition the agent is on the threatening train, and therefore part of the danger, whereas in the other condition the agent is not part of the dangerous situation. This difference might contribute to the effect. Second, in the footbridge condition the agent could potentially sacrifice himself instead of the person next to him (although the reference to heaviness may suggest that the other person will stop the train more efficiently). At any rate, this is not an option in the bystander dilemma. Third, in one condition the act involves a morally irrelevant object (the switch), whereas in the other condition the act involves forceful contact

with the victim. Fourth, in one condition the intervention targets the threatening train, while in the other condition the victim is targeted. Fifth, the distance between the agent and the victim vary across conditions. Sixth, in one condition the potential alternative victim is only mentioned; in the other condition the victim is described as analogous to a heavy object. Seventh, the kind of death one imagines in the two conditions is more vivid and brutal in the footbridge than in the bystander condition; and eighth and last, the test questions differ in a way that can be expected to independently have an effect in the observed direction. Shoving a man is certainly considered less acceptable than turning a train even without the context of a trolley dilemma. A brief summary of the research of the past years is that it has been shown that almost all these confounding factors influence judgments, along with a number of others.

One plausible factor involves differences in *directness*. Previous research with other paradigms has shown that people find indirect harm less aversive than direct harm (Moore et al., 2008; Paharia et al., 2009; Royzman & Baron, 2002). Greene et al. (2009) have split this factor into three components: spatial proximity, physical contact, and personal force. Personal force refers to impacts on victims that are directly generated by muscular force of the agent. Touching and pushing a victim is an example of physical contact and personal force; using a pole for pushing would be an example of personal force without physical contact. Different versions of the

footbridge dilemma were compared in which the three components were pitted against each other. The results show that moral permissibility assessments were explained by the personal force factor. In additional studies it was shown that only personal force that is due to an intentional act is relevant.

Personal force does not provide a full account of intuitions in trolley dilemmas, however. Waldmann and his colleagues (Waldmann & Dieterich, 2007; Waldmann & Wiegmann, 2010) have constructed versions of the trolley dilemma in which the victims in all conditions were sitting in vehicles (which made their kind of death comparable), the agents were remote, the acts were equated, and neither physical contact nor personal force was necessary to act. For example, in the bystander variant a train heading toward a train with five passengers could be redirected to a side track in which a train with one passenger is located by pressing a button in a remote control center. In the contrasted footbridge analog, the setup is the same but now the train on the side track with one passenger could be redirected by pressing a button onto the main track, where this train would stop the threatening runaway train and thus save the five (Waldmann & Wiegmann, 2010). Participants reliably found the intervention in the first condition in which the threatening train was redirected ("threat intervention") more acceptable than the one in the second condition in which the train with the one victim was redirected ("victim intervention"), although no personal force was involved.

One possible explanation of the differences between threat and victim intervention is the DDE (e.g., Cushman et al., 2010; Mikhail, 2011; Royzman & Baron, 2002). Whereas in the threat intervention condition the victim is harmed as a side effect of saving the five, in the contrasted victim intervention condition the victim is used as a means to stop the runaway train. The doctrine of double effect can only be supported by indirect evidence, not by asking subjects. Cushman et al. (2006) have shown that this rule is not consciously accessible to subjects who are requested to provide a justification for their moral judgment. Other moral rules, however, such as the principle that touching and thereby harming a person (contact principle) is impermissible, can be consciously accessed.

A popular paradigm to test whether using a person as a means to save others is really particularly aversive is based on Thomson's (1985) loop idea. In this variant of the bystander dilemma, the side track loops back to the main track right before the

location where the five victims sit. This small variation turns the victim on the side track into a means to save the five. If the runaway train is redirected to the side track without being stopped by the person sitting there, it would go back to the main track and kill the five. Hauser et al. (2007) found that subjects judge the act in this condition more aversive than in the regular bystander (i.e., side effect) condition, but their experiment had the already mentioned confounds. Better-controlled studies did not find a difference (Greene et al., 2009; Waldmann & Dieterich, 2007; but see Sinnott-Armstrong, Mallon, McCoy, & Hull, 2008).

How else can the difference between threat and victim intervention be explained when personal force does not play a role in either condition? Waldmann and Wiegmann (2010) have proposed a *double causal contrast theory* to explain differences in intuitions in scenarios in which other relevant factors, such as distance, personal force, kind of victim, or kind of death have been held constant. The general idea motivating this theory is that people pay special attention to the intervention option when judging moral acceptability. Like all theories of moral judgments this theory predicts that reasoners are sensitive to the global contrast entailed by acting and nonacting (e.g., five victims vs. one), which explains why we differentiate between saving five or saving 1,000,000 (Bartels, 2008; Nichols & Mallon, 2006). However, whereas the DDE additionally is sensitive to the causal processes generated by the intervention (e.g., side effect vs. means), the double contrast theory assumes that we focus on the morally relevant target of intervention (i.e., threats or victims) and assess the harm directly caused by intervening on this target in contrast to the harm in which the target would be directly involved in the absence of the intervention. This local, counterfactual contrast focusing on the target of intervention will, according to this theory, heavily influence the acceptability rating.

How does the double causal contrast theory explain the two standard dilemmas? In the threat intervention condition, the proposed act can be summarized as redirecting the threat. Thus, the morally relevant target is the threatening trolley. To assess the local contrast, we need to focus on the direct harm caused by the target of intervention, which is one seriously harmed person. This outcome is contrasted with the direct harm caused by the target of intervention in the absence of the intervention, which in this condition are five

harmed people. In contrast, in the victim intervention condition, the proposed act can be described as redirecting the victim in the train on the side track. Thus, the local contrast will focus on the train with its single potential victim. Setting this train into motion will directly cause harm to this victim. The fact that five people are saved further in the future is an indirect, more remote consequence of the act and therefore not part of the local contrast. The proposed intervention is contrasted with what would happen to the target of intervention in the absence of an intervention. In this case the person sitting in the train on the safe track would remain unharmed. The local contrast implies that the act is harmful, which predicts the lowered acceptability ratings.

Double causal contrast theory explains why people are not only sensitive to how the victim is directly harmed by the intervention but also that they consider whether the victim would have been harmed in the absence of an intervention (Moore et al., 2008). Moreover, Waldmann and Wiegmann (2010) showed that people accept harming a victim as a means when the local contrast is favorable. In one of their experiments they described a trolley dilemma in which the runaway train threatening five carries a passenger. If nothing was done, this passenger would stay alive and the train would kill the five. The five can be saved, however, if an empty train is redirected toward the threatening train, derailing it by pushing its passenger, who would die in the process, against the emergency brakes. Although here the intervention directly kills one person who plays the role of a means to save the five, subjects find this act highly acceptable. They focus on the threatening train with its single victim as the target of intervention, which leads to a contrast between five and one dead person.

The debate about the role of the DDE focuses on causal and intentional factors underlying moral intuitions. However, there are many other factors influencing judgments in trolley dilemmas. Rai and Holyoak (2010) demonstrate that domain-general factors that have been identified in behavioral economics also affect judgments in trolley dilemmas. Subjects who were asked to generate many reasons in favor of the action paradoxically rated it as *less* permissible than those who generated fewer reasons. This is consistent with research by Schwarz (1998), who showed that ease of retrieval of justifications is used as indicator for the quality of an option in nonmoral consumer choice. Other factors are mood of subjects (Strohminger, Lewis, & Meyer, 2011; Valdesolo &

DeSteno, 2006), thinking styles (Bartels, 2008), preferred ethical position (Lombrozo, 2009), working memory (Moore et al., 2008), test question (see Kahane & Shackel, 2010), kind of victim (Uhlmann, Pizarro, Tannenbaum, & Ditto, 2009), vividness of death (Bartels, 2008), and the order of presenting different dilemmas (Iliev et al., 2009; Liao, Wiegmann, Alexander, & Vong, in press; Petrinovich & O'Neill, 1996; Wiegmann, Okan, & Nagel, in press). In short, it seems hopeless to look for the one and only explanation of moral intuitions in dilemmas. The research suggests that various moral and nonmoral factors interact in the generation of moral judgments about dilemmas.

The Role of Intention

A popular assumption implicit in many normative theories of morality is that we can only be held accountable for outcomes we have caused (Driver, 2008). We cannot possibly be responsible for bad events that are not directly or indirectly causally linked to our acts. In addition, most normative theories assign a special status to harm that was intentionally caused. For example, the doctrine of double effect (see sections on "Moral Grammar Theory" and "Moral Dilemmas") forbids intentionally harming a person, whereas unintentional harm may be permitted in some circumstances, even when the harmful outcome is foreseen. The interplay of intention and causal responsibility has also been central in descriptive theories of blame ascription (Alicke, 2000). A variety of recent studies have taken a closer look at the role of intentions and outcomes in moral judgments.

Cushman (2008) noted that different test questions may influence the relative contribution of these two components, intention and causation, in moral judgments. Cushman adopted a standard definition of intentional action according to which an act is intentionally performed if among other things the expected consequences are both desired and the act is believed to bring about these consequences (see Malle & Knobe, 1997). He used a story in which Jenny, the protagonist, is taking a course in sculpture and is assigned to work with a partner to weld together pieces of metal. The factors desire, belief, and consequences were manipulated independently using different cover stories: Jenny either desired or did not desire to burn her partner's hand, and she believed or did not believe that the act causes the harmful outcome. Moreover, it was varied whether the outcome did or did not occur. Cushman showed that judgments of blame and punishment are more

sensitive to whether the harmful outcome caused by the agent occurs, whereas judgments of wrongness and permissibility are more sensitive to the agent's belief with respect to harming someone. However, the belief factor was the strongest predictor for both kinds of judgments.

Although our normative intuitions imply that we only should be held responsible for outcomes that are under our causal control, a number of experiments about *moral luck* (Williams, 1982) have shown that negative outcomes that are not fully under the agent's control may also influence our judgments. A typical example of moral luck is the following scenario: A father who bathes his child in a tub answers the phone in the nearby living room after telling his child to stay put. He believes that his son will indeed stay put so that nothing bad will happen. The father is typically judged to be more morally blameworthy if his child drowns (an unlucky outcome) than if his child stays safe (a lucky outcome). Thus, in both cases the intentions and the knowledge are the same, but the outcomes vary due to unforeseen random factors. In psychology, the apparently inappropriate weight given to the outcome has been labeled *outcome bias*, which has been documented in many different scenarios (see Baron & Hershey, 1988; Gino et al., 2010).

One obvious theory explaining outcome biases is that people give undue weight to the valence of the outcome, even though the agent did not intend it and is not fully responsible for it. However, Young, Nichols, and Saxe (2010) proposed an alternative theory according to which moral luck depends strongly on belief attribution and only indirectly on the bad outcome. The theory claims that the bad outcome provides evidence that the unlucky agent's beliefs are erroneous. Holding an erroneous belief that can cause harm is blameworthy and therefore leads to harsher moral judgments. In contrast, in the condition of the lucky agent the outcome validates the correctness of the agent's prior beliefs.

Another recent controversy revolves around the causal relationship between intentions and moral judgments. Cushman (2008) and Young et al. (2010) adopt the traditional assumption that this relationship is unidirectional: The agent's intention determines the moral judgment of an act. However, consider the following example presented by Knobe (2003):

The vice-president of a company went to the chairman of the board and said, "We are thinking

of starting a new program. It will help us increase profits, but it will also harm the environment." The chairman of the board answered, "I don't care at all about harming the environment. I just want to make as much profit as I can. Let's start the new program." They started the new program. Sure enough, the environment was harmed. (p. 191)

In a second version of this scenario, the word "harm" was replaced by "help." When subjects were asked whether they think the chairman intentionally harmed the environment, eighty-two percent answered in the affirmative. In contrast, in the help condition seventy-seven percent said that the agent did *not* bring about the good side effect intentionally. Knobe concluded that in judging whether the side effect was brought about intentionally, the moral value of the side effect is crucial. People seem considerably more willing to say that a side effect was brought about intentionally when they regard it as bad than when they regard it as good. This finding suggests the opposite from what is traditionally assumed: The moral evaluation of the outcome seems to determine whether intentionality is attributed, not the other way around.

There have been a lot of attempts to explain the so-called side-effect effect (also known as Knobe effect). Most of the proposed explanations can broadly be put into two groups (see Feltz, 2007; Uttich & Lombrozo, 2010). One group explains the side-effect effect by claiming that moral evaluations actually play a role in our concept of intentional action. According to this group of theories, the concept of intentional action actually includes and can be determined by the moral value of the effects that are caused by the act (see, e.g., Knobe, 2010; Mele & Cushman, 2007; Nichols & Ulatowski, 2007).

The other group denies this claim and explains the side-effect effect by arguing that subjects' judgments of intentional action are biased. For instance, Adams and Steadman (2004) invoke conversational pragmatics and argue that people want to express blame for the agent in the negative side-effect condition by characterizing the outcome as intentional. Another supporter of this view is Nadelhoffer (2004), who claims that subjects' judgments are biased because they get emotionally affected by the bad side effect. Guglielmo and Malle (2010) believe that task demands forced participants to use the term "intentional:" When given a choice, most participants prefer to say that the agent brought about the bad side effect *knowingly* rather than *intentionally*.

(similar to what the DDE would predict; see section on “Moral Grammar Theory”).

Recently, Uttich and Lombrozo (2010) offered an interesting explanation that does not fall into either of these groups. They propose a rational explanation of the side-effect effect according to which the asymmetry in intentionality judgments arises because behavior that conforms to norms (moral or otherwise) is less informative regarding the mental state of the actor than norm-violating behavior (see Machery, 2008, for another theory of this kind). Prescriptive norms give us a positive reason to act, regardless of our intentions. Hence, a behavior that conforms to a norm does not tell us much about the agent’s intentions. In contrast, violating a norm provides us with positive evidence about the agent’s mental state. For example, in Knobe’s examples the norm is not to harm the environment. Thus, when the chairman starts a program that helps the environment, we cannot tell whether he intends this or just follows a norm, whereas in the contrast case the norm-violating behavior provides us with strong evidence of an intention to harm the environment. This theory is not restricted to moral norms; rather, it applies to all norms, moral or nonmoral. Uttich and Lombrozo (2010) could show that virtually the same asymmetry can be observed when the cover stories mention the conventional norm that specific cars usually have a dark color. Knobe (2010) has recently offered a similar explanation, but in contrast to Uttich and Lombrozo he highlights the role of *moral* norms.

In sum, the present research indicates that the role of intention is far more complex than previously thought. Intentions are unobservable states that need to be inferred. Apparently, a large number of factors, including observed behavior, outcomes, causal structure, rationality assumptions, and norms, contribute to these attributions. Moreover, our language allows for subtle differentiations between different types of intentionality (e.g., desire, want, intend, foresee), which form a complex network with other factors underlying moral judgment.

An interesting direction for future research might be to take a closer look at the role of intentions in different moral domains and in different cultures. As for domain differences, Young and Saxe (2011) have shown that intentions are assigned more weight for moral judgments of harm violations, like assault, compared to purity violations, like incest. Thus, differences in the role of intentions between different cultures may arise due to differences in

the culture-specific importance of moral domains. However, it is also possible that cultures differ within domains. In Western societies, the intentions of the agent are viewed as very important when assessing moral accountability, possibly more than in other cultures. Intentional transgressions of moral rules are typically condemned much more than accidental transgressions. In contrast, Rai and Fiske (2011) point out that in honor cultures, a woman who has sexual relations outside marriage, *even against her will*, defiles her family and is therefore punished.

Sacred/Protected Values

A characteristic feature of some moral values is that they resist trade-offs with other values. For example, many people find it impossible, inappropriate, or even outright abhorrent to put a price on human lives, friendships, democratic votes, or the preservation of the environment. It seems that some people ascribe infinite values to such entities, in that they would not accept any amount of any other good (especially not monetary ones) as compensation for the destruction or compromise of them. Such values have been termed “sacred” (Tetlock, Peterson, & Lerner, 1996) or “protected” (Baron & Spranca, 1997). Although both terms refer to the same phenomenon, the corresponding lines of research analyze it from different theoretical viewpoints, yielding different implications and even partially incompatible conclusions.

Tetlock and his colleagues describe sacred values (SVs) in their cultural context and analyze their social psychological functions. According to the revised Value Pluralism Model (Tetlock et al., 1996), people value different things for different reasons. When it comes to interpersonally relevant entities (such as intimate relationships, human rights, or religious symbols), people feel they have a commitment to others within their cultural community; they need to respect these entities in order to demonstrate that they are an estimable member of the community. The categorical nature of these commitments implies that within these sacred domains of social life, favors and goods are usually exchanged without numerical comparison (Fiske & Tetlock, 1997). If people compromise the respective values by trading them off against secular values (such as money, time, or convenience), they disqualify themselves from important social roles. Sacred and secular values are constitutively incommensurable; they cannot be sensibly compared, and mere attempts of comparison can destroy the SVs.

The motivation of people to hold SVs is to preserve their identity as full-fledged moral beings. If they witness others engaging in or merely contemplating taboo trade-offs, they typically react with moral outrage, a unitary response pattern consisting of harsh trait attributions, anger or contempt, and strong punitive impulses toward the offender (Tetlock, Kristel, Elson, Green, & Lerner, 2000). Due to unavoidable resource constraints in the real world, however, people are often forced to trade off SVs themselves. In such cases, they go to great lengths to conceal these trade-offs, for example, by means of decision avoidance or rhetorical obfuscation. Thus, people can be portrayed as both unapologetic defenders of SVs and at the same time as experts in finding ways to camouflage or overlook transgressions (Tetlock, 2003). Despite this discrepancy, Tetlock does not see people as hopeless hypocrites but instead as intuitive theologians striving to “[protect] sacred values from secular encroachments” (Tetlock, 2002, p. 452). Their rigidity is not seen as irrational but instead as serving important psychological functions and, on a larger scale, preventing subversion of meaningful cultural institutions (Fiske & Tetlock, 1997).

Baron approaches protected values (PVs) in the framework of the heuristics and biases program (see also section on “Moral Heuristics”). The main idea is that PVs are derived from deontological rules about acts (e.g., “do not kill”), irrespective of the consequences (Baron & Spranca, 1997). These rules are usually adaptive if treated as rules of thumb, but they may sometimes lead to suboptimal outcomes if they are unreflectively generalized to all contexts (Baron, 1998). In contrast to Tetlock, Baron reduces human values to a single utility metric, treating PVs as biases and stressing the problems they create for a utilitarian analysis.

One implication of the basis for PVs in absolute deontological rules is *quantity insensitivity*. For example, it seems to make only a small difference for people whether an act leads to greater or lesser harm to one of their PVs (Baron & Spranca, 1997), and some people seem to find it equally wrong to compromise a PV once or twice (Ritov & Baron, 1999). Another feature of deontological rules is that they usually prohibit harmful acts but not omissions, since prohibiting the latter would produce potentially unlimited obligations (Baron & Miller, 2000). Thus, PVs are seen as a source of omission bias (Baron & Ritov, 2009; Ritov & Baron, 1999) because actions are more likely to compromise PVs than omissions. For example, Ritov and Baron (1999) presented their

subjects with a scenario in which 20 species of fish living in a river would become extinct unless a dam was opened. However, opening the dam would cause the extinction of two different species living downstream which would otherwise survive. People with a PV against extinguishing species were especially unwilling to open the dam, even though this decision would result in a greater net amount of damage to their cherished natural resource.

Many people seem to readily endorse statements implying PVs when asked directly (e.g., “This should be prohibited no matter how great the benefits from allowing it;” Baron & Spranca, 1997, p. 7). However, according to Baron and Leshner (2000), such judgments may be the result of reflexive, incomplete thinking which can be overcome quite easily. When PVs are challenged with realistic counterexamples involving extremely high benefits or low probabilities for harm to PVs, many people relativize their absolute claims. This finding is taken to indicate that expressions of PVs should not be taken too seriously.

This remarkable tension between rigidity and flexibility has recently been interpreted differently by Bartels, Medin, and colleagues. Instead of seeing deontological judgments as an impediment for consequentialist judgments, they regard both as often positively correlated across people (Iliev et al., 2009). That is, people holding PVs that rigidly prohibit certain actions in one task can be shown to be especially sensitive to consequences of these actions in different tasks, compared to people without PVs. Whether they give more weight to means or ends is largely a function of their attentional focus, which in turn is crucially affected by domain-general individual thinking styles, as well as low-level features of the task, such as framing and context effects (Bartels, 2008). For example, Bartels and Medin (2007) argued that the framing of the response options used by Ritov and Baron (1999) in the river diversion scenario (“Would you open the dam? Yes/No,” followed by a measure for quantity sensitivity) directs the subjects’ attention to the act of killing species. In this condition many people maintain a categorical prohibition against this act, which leads them to express a PV. Bartels and Medin (2007) went on to show that reframing the response alternatives so that they deflect attention away from the action itself to the consequences (by having subjects choose from a list of alternatives the maximum number of species living downstream they would be willing to kill by opening the dam to save the twenty species at risk)

leads people with PVs to become *more* quantity sensitive, and less likely to show an omission bias than those without PVs. It seems as if the moral issue at stake is more central for people with PVs, and that they show amplified reactions in whatever direction their attention is steered by the task at hand (but see Baron & Ritov, 2009). In general, research on sacred and protected values provides an interesting test case showing that theories of moral judgments need to combine domain-specific cognitions (e.g., moral values) and domain-general mechanisms (e.g., attention).

Conclusions and Future Directions

The recent close cooperation both within psychology and across different disciplines has led to numerous new insights about morality. Summarizing the research from the viewpoint of a cognitive psychologist, three general research foci can be identified. First, many researchers have been interested in exploring the role of emotions and affects in moral judgments (see sections on “Emotion-based Theories” and “Dual-Process Theory”). This interest was initially motivated by a critique of previous paradigms (e.g., Kohlberg, 1981) in which conscious reasoning and rational deliberations were given a central place. In contrast, the more recent research has shown that many judgments are based on intuitions that are unconsciously elicited and are often accompanied by affects and emotions. The exact role of emotions is still not entirely clear. Emotions may precede or follow judgments, they may be constitutive for judgments, or they may be independent of rational judgment processes. A likely outcome of this debate may be that all of these possibilities occur, although we still need to know the boundary conditions of the different possibilities.

Second, the research on intuitions and emotions has largely addressed the global question of how reasoning and emotions in general are interrelated, but it has neglected the issue how specific intuitive judgments are caused. Thus, based on this research it is often impossible to make specific predictions about judgments for specific moral issues. The research has frequently been abstractly organized around a dichotomy between conscious reasoning and unconsciously elicited intuitions, which may have led to a neglect of research about the cognitive processes eliciting intuitions. In cognitive psychology, very few processes, not even logical reasoning and problem solving, are considered under full conscious control (see Evans, Chapter 8). Rather,

cognitive theories specify the often unconscious information processing steps leading from an eliciting situation to a judgment. Although we still know little about these processes, some researchers have made progress in recent years specifying moral rules (e.g., doctrine of double effect) or moral heuristics underlying the appraisal of moral scenarios.

Third, an overarching question motivating most research on moral judgment is whether moral cognitions are special, or whether they represent just specific contents that otherwise can be handled by domain-general theories. The present research suggests that there is no innate specialized module devoted to morality that is encapsulated from other cognitive processes. Many studies that were motivated by domain-general theories, for example, behavioral economics, judgment and decision-making theories, or attention theories, have shown that moral reasoning is not an isolated process but rather recruits domain-general processes that may lead to phenomena also found in other domains. On the other hand, a full reduction of moral cognitions to general cognitions also seems implausible. Moral judgments use moral rules, moral values, or norms that have characteristics that differ from the general class of rules. They are typically accompanied by strong affect and emotions, which endow them with a force that goes beyond general conventional norms. Moral rules or norms are typically viewed as authority independent, as ends that have to be honored, as particularly important, and by some people as universally valid. Thus, there is a consensus in the literature that humans are born with dispositions to honor norms that manifest themselves in moral judgments. Whether beyond the general capacity to acquire norms, there is also an innate capacity that predisposes humans to acquire specific *moral* rules, is an open question that is currently strongly debated.

In this review, we concentrated on research about explicit judgment tasks. Some researchers have questioned whether studying isolated judgments, especially with controlled experimental tasks, is ecologically valid (Gigerenzer, 2010). Our position is that we should not primarily study moral judgments to predict behavior, but rather to understand how people judge what is right or wrong. People’s opinions about moral issues, such as abortion, capital punishment, health, or food, are important factors shaping our society. However, it can be argued that implicit judgments are also reflected in *actions*. Although it is well known that moral judgments are not strongly correlated with corresponding actions, it

is interesting to compare explicit with more implicit moral evaluations. There are several interesting lines of research investigating actual behaviors that can be viewed as indicators of implicit moral judgment. For example, it has been shown that people paradoxically feel licensed to behave in morally dubious ways (e.g., cheating, lying, not donating to charity, or making uncooperative decisions) when they have activated a particularly positive view of their moral self (Mazar, Amir, & Ariely, 2008; Mazar & Zhong, 2010; Sachdeva, Iliev, & Medin, 2009). Conversely, they feel compelled to act particularly morally when their moral self-image is threatened ("moral cleansing behavior," see Sachdeva et al., 2009; Tetlock et al., 2000), demonstrating the importance of self-regulatory processes for implicit judgments underlying moral behavior.

People's implicit judgments concerning issues of fairness, altruism, cooperation, and punishment have also been assessed using behavioral measures. Fairness has been extensively investigated in simple bargaining games, primarily in the Ultimatum and Dictator Games, which investigate when subjects would reject unfair distributions of goods even when this implies that they would not get anything (e.g., Camerer, 2003; Camerer & Smith, Chapter 18). Common good games, which study individuals competing with other members of a group for common resources, have been used to obtain behavioral measures of cooperation, defection, and punishment (e.g., Fehr & Gächter, 2000). There is also a huge literature on altruism and prosocial behavior (see Batson, 2011).

We have seen that, although there seems to be an explosion of research on morality in recent years, many questions remain unanswered. Here we just list a few of these questions that seem particularly pressing from the viewpoint of cognitive psychology. For example, we know very little about the appraisal processes leading to moral judgments. Most of the theories dealing with appraisal have been developed in the context of very limited paradigms (e.g., trolley problems), so that the generality of these theories is unknown. Moreover, oversimplified theories of the representation of moral norms have postulated rules that seem to only superficially fit the investigated task. "Do no harm," for example, is certainly a rule that often seems plausible, but it does not capture the context sensitivity that people's judgments display. Thus, if a rule-based account is chosen, a much more complex system of rules needs to be specified, which includes boundary conditions and exceptions. Moreover, if research

on categorization is taken as a model (see Rips et al., Chapter 11), we need to ask whether rules are the only plausible format for the representation of moral knowledge or whether other representational devices, such as exemplars, prototypes, schemas, or analogies, also play a role.

We expect more research concerning the interplay of domain-general and domain-specific process in moral judgments. As the research on trolley dilemmas (see section on "Moral Dilemmas") shows, it seems necessary to negotiate the relative role of these processes for each target problem separately. There has been a tendency in the field to overstate findings as evidence for the use of grand philosophical positions. In our view, it seems implausible to argue that a sociopath reasons like a consequentialist when a much simpler account can be found. The fact that somebody finds smothering a baby abhorrent, or that somebody finds it preferable that one person instead of 1,000,000 people dies, does not turn this person into a deontologist or a consequentialist. It seems more plausible to pinpoint the reason for different judgments on more local factors, such as selective attention to specific aspects of a situation or deficits of affective processing.

Our review was largely limited to studies focusing on Western moral norms (e.g., prohibition of harm), which have been central in studies on the cognitive and affective foundations of moral judgment. The explanation for this one-sidedness is that both researchers and research subjects typically have a Western background (Henrich, Heine, & Norenzayan, 2010). Although anthropology has collected massive evidence showing that there is more to morality than concerns about harm or fairness/justice, most of this research so far is descriptive. We know that other cultures often endorse other norms, but we do not know how moral cognitions in other societies differ from ours. Do people in other cultures employ the same cognitive processes but invoke different moral rules, or are the cognitive processes underlying judgments different in other cultures? The most likely answer is that both possibilities may turn out to be true. If specified very abstractly, a process such as attentional focus will certainly influence judgments in different cultures, although the target of the focus will of course shift. On the other hand, we do not know whether general regularities that go beyond specific rules but are less abstract than attention universally play a similar role. For example, the section on "The Role of Intention" highlighted the role of intention in moral

blame. An interesting question might be whether intentional attributions and the weighing of intentions are similar in different domains and in different cultures. In sum, moral cognitions are most certainly an interesting topic for future research, but we have only started to understand this fascinating competency.

Motivated Thinking

Daniel C. Molden and E. Tory Higgins

Abstract

Once controversial, the idea that people's motivations can influence their cognitions now plays an important role in current research on thinking and reasoning. This chapter describes the effects on cognition of motivations that originate from three separate sources: (a) specific desired conclusions (e.g., perceptions of oneself as successful, loved, or in control); (b) more general desired conclusions (e.g., judgments that are as concise and unambiguous, or as accurate as possible); and (c) preferences for reaching such conclusions using particular types of judgment strategies (e.g., a focus on pursuing opportunities for gain versus protecting against the possibility of loss). Evidence is reviewed for the influence of each of these motivations on a variety of cognitive processes, illustrating that, in addition to being "cognitive misers" whose biases result from limited cognitive-processing capacity, people are "motivated tacticians" whose biases result from preferences for processing information in ways that serve their current motivational concerns.

Key Words: self-enhancement motivations, need for belonging, need for control, accuracy motivations, need for closure, regulatory focus, regulatory mode, regulatory fit

At one time or another, every one of us has engaged in "wishful thinking" or "let our hearts run away with our heads." That is, every one of us has experienced the effects of our motivations on our thoughts and behaviors. Over the past 10–15 years, researchers have shown a renewed interest in these types of experiences and conducted many investigations of how people's drives, needs, desires, motives, and goals can profoundly influence their judgment and reasoning across many different domains. This chapter provides an overview of such research on motivated thinking and describes how, in addition to being "cognitive misers" whose biases result from generally limited cognitive-processing capacity, people are "motivated tacticians" whose biases result from specific preferences for processing information in ways that serve their current motivational concerns.

Psychologists have long placed the impact of motivation on basic cognitive processes at the center of their analysis of human behavior (e.g., Allport, 1920; Lewin, 1935; Murray, 1938). However, for a period of time, this impact was questioned and effects related to motivated thinking were recast as purely cognitive phenomena stemming from imperfect information processing by imperfect perceivers (e.g., Bem, 1967; Nisbett & Ross, 1980). Yet once it became clear that debates about the workings of motivational *versus* cognitive processes in judgment and behavior were fruitless and counterproductive (e.g., Tetlock & Levi, 1982), a new wave of research emerged that emphasized the interface between these processes and began to identify more precisely the distinct mechanisms by which drives, needs, motives, and goals alter people's judgment and

actions (see, Dunning, 1999; Higgins & Molden, 2003; Kruglanski, 1996; Kunda, 1990).

In this chapter, we review this “second generation” of research on motivated thinking and consider some of the basic principles that have emerged. We examine two general classes of motivational influences that have been identified. The first involves people’s desires for reaching particular types of judgment *outcomes*, and the second involves people’s desires to use particular types of judgment *strategies*. Because we adopt a broad focus and discuss many different varieties of motivated thinking, we are selective rather than comprehensive in the phenomena described. The programs of research we highlight are those we believe to be representative of the larger literature and especially relevant not only to the study of reasoning but to other areas of experimental psychology.¹ After reviewing the separate influences of outcome- and strategy-based motivations, we conclude by suggesting potential directions for future research, giving special attention to possible interactions between a variety of motivations that might be simultaneously activated.

Outcome-Motivated Thinking

The most prominent approach to motivated reasoning, in both classic and contemporary perspectives, has been to examine the influence on people’s thought processes of their needs, preferences, and goals to reach desired outcomes (or avoid undesired outcomes). Although the types of desired outcomes studied have been highly diverse, they can be divided into two general classes: *directional* outcomes and *nondirectional* outcomes (see Kruglanski, 1996; Kunda, 1990). Individuals who are motivated by directional outcomes are interested in reaching specific desired conclusions, such as impressions of themselves as intelligent, caring, and worthy people (e.g., Dunning, 1999; Kunda, 1990); perceptions of belonging and social connection with others (e.g., Baumeister & Leary, 1995; Molden & Maner, in press); and feelings of control and understanding (e.g., Heine, Proulx, & Vohs, 2006; Pittman & D’Agostino, 1989). That is, such directional outcomes inherently specify the precise content of the conclusions people are motivated to reach. In contrast, individuals who are motivated by nondirectional outcomes have more general concerns such as reaching the most accurate conclusion possible (e.g., Fiske & Neuberg, 1990) or reaching a conclusion that is concise and unambiguous (e.g., Kruglanski

& Webster, 1996), whatever this conclusion may be. That is, nondirectional outcomes do not directly specify the precise content of the conclusions people are motivated to reach (although, as discussed in detail later, these outcomes can certainly still indirectly alter what conclusions they finally do reach).

Whether outcome motivation is directional or nondirectional, this motivation has been conceptualized as affecting thought and reasoning in the same general way: by directing people’s cognitive processes (e.g., their attributions, information search, or recall) in a manner that helps ensure that they reach the desired outcomes. In the next sections, we review several programs of research that have examined more closely the specific mechanisms by which this can occur, first in relation to motivations for directional outcomes and then in relation to motivations for nondirectional outcomes. Following this, we discuss several limitations of the effects of outcome motivation on reasoning and identify circumstances in which these motivations are most likely to have an impact.

Influences of Motivations for Directional Outcomes

Overall, the kinds of phenomena that have been studied most extensively in research on motivated thinking involve preferences for directional outcomes, that is, individuals’ desires to reach specific conclusions about themselves and others (see Dunning, 1999; Kunda, 1990; Murray, 1999). Overall, the outcomes that have, by far, received the most attention involve people’s well-documented preference for viewing themselves, and those close to them, in a generally positive manner (i.e., desires to preserve self-esteem; see Baumeister, 1998). However, more recently, other outcomes, such as desires to feel connected to others (Baumeister & Leary, 1995; Molden & Maner, in press) and desires for understanding of and control over one’s environment (Heine et al., 2006; Pittman & D’Agostino, 1989; Seligman, 1976) have also received more attention as well. Given the extensive reviews of esteem-related effects on motivated thinking available elsewhere (Kruglanski, 1996; Kunda, 1990; Molden & Higgins, 2005), we give priority to detailing the influence of other types of directional motivations here.

In the next sections, we review several effects of directional motivations involving many different cognitive processes, including attribution, evaluation of truth and legitimacy, attention and information

search, recall and knowledge activation, and the organization of concepts in memory. The studies described provide evidence for motivational effects on cognition using several different strategies. One is to correlate individual differences in the general importance of particular needs or goals with different judgment outcomes; another is to experimentally vary the contextual salience of particular motivations or the relevance of these motivations to the judgment at hand and examine the consequences; still another is to threaten or challenge people's progress toward fulfilling particular motivations and assess how people think and behave in response to this threat. Despite these variations in method, the basic logic of all of these studies is that greater motivational activation, whether from chronic personality orientations, temporary salience, or in response to a current challenge, should produce more motivationally consistent thinking and reasoning.

EFFECTS ON ATTRIBUTION

One early demonstration of the effects of motivation on judgment came from work on the explanation of behavior and the attribution of particular traits to oneself or others (see Kelley, 1973). Whereas many initial studies focused on how esteem-related motivations influenced people's claims of personal responsibility for their successes, and denial of responsibility for their failures (for a meta-analysis see Mezulis, Abramson, Hyde, & Hankin, 2004), recent programs of research have examined the attributional effects of motivations for belonging and feelings of control as well.

For example, one series of studies on how motives for social connection affect self-perception showed that students who viewed personality profiles of attractive, opposite-sex individuals as part of a "matchmaking" exercise later attributed the traits listed in the profiles more strongly to themselves, enhancing what they had in common with these individuals (Slotter & Gardner, 2009). Furthermore, such attributions emerged even for traits that students had identified weeks earlier as not describing them very well. Consistent with the motivational nature of this phenomenon, these effects were strongest among individuals who wanted to initiate a romantic relationship. Moreover, students who viewed identical personality profiles as part of a student-government campaign did not strongly attribute such traits to themselves.

Additional studies have demonstrated similar effects of motivations for social connection on

perceptions of others. Students who had learned that no one wanted to work with them on a group task later attributed more friendliness and likability to individuals they viewed in photographs than did students who had learned that many people wanted to work with them (Maner, DeWall, Baumeister, & Schaller, 2007). As is again consistent with the motivational nature of these effects, such findings were limited to individuals who were not overly fearful of negative evaluations from others, and thus sufficiently interested in pursuing *reconnection* following social exclusion (see also Maner et al., 2005).

Research on how motivations for feelings of control influence attribution has demonstrated analogous effects. Although some initial findings suggested that decreased feelings of control generally increase the effort and attention people give to their attributions overall (Pittman & D'Agostino, 1989), recent studies have indicated that people who experience less control selectively choose attributions that specifically bolster either their sense of personal control or perceptions that the world generally is an understandable and predictable place. For example, when people's feelings of control are threatened by reminding them that they will eventually die, they explain life-threatening events that happen to others more strongly in terms of these other individuals' unique traits and behaviors (Hirschberger, 2006). Such attributions presumably allow people to see the events as more avoidable and help them restore some sense of control (see also Fritzsche, Jonas, & Fankhänel, 2008). Similarly, when people are asked to relive instances in which they themselves were not in control, they subsequently attribute greater control to external institutions and agents, such as governments and God, than people who relive instances in which they had personal control (Kay, Gaucher, Napier, Callan, & Laurin, 2008). However, this effect occurs only when such external agents are perceived to be fair and benevolent and actually allow people to maintain a general sense of predictability and control (see also Kraus, Piff, & Keltner, 2009). Finally, when feelings of control are threatened through interactions with unpredictable mechanical objects or computer programs, people form stronger attributions of human-like agency and intention (Waytz et al., 2010), which also helps restore some feelings of understanding and predictability. Therefore, overall, increased motivations for both social connection and control produce attributions that better allow people to reach their desired conclusions.

EFFECTS ON EVALUATION OF TRUTH AND LEGITIMACY

In addition to favoring motivationally relevant attributions, people also preferentially evaluate the truth and legitimacy of information that supports (versus contradicts) motivationally relevant outcomes. A classic example of this effect, to which many researchers can perhaps relate, is that individuals reading about scientific studies that appear to support their cherished attitudes describe the studies as being better conducted, and their conclusions as being more valid, than individuals for whom the same studies are in conflict with their cherished attitudes (Lord, Ross, & Lepper, 1979; see also Beauregard & Dunning, 1998; Ditto, Scepansky, Munro, Apanovitch, & Lockhart, 1998; Kunda, 1987; Tetlock, 1998).

Similar phenomena have been observed for judgments about the rightness or wrongness of institutional practices. For example, people who were induced to believe that the institutions of the society to which they belonged (e.g., governments, universities, businesses) had greater control over their personal outcomes were more likely to judge the current institutional practices (whatever they were) as legitimate and right (Kay et al., 2009; see also Kay, Jost, & Young, 2005). Moreover, a nationally representative survey in the United States showed that people with stronger convictions concerning the moral wrongness of physician-assisted suicide not only viewed a 2006 decision by the Supreme Court supporting the legality of such measures as more unfair and personally unacceptable, they also questioned the legitimacy of the court itself and were more supportive of measures to reduce the court's ability to make these types of decisions. In contrast, people with stronger convictions concerning the moral rightness of physician-assisted suicide elevated the legitimacy of the court and its powers in such matters (Skitka, Bauman, & Lytle, 2009). Thus, overall, people give greater legitimacy to information and actions that are consistent with their desired conclusions but are more skeptical of the exact same information and actions when they are inconsistent with these conclusions.

EFFECTS ON ATTENTION AND INFORMATION SEARCH

Beyond affecting judgments of the validity of particular information, people's motivations can also influence whether they even attend to or notice motivationally consistent or inconsistent

information. Decades of research has investigated whether the information that people seek out or avoid is affected by their predominant attitudes, beliefs, and behaviors. A recent meta-analysis of this research revealed a sizable bias toward selectively attending to motivationally consistent information (Hart et al., 2009). Moreover, consistent with a motivational perspective of this effect, the bias was larger the more committed people were to their attitudes, beliefs, or behaviors and the more central the focal issue was to people's personal values.

Recent research has also demonstrated that such effects occur not only for conscious, explicit decisions about what types of information to process further but also for more unconscious and implicit attentional processes. For example, studies using eye-tracking and visual reaction-time measures have shown that (a) when motivations for belonging are threatened, people selectively fixate their attention on smiling faces that could signal opportunities for social inclusion (and not just on positive stimuli in general; DeWall, Maner, & Rouby, 2009); (b) when romantic motivations are activated (i.e., people are sexually aroused), they selectively fixate their attention on physically attractive faces of the opposite sex that could signal opportunities to fulfill those motivations (but not attractive faces of the same sex or unattractive faces of the opposite sex that do not signal such opportunities; Maner, Gailliot, Rouby, & Miller, 2007); and (c) when jealousy motivations are activated (i.e., people are concerned about romantic infidelity), they selectively fixate their attention on attractive faces of the same sex that could potentially represent romantic rivals (but not attractive faces of the opposite sex or unattractive faces of the same sex that do not represent rivals; Maner, Miller, Rouby, & Gailliot, 2009). Similarly, when people's motivations for control are threatened by the recall of a personal experience of being out of control, they subsequently attempt to impose order on their visual field and are more likely to report seeing coherent images in slides of white noise (Whitson & Galinsky, 2008; see also Proulx & Heine, 2009). Finally, when a particular stimulus has temporarily assumed greater value because it signals task completion or represents some kind of reward, people show sustained attention to this stimulus despite distractors (Raymond & O'Brien, 2009) and overestimate how close the stimulus appears to be (Balceris & Dunning, 2007, 2010).

The motivational influences that we have discussed in this section thus far all concern the *quality*

of attention and information search. However, such influences can also at times affect the *quantity* of information processing (Kruglanski, 1996). Evidence that is motivationally consistent receives decreased processing and quick acceptance, whereas evidence that is motivationally inconsistent receives more thorough processing and hesitant acceptance. That is, when people encounter information inconsistent with desired conclusions, they spend more time considering the validity of this evidence and exert more effort generating hypotheses about why it might be unreliable (see Ditto et al., 1998; Giner-Sorolla & Chaiken, 1997). For example, individuals high in prejudice show increased processing of information about behaviors of African Americans that contradicts, rather than confirms, negative stereotypes in attempts to explain why this counter-stereotypical behavior is simply a fluke (Sherman, Stroessner, Conrey, & Azam, 2005). Moreover, confirming that it is the quantity of processing that plays a critical role, when additional processing toward motivationally inconsistent information is inhibited by placing people under *cognitive load*, the typical motivational differences in people's judgments disappear (see also Plaks & Stecher, 2007; Skitka, Mullen, Griffin, Hutchinson, & Chamberlin, 2002).

EFFECTS ON RECALL AND KNOWLEDGE ACTIVATION

Another means by which motivations influence cognitive processing during judgment involves the activation and retrieval of knowledge stored in memory. Initial studies of esteem-related motivations demonstrated that such influences included (a) selective recall of motivationally consistent information from memory (e.g., Santioso, Kunda, & Fong, 1990), (b) motivationally consistent reconstruction and distortion of previous memories (e.g., McDonald & Hirt, 1997; Stillwell & Baumeister, 1997), and (c) increased implicit accessibility of motivationally consistent concepts in memory (Moskowitz, Gollwitzer, Wasel, & Schaal, 1999; Sinclair & Kunda, 1999). Further studies involving a variety of other types of motivations have demonstrated similar influences as well.

For example, in an illustration of selective recall and distortions of memory related to motivations for social connection, the more individuals typically adopt social goals that revolve around avoiding rejection, embarrassment, and bad feelings, the more negative and fewer positive social events

they recall and the more negatively they reconstruct those positive and neutral events they do recall (Strachman & Gable, 2006). Thus, individuals focused on avoiding rejection appear to selectively focus on this experience, presumably to vigilantly prepare themselves to prevent or cope with future failures of social connection. Similarly, the more individuals are typically motivated to remain autonomous in their relationships, the more they recall being less supportive than they actually were during a conflict with their relationship partner (Simpson, Rholes, & Winterheld, 2010). In contrast, the more individuals are typically motivated to continually pursue intimacy in their relationships, the more they recall feeling emotionally closer to their partner than they actually did during the conflict. Moreover, both of these conflict-related effects are particularly strong when individuals experience the conflict as distressing and their relationship concerns are more active. In another example of these type of effects that involve motivations for understanding and control, people selectively recall past events that imply they deserve a current outcome, thereby making the current outcome seem more under their control. That is, people who have just experienced a lucky break recall having performed more good deeds in the recent past, whereas those who have just experienced an unlucky break recall having performed more bad deeds in the recent past (Callan, Kay, Davidenko, & Ellard, 2009).

As with the effects of motivation on attention and information search described earlier, the effects of motivation on knowledge activation also operate at a more automatic and implicit level. When people's motivations for belonging are threatened after reliving an experience of social exclusion, they respond by spontaneously activating concepts related to the social groups to which they belong, as indicated by faster responses to these concepts in lexical decision tasks (Knowles & Gardner, 2008). Increased motivations for belonging can also increase the spontaneous activation of attitudes that match those of liked others. For example, participants interacting with an experimenter wearing a t-shirt that said "Eracism" showed weaker implicit activation of negative stereotypes associated with African Americans when this experimenter was friendly, but not when this experimenter was rude (Sinclair, Lowery, Hardin, & Colangelo, 2005). Motivations for control can have analogous effects as well. People whose feelings of control were challenged after viewing a video clip in which a person was stalked by a serial killer

spontaneously activated emotional concepts related to anger when viewing pictures of potentially hostile individuals and perceived greater anger in these individuals' objectively neutral expressions (Maner et al., 2005; see also DeWall & Baumeister, 2007).

EFFECTS ON ORGANIZATION OF CONCEPTS IN MEMORY

Finally, beyond affecting the activation of knowledge from memory, motivation for directional outcomes can influence how people come to organize this knowledge. Although less research has examined this phenomena, and only the effects of esteem-related motivations have been thoroughly investigated (but see Slotter & Gardner, 2009), several important outcomes have been identified. When motivations to sustain or protect esteem are activated, people (*a*) alter their self-concept to include attributes they believe will bring about successful outcomes (e.g., Klein & Kunda, 1992; Kunda & Santioso, 1989); (*b*) come to view the attributes they already possess as essential prerequisites for successful outcomes (Dunning, Leuenberger, & Sherman, 1995; Dunning, Perie, & Story, 1991; Kunda, 1987); and (*c*) redefine the criteria for successful outcomes or positive qualities in general so as to ensure that they meet these criteria (Beauregard & Dunning, 1998; Dunning & Cohen, 1992; see also Alicke, LoSchiavo, Zerbst, & Zhang, 1997).

In sum, motivations for directional outcomes can affect basic cognitive processes and influence thinking in several profound ways. These types of motivations influence not only how people search for, evaluate, and explain information but also how they activate, access, and organize their knowledge about themselves and others. The next section reviews research indicating that motivations for nondirectional outcomes can also have strong effects on information processing.

Influences of Motivations for Nondirectional Outcomes

Although there has been less research overall on motivation for nondirectional outcomes, some effects of this motivation have been considered in depth (e.g., Cacioppo, Petty, Feinstein, & Jarvis, 1996; Fiske & Neuberg, 1990; Kruglanski & Webster, 1996; Lerner & Tetlock, 1999). The two most prominent nondirectional motivations that have been studied are desires for *accuracy* (Fiske & Neuberg, 1990) and desires for simplicity and clarity, or *closure* (Kruglanski & Webster, 1996). As we

noted earlier, although accuracy and closure clearly represent particular outcomes that people are motivated to achieve during judgment, they are nondirectional outcomes because they do not dictate the specific content of the conclusions people want to reach. In the following sections, we consider the effects of these two motivations on many of the same cognitive processes as were discussed in the previous section.

Both accuracy and closure motivation have been studied in a variety of ways. Motivations for accuracy have been manipulated in terms of wanting to know as much as possible about a person on whom one is going to be dependent (Neuberg & Fiske, 1987), feelings of accountability for one's judgments (e.g., Tetlock, 1983), a "fear of invalidity" (e.g., Kruglanski & Freund, 1983), as well as simple desires to be as correct as possible (e.g., Neuberg, 1989). Motivations for closure have been manipulated in terms of time pressure (Kruglanski & Freund, 1983), desires to complete judgment tasks that are dull and unattractive (Webster, 1993), and desires to escape noisy environments (Kruglanski, Webster, & Klem, 1993; see Kruglanski & Webster, 1996). In the following discussion, we initially treat each of these varieties of accuracy or closure motivation as equivalent and then later consider some important differences among the effects of the various operationalizations.

EFFECTS ON ATTRIBUTION

In addition to specific biases stemming from esteem-, belonging-, and control-related motivations, research on attribution has identified more general biases, such as the tendency to fixate on one particular cause for some action or event while failing to adequately consider other possible alternatives (see Krull & Erickson, 1995). Although these attributional biases are frequently discussed in terms of the limits of cognitive capacity, there is evidence to suggest that they can be influenced by accuracy and closure motivations as well. For example, Tetlock (1985) demonstrated that, instead of the typical tendency to consider only one predominant explanation for others' observable behavior (i.e., that these individuals' general traits and attitudes were driving their actions), people with increased motivations for accuracy more evenly considered additional salient explanations (i.e., that temporary external circumstances could be influencing their actions). In contrast, Webster (1993) found that, when forming the same types of explanations

for behavior, increased motivations for closure had the opposite effect. People who wanted to quickly complete the attribution task and move on to a more desirable task displayed an even greater tendency to consider only one predominant explanation for others' behaviors than is typically found. Thus, motivations for accuracy versus closure can have opposite effects on people's attributional considerations of alternative causes (see Kruglanski & Webster, 1996).

EFFECTS ON INFORMATION SEARCH

Research on motivations for directional outcomes has demonstrated that people engage in prolonged information search when encountering evidence that disagrees with what they want to believe, and reduced information search when encountering evidence that agrees with what they want to believe. In contrast, accuracy motivation produces prolonged information search, and closure motivation produces reduced information search, regardless of whether the evidence encountered agrees or disagrees with prior personal beliefs.

For example, in one study on accuracy motivations, people instructed to form accurate impressions of an interview partner spent more time listening to their partner and provided more opportunities for this person to elaborate his or her opinions as compared to people given no special instructions (Neuberg, 1989). Moreover, these effects were found even when people began the interview with negative expectations (see also Maheswaran & Chaiken, 1991; for an extended review of related research see Chen & Chaiken, 1999; Eagly & Chaiken, 1993). More recent studies have further shown that people acting as the sole advisor for an upcoming decision to be made by someone else sought out more information about both the strengths and weakness of different choice alternatives (Jonas & Frey, 2003; see also Jonas, Schulz-Hardt, & Frey, 2005). These advisors also displayed equal attention toward either type of information, as compared to people deciding for themselves, who selectively viewed information about the strengths of their initially preferred choice. Most important, these differences between advisors and deciders were mediated by advisors' reports of greater concerns with accuracy in making the recommendations.

As an example of the effects of closure motivation on information search, in several studies people with varying motivations for closure worked with a partner to discuss the verdict of a mock trial based

on summarized legal analyses that were provided to them (Kruglanski et al., 1993). Prior to the discussion, individuals with stronger closure motivations expressed preferences for an easily persuadable partner, and, once the discussion began, they attempted to bring it to an end quickly and were more unwilling to consider alternative arguments. Similarly, in other studies in which people could perform unlimited trials of a perceptual task until they felt ready to make a judgment, individuals with stronger closure motivations requested fewer trials, even when the task was difficult and this decision jeopardized their performance (Roets, van Hiel, Cornelis, & Soetens, 2008). Indeed, recent studies have even demonstrated that individuals with stronger closure motivations experience greater feelings of threat and aversive physiological arousal when continuing to process information without reaching a definitive conclusion (Roets & van Hiel, 2008), and they experience greater regret when making choices that alter the status quo (thus removing closure; Mannetti, Pierro, & Kruglanski, 2007).

EFFECTS ON EVALUATION COMPLEXITY

In addition to affecting how long people evaluate and analyze information, motivations for nondirectional outcomes also influence the complexity of this analysis. Accuracy-motivated individuals form judgments that show greater consideration of ambiguity between conflicting opinions and evidence, whereas closure-motivated individuals show less consideration of ambiguity (Tetlock, 1983, 1998; see also Lerner & Tetlock, 1999). These findings have emerged from experiments in which people record their thoughts about topics such as affirmative action, American foreign policy, and the causes of certain historical events, which are then coded for the degree to which multiple perspectives on an issue are both identified and integrated into a framework that includes complex connections between them. Whether novices (e.g., college students) or experts (e.g., professional historians) on the issues they are analyzing, people with increased accuracy motivation provide more integrated and more complex analyses, whereas those with increased closure motivation provide less integrated and simpler analyses.

EFFECTS ON RECALL AND KNOWLEDGE ACTIVATION

Whereas motivations for directional outcomes have qualitative effects on what types of knowledge people recall and activate, motivations for

nondirectional outcomes have largely quantitative effects. Once again, accuracy motivation and closure motivation have opposite influences.

When motivated to form accurate impressions of others with whom they later expect to be partnered, people pay more attention to and remember more information about these individuals than when they do not expect any future interactions (Berscheid, Graziano, Monson, & Dermer, 1976; see also Srull, Lichtenstein, & Rothbart, 1985). However, individuals with dispositionally high need for closure spend less time reviewing information about others' behaviors and recall fewer of these behaviors (Dijksterhuis, van Knippenberg, Kruglanski, & Schaper, 1996). In addition, when forming impressions of others, people with increased motivations for accuracy activate more unique, or *individuating*, trait and behavioral information (Kruglanski & Freund, 1983; Neuberg & Fiske, 1987), whereas people with increased motivations for closure rely instead on common information associated with stereotypes about members of particular social categories (Dijksterhuis et al., 1996; Kruglanski & Freund, 1983; see also Moskowitz, 1993). These individuation effects can even operate at a perceptual level; although people typically show a *cross-race effect*, in which they display better recognition for faces of their own versus another race, individuals with increased motivations to accurately individuate other-race faces do not differ in their recognition of same-race versus other-race faces (Hugenberg, Miller, & Claypool, 2007).

Beyond influencing the recall and activation of knowledge from memory, accuracy and closure motivations also affect people's application of this activated knowledge during judgment. Typically, concepts or attitudes that are recently or frequently activated create biases such that people either directly assimilate to or contrast from accessible constructs without considering alternative perspectives (see Higgins, 1996). Increased accuracy motivations attenuate these biases by increasing the activation of alternative interpretations. Thus, when evaluating behaviors that are somewhat ambiguous, people with strong accuracy motivations are less likely to interpret these behaviors solely based on whatever personality traits are most accessible (Thompson et al., 1994; see also Dijksterhuis, Spears, & Lepinasse, 2001; Schuette & Fazio, 1995).

In contrast to this effect of accuracy motivations, increased closure motivations exacerbate accessibility-related biases by decreasing the activation of alternative interpretations (see Kossowska, 2007). People

are more likely to interpret ambiguous behaviors based on accessible personality traits when their closure motivation is high (Ford & Kruglanski, 1995; see also Sanbonmatsu & Fazio, 1990). In addition, people with stronger motivations for closure are more likely to falsely "transfer" their accessible memories of and feelings toward individuals they know well to a new individual who shares a few of the same qualities as the known individuals (Pierro & Kruglanski, 2008; see also Lun, Sinclair, Whitchurch, & Glenn, 2007). Finally, stronger motivations for closure can even influence the extent to which people display broad cultural differences in judgment and behavior. Several different programs of research have suggested that the general mindsets for judgment and information processing that people develop from living in different cultures can function like accessible knowledge structures (see Hong, Morris, Chiu, & Benet-Martínez, 2000); closure motivations thus again increase people's application of this accessible knowledge and their conformity to the cultural norms that are currently most predominant (Chiu, Morris, Hong, & Menon, 2000; Fu et al., 2007; Kosic, Kruglanski, Pierro, & Mannetti, 2004; see Kruglanski, Pierro, Mannetti, & De Grada, 2006).

Overall, then, motivations for nondirectional outcomes can also affect basic cognitive processes and profoundly influence thinking. Whereas motivations for directional outcomes were earlier shown to alter *how* people activate, evaluate, and explain information during reasoning, motivations for non-directional outcomes (at least in terms of the accuracy and closure motivations reviewed here) instead alter *how much* activation, evaluation, or explanation, in fact, occurs. Furthermore, as the findings just reviewed illustrate, such quantitative differences in thought can often affect the overall outcomes of people's judgments and decisions just as much as the qualitative differences described earlier.²

Limits to Outcome-Motivated Thinking

Although people have an impressive array of cognitive mechanisms at their disposal when pursuing desired outcomes during judgment, limits do exist concerning when they engage these mechanisms. These limits are first described for directional thinking and then for nondirectional thinking.

REALITY CONSTRAINTS ON MOTIVATIONS FOR DIRECTIONAL OUTCOMES

Despite any specific outcomes for which people have some preference for during judgment, most

individuals still acknowledge the existence of some kind of “objective reality” about whatever information they are considering. That is, motivated thinking related to directional outcomes operates within what Kunda (1990) termed *reality constraints*. Therefore, although people may choose motivationally consistent attributions, engage in selective recall, or criticize motivationally inconsistent evidence, they are not entirely unresponsive to world around them (except perhaps in extreme circumstances; see Bachman & Cannon, Chapter 34).

Indeed, the meta-analysis by Hart et al. (2009) that showed a sizable effect for selective attention toward motivationally consistent information also showed a significant effect for information quality as well. That is, compared to information that was diagnostic and relevant for people’s judgments, non-diagnostic and irrelevant information did not receive as much attention, even if this latter information was motivationally consistent. Moreover, if the only motivationally consistent information available was of low quality, people actually showed greater attention toward motivationally inconsistent information. Thus, although a simultaneous comparison of the independent effects of motivation versus information quality on selective attention revealed that the motivational effects were larger, information quality still had a significant influence beyond people’s motivations, as would be expected if people are generally sensitive to reality constraints.

Some studies have even gone a step further and begun to outline circumstances in which reality constraints are likely to have more or less influence. One clear finding from these studies is that people’s judgments are guided by motivations for directional outcomes to a greater extent when what they are interpreting or judging involves some vagueness or ambiguity (e.g., Dunning, Meyerowitz, & Holtzberg, 1989; Hsee, 1995). For example, when there is more potential for constructing idiosyncratic criteria for a particular attribution (e.g., judging whether one possesses somewhat vague traits like insecurity), then people select criteria that best allow them to reach their desired conclusion. However, when there is less potential for this construction (e.g., judging whether one possesses more precise traits such as punctuality), people engage in less motivated reasoning (Dunning et al., 1989). Also, when there is ambiguity concerning others’ expressions and identities or one is forming impressions of strangers with whom one has not interacted, there is greater potential for motivationally consistent

projection of emotion or potential friendliness (Maner et al., 2005). However, when such ambiguity does not exist, the likelihood of motivationally consistent projection decreases. For example, when motivations for belonging are threatened by experiences of rejection, people do not attribute greater friendliness to the individuals responsible for this exclusion, whose feelings toward them are anything but ambiguous (Maner et al., 2007). Overall, these results suggest that thinking and reasoning inspired by directional outcomes does not so much lead people to ignore the sometimes disappointing reality they face as it inspires them to exploit in their favor whatever uncertainties there are in this reality.

COGNITIVE-RESOURCE CONSTRAINTS ON ACCURACY MOTIVATION

Most of the effects of accuracy motivation reviewed earlier were driven by increased information processing during judgment. Therefore, the effects of strong accuracy motivation should be reduced under circumstances in which people’s ability to engage in such information processing is constrained (Fiske & Neuberg, 1990). Indeed, Pendry and Macrae (1994) showed that whereas accuracy-motivated individuals increased their use of information about individuating traits in judging others’ behaviors when they possessed their full information-processing resources, as described earlier (see Neuberg & Fiske, 1987), accuracy-motivated individuals whose processing resources were depleted based their impression primarily on categorical information, similar to those who had little accuracy motivation (see also Kruglanski & Freund, 1983). In addition, Sanbonmatsu and Fazio (1990) demonstrated that the reduction in people’s assimilation of their judgments to highly accessible attitudes associated with accuracy motivation disappears when people are placed under time pressure that prevents extended information processing (see also Roets et al., 2008).

THE TENUOUS LINK BETWEEN ACCURACY MOTIVATION AND ACCURATE REASONING

Another important consideration regarding the effects of accuracy motivation on thinking and reasoning is that even when people high in accuracy motivation can engage in extended information processing, this does not guarantee that they will make more accurate judgments. At times, evidence beyond what is immediately and effortlessly available does not exist or has faded from memory (see,

e.g., Thompson et al., 1994). Moreover, people can be influenced by biases of which they are either unaware or uncertain how to correct. In these circumstances, although accuracy motivation might increase information search, recall, and consideration of multiple interpretations, it would not be expected to eliminate judgment errors (Fischhoff, 1982), and it could even increase them (Pelham & Neter, 1995; Tetlock & Boettger, 1989).

DISTINCTIONS AMONG CIRCUMSTANCES THAT LEAD TO ACCURACY MOTIVATION

As alluded to earlier, the different types of accuracy-motivation inductions reviewed here are not always equivalent and can have markedly different effects. For example, although having one's outcomes dependent on another person can increase desires for accuracy in diagnosing that person's true character (e.g., Neuberg & Fiske, 1987), in other cases, such circumstances can produce a desire to see a person upon whom one is depending in the best possible light (e.g., Berscheid et al., 1976; Klein & Kunda, 1992; see Kruglanski, 1996). Also, although believing that one's judgment has important consequences may motivate an accurate consideration of all the relevant evidence, it could also motivate more general increases in information processing that is not necessarily focused on accuracy (see note 2; Petty & Wegener, 1999). Finally, although justifying one's judgments to others can motivate accuracy when the preferences of the audience are unknown, it can also produce motivations for more directional outcomes, such as ingratiation toward this audience, when the opinion of the audience is known (Jonas et al., 2005; Lerner & Tetlock, 1999; Tetlock, 1983). Therefore, when attempting to anticipate the effects of accuracy motivation on reasoning in a particular situation, it is important to consider both the current source of this motivation and the larger context in which it occurs.

THE INFLUENCE OF INFORMATION AVAILABILITY ON CLOSURE MOTIVATION

Certain qualifications should also be noted regarding the effects of closure motivation. The findings reviewed earlier involved the tendency for people with strong closure motivation to quickly assimilate their judgments to readily available or highly accessible information, leading to an early "freezing" of their information search. However, in situations in which there is little information available, strong closure motivation may inspire efforts

to find something clear and concise to "seize" upon and *increase* information search (see Kruglanski & Webster, 1996). For example, individuals with stronger closure motivation prefer easily persuadable partners and are unwilling to consider alternative arguments only when they have enough information at their disposal to form some clear initial impression; without such information these individual express a desire for partners who are highly *persuasive* and quickly shift toward their partner's point of view (Kruglanski et al., 1993). Similarly, when individuals with strong closure motivation are forced to adopt roles that are culturally unfamiliar, they again display an increase rather than a decrease in information search (Fu et al., 2007).

Conclusions on Outcome-Motivated Thinking

Recent research has uncovered many potential routes by which people's desires for particular judgment outcomes can affect their thinking and reasoning. To summarize, a number of basic cognitive processes during reasoning are influenced by both motivations for directional outcomes, where people have a specific, content-dependent conclusion they want to reach, and motivations for nondirectional outcomes, where people's preferred conclusions are more general and content independent. These include (a) the explanation of events and behaviors; (b) the organization, recall, and activation of knowledge in memory; and (c) the pursuit and evaluation of evidence relevant to decision making. Outcome-motivation effects involve both how such cognitive processes are initiated and directed, as well as how thoroughly these processes are implemented. Moreover, in any given situation, the specific cognitive processes influenced by outcome motivation are typically those that aid the gathering and interpretation of information supporting the favored outcome. In this self-fulfilling way, people's outcome-motivated reasoning often brings about their desired conclusions.

Strategy-Motivated Thinking

Although outcome-motivated thinking has been the most widely studied form of motivated reasoning, there are other varieties of motivational influences on cognition. One alternative perspective suggests that people are motivated not only with respect to the outcomes of their judgments but also with respect to the manner in which they make these judgments. That is, not only do people have

preferred conclusions, but they also have *preferred strategies* for reaching their conclusions (Higgins and Molden, 2003; cf. Tyler & Blader, 2000). Therefore, independent of whatever outcome holds the most interest for them, people may be motivated to reach these outcomes using strategies that “feel right” and sustain their current motivational orientation. Several lines of research have recently examined how motivations for particular judgment strategies can also influence people’s basic cognitive processes. In the vast majority of these studies, strategic motivations were measured and manipulated in one of two ways: in terms of people’s *regulatory focus* (see Higgins, 1997) or their *regulatory mode* (Kruglanski et al., 2000).

Regulatory focus describes the distinction between two basic motivational orientations: those involving *promotion concerns* focused on advancement and approaching gains versus avoiding nongains, and those involving *prevention concerns* focused on security and approaching nonlosses versus avoiding losses. Because they revolve around advancement, promotion concerns create preferences for *eager strategies* emphasizing a broad, open-minded search for opportunities for gain, even at the risk of committing errors and accepting losses. In contrast, because they revolve around security, prevention concerns create preference for *vigilant strategies* emphasizing a more narrow, close-minded focus on protecting against loss, even at the risk of missing opportunities for potential gain (Higgins, 1997; Molden, Lee, & Higgins, 2008).

Regulatory mode describes the distinction between two additional motivational orientations: those involving *locomotion* concerns with initiating action and continual, smooth movement toward achieving goals by whatever means available, versus those involving *assessment* concerns with ensuring a critical analysis of the most effective and appropriate means of goal pursuit before any action is taken. Because they revolve around movement, locomotion concerns create preferences for strategies of successive elimination and moving from state to state to sustain a feeling of continuous movement. In contrast, because they revolve around analysis, assessment concerns create preferences for strategies of exhaustive comparison and delayed responses to sustain a feeling of thoroughness and a focus what is optimal (Higgins, Kruglanski, & Pierro, 2003; Kruglanski et al., 2000).

Thus, even in circumstances in which individuals are pursuing the same outcome (e.g., achieving the

best performance possible), they may show significant differences in their pursuit of this outcome depending upon whether they are currently promotion- versus prevention-focused (e.g., by trying any available means that might possibly lead to success versus using only the few means that would most probably lead to success, respectively), or whether they are locomotion- versus assessment-focused (e.g., by concentrating on continually taking whatever actions they can to maintain movement toward achievement versus thoroughly and critically evaluating what specific actions are most likely to boost achievement and should be the main focus their efforts, respectively). The studies reviewed next illustrate the general effects of these types of strategic motivations on several aspects of thinking and reasoning that are similar to those reviewed in the previous sections (for larger overviews, see Kruglanski, Orehhek, Higgins, Pierro, & Shalev, 2010; Molden et al., 2008).

Influences of Motivated Strategies of Judgment

EFFECTS ON THE CONSIDERATION OF ALTERNATIVE HYPOTHESES

Considering alternative hypotheses is a fundamental component of many varieties of thinking. As alluded to earlier, people’s strategic motivations can influence their preferred way of evaluating these alternatives. First, the eager, open-minded strategies motivated by promotion concerns should lead people to broadly consider multiple alternatives so as to increase the chance of finding the correct answer. In contrast, the vigilant, close-minded strategies motivated by prevention concerns should lead people to narrow their consideration to fewer alternatives so as to increase the chance of rejecting incorrect answers (see Molden et al., 2008). Thus, when forming impressions, promotion-focused individuals should tend to consider and endorse a greater number of possibilities than prevention-focused individuals.

These effects were illustrated in several studies by Liberman, Molden, Idson, and Higgins (2001). One important instance of considering alternatives occurs when people form hypotheses about what they are perceiving (see Hegarty & Stull, Chapter 31); when asked to identify vague and distorted objects in a series of photographs, promotion-focused individuals generated a greater number of alternatives than prevention-focused individuals (see also Friedman & Förster, 2001). Another important instance of considering alternatives, discussed previously, occurs when people form attributions about

their own and others' actions (Kelley, 1973); when asked to evaluate explanations for a target person's behavior, promotion-focused individuals again endorsed a greater number of alternatives than prevention-focused individuals. Molden and Higgins (2008) found similar effects when people explained their own behavior following success or failure at an intellectual task. Yet another important instance of considering alternatives occurs when people assign individuals and objects to general categories (see Rips, Medin, & Smith, Chapter 11); Molden and Higgins (2004) found that when asked to categorize the actions of particular individuals, promotion-focused individuals once again generated more alternatives than prevention-focused individuals.

Several of these studies by Molden and colleagues further showed that motivational differences in people's consideration of alternatives had significant consequences for the final impressions they formed (Liberman et al., 2001; Molden & Higgins, 2008). In general, the more alternative explanations people consider for a particular outcome, the less confident they can be in the validity of any single explanation (see Kelley, 1973). Thus, promotion-focused individuals ultimately formed more equivocal impressions and displayed less generalization of their attributions to future situations than prevention-focused individuals.³

There is also evidence that locomotion versus assessment concerns can influence people's consideration of alternatives (Avnet & Higgins, 2003). As noted earlier, locomotion concerns create preferences for strategies of progressive elimination, whereas assessment concerns create preferences for strategies of exhaustive comparison. Supporting these preferences, individuals whose locomotion concerns were activated later showed greater satisfaction with a decision when they used a progressive elimination strategy (i.e., successively making comparisons among choice alternatives based on one attribute dimension at a time and on each round eliminating the worst option for that attribute) than when they used an exhaustive comparison strategy (i.e., simultaneously comparing all of the alternatives on all of the attribute dimensions). Individuals whose assessment concerns were activated showed an opposite pattern of satisfaction.

Overall, then, strategic preferences play a substantial role in people's generation of and selection among alternatives during a number of important cognitive processes. Furthermore, several of the studies reviewed earlier also included measures of

people's motivations for more general outcomes such as accuracy and closure, and the effects of regulatory focus and regulatory mode remained when statistically controlling for these outcome motivations. Moreover, whereas the effects of accuracy or closure motivations on people's consideration of alternatives are typically driven by differences in the time or effort people invest in gathering or considering these alternatives during decision making, the effects of concerns with promotion versus prevention or locomotion versus assessment were instead typically driven more by differences in how people weighted and selected among those alternatives that they have gathered (see e.g., Liberman et al., 2001). Such findings thus support the classification of strategic preferences as a separate source of motivated thinking.

EFFECTS ON COUNTERFACTUAL THINKING

Besides generating and evaluating hypotheses, another way in which people consider alternatives during reasoning is in their use of *counterfactuals*. Counterfactual thinking involves mentally undoing the present circumstances by pondering what would have happened if only different decisions had been made or different actions taken (Roese, 1997). Many studies have characterized different varieties of counterfactual thinking, but one broad distinction involves *additive* counterfactuals concerning the reversal of previous inaction (if only I had acted, things might have gone better), versus *subtractive* counterfactuals concerning the reversal of previous actions (if only I had not acted, things wouldn't be so bad).

Because additive counterfactuals allow the mental correction of missed opportunities for gain, this type of thinking represents a more eager strategy of considering alternative realities. In contrast, because subtractive counterfactuals allow the correction of mistakes that resulted in loss, this type of thinking represents a more vigilant strategy of considering alternate realities. Consistent with this logic, both when analyzing hypothetical examples and when describing particular instances of their own behavior, promotion-focused individuals offer more additive counterfactuals, whereas prevention-focused individuals offer more subtractive counterfactuals (Roese, Hur, & Pennington, 1999; see also Molden, Lucas, Gardner, Dean, & Knowles, 2009). Research on counterfactual thinking has traditionally assumed that subtractive counterfactuals are more common than additive counterfactuals and that failures associated with action inspire more regret than failures

associated with inaction (Roese, 1997). However, the results of these studies demonstrate that people's strategic preferences can alter these typical circumstances, leading additive counterfactuals to be more common for promotion-focused individuals and to cause these individuals greater regret (see also Camacho, Higgins, & Lugar, 2003).

Whereas strategic preferences associated with promotion or prevention concerns influence the type of counterfactuals people generate, strategic preferences associated with locomotion or assessment concerns influence how many counterfactuals people generate overall. In general, counterfactual thinking functions as a means of analyzing past decisions to ensure better decisions in the future (Roese, 1997). Therefore, increased motivations to critically evaluate one's decision-making processes should increase counterfactual thinking, whereas increased motivations to "move on" after making a decision should decrease counterfactual thinking. Consistent with this logic, both when considering hypothetical examples and when describing particular instances of their own behavior, individuals with stronger assessment concerns generated more counterfactuals and displayed stronger experiences of regret, whereas individuals with stronger locomotion concerns generated fewer counterfactuals and displayed less regret (Pierro et al., 2008).

EFFECTS ON TRADE-OFFS BETWEEN FAST AND ACCURATE INFORMATION PROCESSING

A major question across many areas of psychology has been when and why people emphasize either speed or accuracy during decision making (e.g., Josephs & Hahn, 1995; Zelaznik, Mone, McCabe, & Thaman, 1988). Förster, Higgins, and Bianco (2003) investigated whether promotion-focused preferences for eager strategies would result in a priority for faster information processing and a higher quantity of output in a search for possible opportunities for gain, whereas prevention preferences for strategic vigilance would result in a priority for more accurate information processing and a higher *quality* of output in an effort to protect against loss. That is, analogous to the findings of Molden and colleagues described earlier (Liberman et al., 2001; Molden & Higgins, 2004, 2008), promotion-focused individuals might selectively pursue faster information processing to increase the number of correct answers they might identify, whereas prevention-focused individuals might selectively pursue more accurate information processing to

increase the number of incorrect answers they might eliminate. On several different motor-performance and information-processing tasks, individuals with either a chronic or temporarily activated focus on promotion did indeed perform these tasks faster, but with lower accuracy, whereas individuals with a chronic or temporarily activated focus on prevention performed more slowly but with greater accuracy. Moreover, these effects of strategic preferences were stronger at the end than at the beginning of the task, showing the classic "goal looms larger" effect in which motivational intensity increases as people move closer to goal completion (see Lewin, 1935).

Concerns with locomotion versus assessment can also affect the priority given to fast or accurate information processing. Mauro, Pierro, Mannetti, Higgins, and Kruglanski (2009) showed that when performing a group decision-making task, the preferences for progress and movement held by those focused on locomotion resulted in faster, but less accurate decisions, whereas the preferences for prolonged, careful analysis held by those focused on assessment resulted in slower but more accurate decisions (see also Mannetti et al., 2009). Interestingly, results further showed that when both preferences were represented in groups featuring equal numbers of locomotion- and assessment-focused individuals, decisions were made with a high level of accuracy without sacrificing speed.

EFFECTS ON KNOWLEDGE ACTIVATION AND RECALL

Analogous to the selective recall and activation of information from memory inspired by motivations for directional outcomes, another influence of strategic preferences is to increase sensitivities to, and recall of, information that is particularly relevant to these preferences. In one study, after reading an essay about the life of a hypothetical target person in which this person used both eager, advancement-oriented strategies (e.g., waking up early in order to be on time for a favorite class) and vigilant, protection-oriented strategies (e.g., being careful not to sign up for a class schedule that conflicted with other desired activities), promotion-focused individuals showed greater recall for events involving the use of eager as compared to vigilant strategies, whereas prevention-focused individuals showed the reverse effect (Higgins, Roney, Crowe, & Hymes, 1994). Similarly, in another study, promotion-focused individuals showed greater recall for a target person's experiences of both the presence and absence of gains

(e.g., finding \$20 on the street or missing a movie that he wanted to see, respectively), whereas prevention-focused individuals showed greater recall for a target person's experiences of both the presence and absence of losses (e.g., being stuck in a crowded subway for an extended period of time or getting a day off from a particularly arduous class schedule, respectively; Higgins & Tykocinski, 1992). Future research should examine whether locomotion or assessment concerns can have the same types of effects.

STRATEGIC PREFERENCES AND REGULATORY FIT

The studies reviewed thus far have demonstrated that people's motivational concerns lead them to prefer and choose particular types of judgment strategies. However, the extent to which people can follow their preferences can vary by their circumstances. For example, some situations may generally require greater use of one type of strategy versus another, such as when one supervisor demands constant innovation and the pursuit of multiple approaches for a particular goal, whereas another supervisor demands the use of proven techniques and careful analysis of how to pursue the goal. Given such situational variability, a major focus of research on strategic preferences has been on whether the strategy demanded by a situation fits or does not fit individuals' current motivational concerns (see Higgins, 2000, 2008).

Although space limitations prevent a thorough review of the research on such *regulatory fit* here, the general findings have been that regulatory fit increases the perceived value of the goal one is pursuing and strengthens engagement during goal pursuit. That is, whether arising from strategies that fit promotion versus prevention concerns or locomotion versus assessment concerns, circumstances that create regulatory fit (as compared to nonfit) lead people to "feel right" about their goal pursuit, engage more strongly, and react more intensely to goal success or failure. When regulatory fit exists, people thus (*a*) see the strategies they are using as the right way to approach goal pursuit (Camacho et al., 2003; Pierro, Presaghi, Higgins, & Kruglanski, 2009), (*b*) show greater enjoyment of goal-directed action (Freitas & Higgins, 2002; Pierro, Kruglanski, & Higgins, 2006); and (*c*) assign greater worth to the outcomes they are pursuing (Avnet & Higgins, 2003; Higgins, Idson, Freitas, Spiegel, & Molden, 2003). More recently, research has also explored the broader consequences of regulatory fit experiences for judgment and

information processing. This research has further shown that, as compared to experiences of nonfit, experiences of fit (*a*) facilitate a more flexible, active, and exploratory response strategy (due to the increased enjoyment and valuing of goal-directed action, see Maddox & Markman, 2010) and (*b*) encourage reduced information search and an increased application of whatever knowledge happens to be particularly accessible in memory (because this knowledge "feels right," see Koenig, Cesario, Molden, Kosloff, & Higgins, 2010; Vaughn et al., 2006).

Conclusions on Strategy-Motivated Thinking

In sum, several continuing programs of research have now demonstrated that, beyond the effects on reasoning of people's desires for particular judgment outcomes, there are additional effects on reasoning of people's desires to use particular judgment strategies. Whether strategic preferences arise from concerns with promotion versus prevention or locomotion versus assessment, these preferences influence (*a*) the generation and testing of hypotheses, (*b*) the occurrence of counterfactual thinking, (*c*) the prioritization of fast versus accurate information processing, (*d*) knowledge activation and recall, and (*e*) cognitive flexibility during judgment and decision making. Like outcome-motivation effects, strategy-motivation effects include what cognitive processes are initiated, how thoroughly these processes are implemented, and how much the resulting information that is gathered is valued in a final decision.

Conclusions and Future Directions

The sheer number and diversity of the studies reviewed here is a testament to the growing recognition of the importance of motivational perspectives on cognition. The richness and consistency of the findings emerging from these studies is also a testament to the utility of this perspective in the study of thinking and reasoning. We optimistically forecast a continued expansion of research informed by motivational perspectives and, in conclusion, briefly outline several directions we believe should be priorities for the future.

The first direction involves a greater exploration of how, beyond the common effects of the various outcome- or strategy-related motivations reviewed here, different types of directional or strategic motivations may have unique effects. For example, although we have discussed how motives for esteem, belonging, and control all generally influence the selective recall

of motivationally relevant information, given that these motives all represent fundamentally different needs, there might be additional processes that each motive affects in different ways (cf., Maner, 2009). Some preliminary evidence for these types of distinct effects already exists. People respond to interaction partners differently when motives for belonging and control have both been threatened rather than either one of these on its own (Warburton, Williams, & Cairns, 2006). People also use fundamentally different strategies in their attempts to compensate for esteem threats versus belonging threats (Knowles, Lucas, Molden, Gardner, & Dean, 2010). Future studies should thus continue to better define both the commonalities and differences in the effects of various motivations on cognition.

A second direction for future research involves further investigation of the interaction between different types of motivations in thought and behavior. For example, De Dreu, Nijstad, and van Knippenberg (2008) have begun to analyze group decision making in terms of the joint effects of directional motivations involving people's desires for more self-focused or other-focused outcomes and nondirectional motivations involving their desires for closure. They argue that when closure motivation is high, people pursue low effort means of attaining self-focused or other-focused outcomes (e.g., laziness and inaction versus conformity to a group position, respectively), but that when closure motivation is low (or accuracy motivation is high) people use more elaborate means to attain these outcomes (e.g., advocating one's own position and disagreeing with others versus attempting to reconcile differing opinions, respectively). Because at any given time people are rarely focused on only achieving a single goal, this focus on the implications of multiple active motivations is an important expansion of existing perspectives and is perhaps a better reflection of how people experience the influence of different motivations in the judgments they make in their daily lives (Fishbach & Ferguson, 2007). Additional research could also explore how, beyond particular types of motivations that interact, there could also be other types of motivations that are incompatible and inhibit each other when active (e.g., motivations for dominance and control versus motivations for egalitarianism and equality or motivations for order versus motivations for freedom and independence; see Maio, Pakizeh, Cheung, & Rees, 2009).

One final direction for future research is the synthesis of research on how motivation influences

reasoning with research on how affect influences reasoning (e.g., Forgas, 2001; Martin & Clore, 2001). Many of the changes in the quality and quantity of information processing found in research on emotion and cognition bear a striking resemblance to the motivational effects reviewed here. For example, positive moods have generally been found to support less thorough and complex information processing, similar to closure motivation, whereas negative moods have generally been found to support more thorough and complex information processing, similar to accuracy motivation (for a review, see Schwarz & Clore, 2007). In addition, a recent meta-analysis on the range of cognitive effects of happy or anxious emotions has related these effects to the strategic motivations inspired by promotion or prevention concerns (Baas, De Dreu, & Nijstad, 2008). Indeed, Lucas, Molden, and Gardner (unpublished data) have even recently found evidence that the common effects of a wide variety of anxiety-provoking experiences (e.g., fears of contamination, worries about social rejection, discomfort with uncertainty) on more vigilant and avoidant mindsets is partially mediated by the fact that these experiences all evoke prevention-focused strategic motivations (see also Higgins, 1997). We should emphasize that we are not proposing that the instances of motivated thinking reviewed here are ultimately just rooted in emotion, as many of the studies reviewed carefully controlled for affective influences and continued to find independent effects. Rather, we are suggesting that it would be fruitful to further investigate both how affective thinking may give rise to motivational thinking and how motivational thinking may give rise to affective thinking (see also Higgins, 2001).

To conclude, this chapter has reviewed research that displays the broad applicability of motivational perspectives to the study of thinking and reasoning. Through this review, we have attempted to convey the potential utility of these perspectives and to advocate a greater incorporation of principles of outcome- and strategy-based motivation in future research. The further refinement and elaboration of these principles, we believe, will benefit not only the study of judgment and reasoning but also cognitive science in general.

Notes

1 One literature notably absent from our review concerns affective and emotional influences on reasoning. This important, and extensive, literature certainly enjoys a central place in the study of motivated thinking. However, the topic of affect and cognition has been the subject of several entire handbooks on

its own (seeForgas, 2001; Martin & Clore, 2001), not to mention its own separate journal (*Cognition and Emotion*). Therefore, rather than attempt a limited overview of this major topic alongside the others mentioned earlier, we instead refer the interested reader to these other sources. The larger relation between research on emotional thinking and the research described here is discussed briefly later in the chapter.

2 Another type of nondirectional outcome motivation that has been the focus of considerable study is the *need for cognition*, or a general desire for elaborative thinking and increased cognitive activity (Cacioppo et al., 1996). At times, the need for cognition has been considered equivalent to accuracy motivation (Chen & Chaiken, 1999). Consistent with this perspective, research has shown that an increased need for cognition can affect thinking in the same way as heightened accuracy motivation, reducing biases during attribution (D'Agostino & Fincher-Kiefer, 1992), increasing recall (Srull et al., 1985), lessening assimilation to highly accessible attitudes (Florack, Scarabis, & Bless, 2001), and increasing information search (Verplanken, 1993). However, at times the effects of the need for cognition differ from those of accuracy motivation. Accuracy motivation, because it inspires a thorough consideration of *all* available evidence, weakens the tendency to base judgments on early superficial impressions (i.e., primacy effects; Kruglanski, & Freund, 1983). In contrast, the need for cognition, because it simply inspires cognitive elaboration even if this involves only part of the available evidence, can lead to increased rumination on one's early superficial impressions and *strengthen* primacy effects (see Petty & Wegener, 1999). Given these conceptual and empirical distinctions, we have not included research on need for cognition in our larger review of the effects of accuracy motivation and consider it a separate form of nondirectional outcome motivation (for a review of need for cognition effects, see Cacioppo et al., 1996).

3 Although the studies reviewed consistently show that promotion-focused individuals typically consider more alternatives than prevention-focused individuals during judgment, several other studies have identified circumstances that produce an important reversal of this effect (Scholer, Stroessner, & Higgins, 2008). When specifically contemplating possible threats or identifying negative outcomes, vigilant strategies of protecting against loss actually require a broader consideration of any alternatives that might signal the presence of a threat, whereas eager strategies of seeking gains are less focused on the potential for threat. Therefore, in these circumstances prevention-focused individuals consider more alternative threats and negatively valenced pieces of information than promotion-focused individuals (see also Scholer, Zou, Fujita, Stroessner, & Higgins, 2010; cf. Mishra & Lalumière, 2010).

Problem Solving

Miriam Bassok and Laura R. Novick

Abstract

This chapter follows the historical development of research on problem solving. It begins with a description of two research traditions that addressed different aspects of the problem-solving process: (1) research on *problem representation* (the Gestalt legacy) that examined how people understand the problem at hand, and (2) research on *search in a problem space* (the legacy of Newell and Simon) that examined how people generate the problem's solution. It then describes some developments in the field that fueled the integration of these two lines of research: work on problem isomorphs, on expertise in specific knowledge domains (e.g., chess, mathematics), and on insight solutions. Next, it presents examples of recent work on problem solving in science and mathematics that highlight the impact of visual perception and background knowledge on how people represent problems and search for problem solutions. The final section considers possible directions for future research.

Key Words: problem solving, representation, search, expertise, insight, Gestalt, diagrams, math, science

Overview

People are confronted with problems on a daily basis, be it trying to extract a broken light bulb from a socket, finding a detour when the regular route is blocked, fixing dinner for unexpected guests, dealing with a medical emergency, or deciding what house to buy. Obviously, the problems people encounter differ in many ways, and their solutions require different types of knowledge and skills. Yet we have a sense that all the situations we classify as problems share a common core. Karl Duncker defined this core as follows: “A problem arises when a living creature has a goal but does not know how this goal is to be reached. Whenever one cannot go from the given situation to the desired situation simply by action [i.e., by the performance of obvious operations], then there has to be recourse to thinking” (Duncker, 1945, p. 1). Consider the broken light bulb. The obvious operation—holding the glass part of the bulb with one’s fingers while unscrewing the

base from the socket—is prevented by the fact that the glass is broken. Thus, there must be “recourse to thinking” about possible ways to solve the problem. For example, one might try mounting half a potato on the broken bulb (we do not know the source of this creative solution, which is described on many “how to” Web sites).

The above definition and examples make it clear that what constitutes a problem for one person may not be a problem for another person, or for that same person at another point in time. For example, the second time one has to remove a broken light bulb from a socket, the solution likely can be retrieved from memory; there is no problem. Similarly, tying shoes may be considered a problem for 5-year-olds but not for readers of this chapter. And, of course, people may change their goal and either no longer have a problem (e.g., take the guests to a restaurant instead of fixing dinner) or attempt to solve a different problem (e.g., decide what restaurant to

go to). Given the highly subjective nature of what constitutes a problem, researchers who study problem solving have often presented people with novel problems that they should be capable of solving and attempted to find regularities in the resulting problem-solving behavior. Despite the variety of possible problem situations, researchers have identified important regularities in the thinking processes by which people (*a*) *represent*, or understand, problem situations and (*b*) *search* for possible ways to get to their goal.

A problem representation is a model constructed by the solver that summarizes his or her understanding of the problem components—the *initial state* (e.g., a broken light bulb in a socket), the *goal state* (the light bulb extracted), and the set of possible *operators* one may apply to get from the initial state to the goal state (e.g., use pliers). According to Reitman (1965), problem components differ in the extent to which they are *well defined*. Some components leave little room for interpretation (e.g., the initial state in the broken light bulb example is relatively well defined), whereas other components may be *ill defined* and have to be defined by the solver (e.g., the possible actions one may take to extract the broken bulb). The solver's representation of the problem guides the search for a possible solution (e.g., possible attempts at extracting the light bulb). This search may, in turn, change the representation of the problem (e.g., finding that the goal cannot be achieved using pliers) and lead to a new search.

Such a recursive process of representation and search continues until the problem is solved or until the solver decides to abort the goal.

Duncker (1945, pp. 28–37) documented the interplay between representation and search based on his careful analysis of one person's solution to the “Radiation Problem” (later to be used extensively in research on analogy, see Holyoak, Chapter 13). This problem requires using some rays to destroy a patient's stomach tumor without harming the patient. At sufficiently high intensity, the rays will destroy the tumor. However, at that intensity, they will also destroy the healthy tissue surrounding the tumor. At lower intensity, the rays will not harm the healthy tissue, but they also will not destroy the tumor. Duncker's analysis revealed that the solver's solution attempts were guided by three distinct problem representations. He depicted these solution attempts as an inverted search tree in which the three main branches correspond to the three general problem representations (Duncker, 1945, p. 32). We reproduce this diagram in Figure 21.1. The desired solution appears on the rightmost branch of the tree, within the general problem representation in which the solver aims to “lower the intensity of the rays on their way through healthy tissue.” The actual solution is to project multiple low-intensity rays at the tumor from several points around the patient “by use of lens.” The low-intensity rays will converge on the tumor, where their individual intensities will sum to a level sufficient to destroy the tumor.

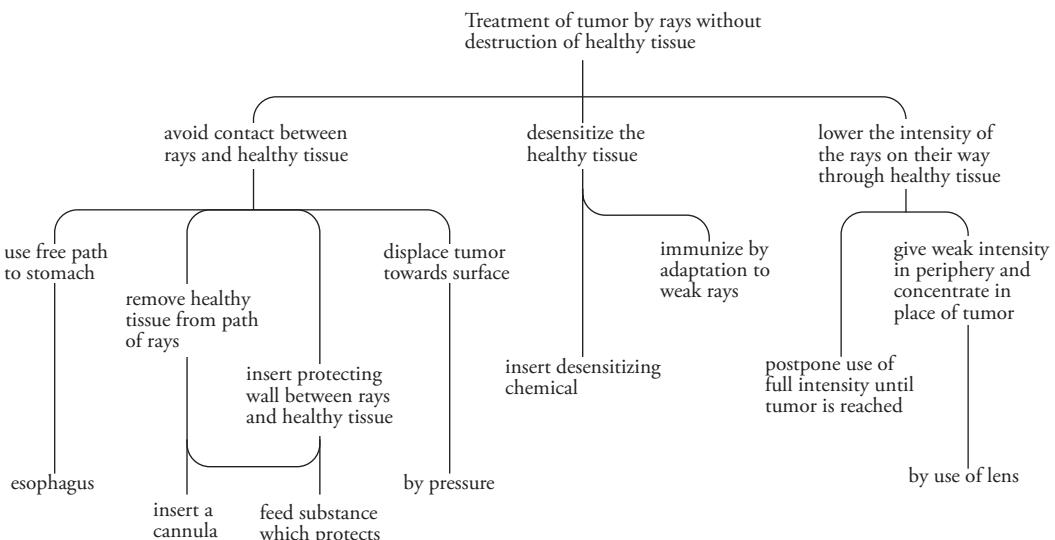

Fig. 21.1 A search-tree representation of one subject's solution to the radiation problem, reproduced from Duncker (1945, p. 32).

Although there are inherent interactions between representation and search, some researchers focus their efforts on understanding the factors that affect how solvers represent problems, whereas others look for regularities in how they search for a solution within a particular representation. Based on their main focus of interest, researchers devise or select problems with solutions that mainly require either constructing a particular representation or finding the appropriate sequence of steps leading from the initial state to the goal state. In most cases, researchers who are interested in problem representation select problems in which one or more of the components are ill defined, whereas those who are interested in search select problems in which the components are well defined. The following examples illustrate, respectively, these two problem types.

The Bird-and-Trains problem (Posner, 1973, pp. 150–151) is a mathematical word problem that tends to elicit two distinct problem representations (see Fig. 21.2a and b):

Two train stations are 50 miles apart. At 2 p.m. one Saturday afternoon two trains start toward each other, one from each station. Just as the trains pull out of the stations, a bird springs into the air in front of the first train and flies ahead to the front of the second train. When the bird reaches the second train, it turns back and flies toward the first train. The bird continues to do this until the trains meet. If both trains travel at the rate of 25 miles per hour and the

bird flies at 100 miles per hour, how many miles will the bird have flown before the trains meet?

Some solvers focus on the back-and-forth path of the bird (Fig. 21.2a). This representation yields a problem that would be difficult for most people to solve (e.g., a series of differential equations). Other solvers focus on the paths of the trains (Fig. 21.2b), a representation that yields a relatively easy distance-rate-time problem.

The Tower of Hanoi problem falls on the other end of the representation-search continuum. It leaves little room for differences in problem representations, and the primary work is to discover a solution path (or the best solution path) from the *initial state* to the *goal state*.

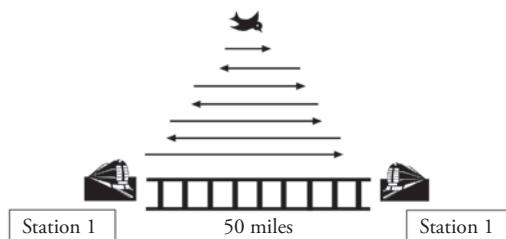

There are three pegs mounted on a base. On the leftmost peg, there are three disks of differing sizes. The disks are arranged in order of size with the largest disk on the bottom and the smallest disk on the top. The disks may be moved one at a time, but only the top disk on a peg may be moved, and at no time may a larger disk be placed on a smaller disk. The goal is to move the three-disk tower from the leftmost peg to the rightmost peg.

Figure 21.3 shows all the possible legal arrangements of disks on pegs. The arrows indicate transitions between states that result from moving a single disk, with the thicker gray arrows indicating the shortest path that connects the initial state to the goal state.

The division of labor between research on representation versus search has distinct historical antecedents and research traditions. In the next two sections, we review the main findings from these two historical traditions. Then, we describe some developments in the field that fueled the integration of these lines of research—work on problem isomorphs, on expertise in specific knowledge domains (e.g., chess, mathematics), and on insight solutions. In the fifth section, we present some examples of recent work on problem solving in science and mathematics. This work highlights the role of visual perception and background knowledge in the way people represent problems and search for problem solutions. In the final section, we consider possible directions for future research.

Our review is by no means an exhaustive one. It follows the historical development of the field and highlights findings that pertain to a wide variety of problems. Research pertaining to specific types

(a) A representation focused on the bird.

(b) A representation focused on the trains.

of problems (e.g., medical problems), specific processes that are involved in problem solving (e.g., analogical inferences), and developmental changes in problem solving due to learning and maturation may be found elsewhere in this volume (e.g., Holyoak, Chapter 13; Smith & Ward, Chapter 23; van Steenburgh et al., Chapter 24; Simonton, Chapter 25; Opfer & Siegler, Chapter 30; Hegarty & Stull, Chapter 31; Dunbar & Klahr, Chapter 35; Patel et al., Chapter 37; Lowenstein, Chapter 38; Koedinger & Roll, Chapter 40).

Problem Representation: The Gestalt Legacy

Research on problem representation has its origins in Gestalt psychology, an influential approach in European psychology during the first half of the 20th century. (Behaviorism was the dominant perspective in American psychology at this time.) Karl Duncker published a book on the topic in his native German in 1935, which was translated into English and published 10 years later as the monograph *On Problem-Solving* (Duncker, 1945). Max Wertheimer also published a book on the topic in 1945, titled *Productive Thinking*. An enlarged edition published

posthumously includes previously unpublished material (Wertheimer, 1959). Interestingly, 1945 seems to have been a watershed year for problem solving, as mathematician George Polya's book, *How to Solve It*, also appeared then (a second edition was published 12 years later; Polya, 1957).

The Gestalt psychologists extended the organizational principles of visual perception to the domain of problem solving. They showed that various visual aspects of the problem, as well as the solver's prior knowledge, affect how people understand problems and, therefore, generate problem solutions. The principles of visual perception (e.g., proximity, closure, grouping, good continuation) are directly relevant to problem solving when the physical layout of the problem, or a diagram that accompanies the problem description, elicits inferences that solvers include in their problem representations. Such effects are nicely illustrated by Maier's (1930) nine-dot problem: Nine dots are arrayed in a 3x3 grid, and the task is to connect all the dots by drawing four straight lines without lifting one's pencil from the paper. People have difficulty solving this problem because their initial representations generally include a constraint, inferred from the configuration

of the dots, that the lines should not go outside the boundary of the imaginary square formed by the outer dots. With this constraint, the problem cannot be solved (but see Adams, 1979). Without this constraint, the problem may be solved as shown in Figure 21.4 (though the problem is still difficult for many people; see Weisberg & Alba, 1981).

The nine-dot problem is a classic *insight* problem (see van Steenburgh et al., Chapter 24). According to the Gestalt view (e.g., Duncker, 1945; Kohler, 1925; Maier, 1931; see Ohlsson, 1984, for a review), the solution to an insight problem appears suddenly, accompanied by an “aha!” sensation, immediately following the sudden “restructuring” of one’s understanding of the problem (i.e., a change in the problem representation): “The decisive points in thought-processes, the moments of sudden comprehension, of the ‘Aha!’, of the new, are always at the same time moments in which such a sudden restructuring of the thought-material takes place” (Duncker, 1945, p. 29). For the nine-dot problem, one view of the required restructuring is that the solver relaxes the constraint implied by the perceptual form of the problem and realizes that the lines may, in fact, extend past the boundary of the imaginary square. Later in the chapter, we present more recent accounts of insight.

The entities that appear in a problem also tend to evoke various inferences that people incorporate into their problem representations. A classic demonstration of this is the phenomenon of *functional fixedness*, introduced by Duncker (1945): If an object is habitually used for a certain purpose (e.g., a box serves as a container), it is difficult to see

that object as having properties that would enable it to be used for a dissimilar purpose. Duncker’s basic experimental paradigm involved two conditions that varied in terms of whether the object that was crucial for solution was initially used for a function other than that required for solution.

Consider the candles problem—the best known of the five “practical problems” Duncker (1945) investigated. Three candles are to be mounted at eye height on a door. On the table, for use in completing this task, are some tacks and three boxes. The solution is to tack the three boxes to the door to serve as platforms for the candles. In the control condition, the three boxes were presented to subjects empty. In the functional-fixedness condition, they were filled with candles, tacks, and matches. Thus, in the latter condition, the boxes initially served the function of container, whereas the solution requires that they serve the function of platform. The results showed that 100% of the subjects who received empty boxes solved the candles problem, compared with only 43% of subjects who received filled boxes. Every one of the five problems in this study showed a difference favoring the control condition over the functional-fixedness condition, with average solution rates across the five problems of 97% and 58%, respectively.

The function of the objects in a problem can be also “fixed” by their most recent use. For example, Birch and Rabinowitz (1951) had subjects perform two consecutive tasks. In the first task, people had to use either a switch or a relay to form an electric circuit. After completing this task, both groups of subjects were asked to solve Maier’s (1931) two-ropes problem. The solution to this problem requires tying an object to one of the ropes and making the rope swing as a pendulum. Subjects could create the pendulum using either the object from the electric-circuit task or the other object. Birch and Rabinowitz found that subjects avoided using the same object for two unrelated functions. That is, those who used the switch in the first task made the pendulum using the relay, and vice versa. The explanations subjects subsequently gave for their object choices revealed that they were unaware of the functional-fixedness constraint they imposed on themselves.

In addition to investigating people’s solutions to such practical problems as irradiating a tumor, mounting candles on the wall, or tying ropes, the Gestalt psychologists examined how people understand and solve mathematical problems that require domain-specific knowledge. For example,

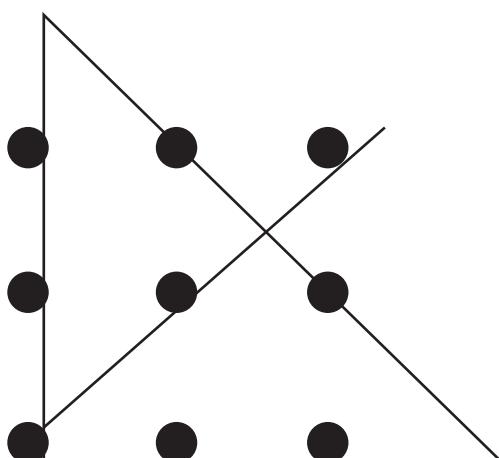

Fig. 21.4 A solution to the nine-dot problem.

Wertheimer (1959) observed individual differences in students' learning and subsequent application of the formula for finding the area of a parallelogram (see Fig. 21.5a). Some students understood the logic underlying the learned formula (i.e., the fact that a parallelogram can be transformed into a rectangle by cutting off a triangle from one side and pasting it onto the other side) and exhibited "productive thinking"—using the same logic to find the area of the quadrilateral in Figure 21.5b and the irregularly shaped geometric figure in Figure 21.5c. Other students memorized the formula and exhibited "reproductive thinking"—reproducing the learned solution only to novel parallelograms that were highly similar to the original one.

The psychological study of human problem solving faded into the background after the demise of the Gestalt tradition (during World War II), and problem solving was investigated only sporadically until Allen Newell and Herbert Simon's (1972) landmark book *Human Problem Solving* sparked a flurry of research on this topic. Newell and Simon adopted and refined Duncker's (1945) methodology of collecting and analyzing the think-aloud protocols that accompany problem solutions and extended Duncker's conceptualization of a problem solution as a search tree. However, their initial work did not aim to extend the Gestalt findings

pertaining to problem representation. Instead, as we explain in the next section, their objective was to identify the general-purpose strategies people use in searching for a problem solution.

Search in a Problem Space: The Legacy of Newell and Simon

Newell and Simon (1972) wrote a magnum opus detailing their theory of problem solving and the supporting research they conducted with various collaborators. This theory was grounded in the information-processing approach to cognitive psychology and guided by an analogy between human and artificial intelligence (i.e., both people and computers being "Physical Symbol Systems," Newell & Simon, 1976; see Doumas & Hummel, Chapter 5). They conceptualized problem solving as a process of search through a *problem space* for a path that connects the initial state to the goal state—a metaphor that alludes to the visual or spatial nature of problem solving (Simon, 1990). The term *problem space* refers to the solver's representation of the task as presented (Simon, 1978). It consists of (1) a set of knowledge states (the initial state, the goal state, and all possible intermediate states), (2) a set of operators that allow movement from one knowledge state to another, (3) a set of constraints, and (4) local information about the path one is taking through the space (e.g., the current knowledge state and how one got there).

We illustrate the components of a problem space for the three-disk Tower of Hanoi problem, as depicted in Figure 21.3. The initial state appears at the top (State #1) and the goal state at the bottom right (State #27). The remaining knowledge states in the figure are possible intermediate states. The current knowledge state is the one at which the solver is located at any given point in the solution process. For example, the current state for a solver who has made three moves along the optimum solution path would be State #9. The solver presumably would know that he or she arrived at this state from State #5. This knowledge allows the solver to recognize a move that involves backtracking. The three operators in this problem are moving each of the three disks from one peg to another. These operators are subject to the constraint that a larger disk may not be placed on a smaller disk.

Newell and Simon (1972), as well as other contemporaneous researchers (e.g., Atwood & Polson, 1976; Greene, 1974; Thomas, 1974), examined how people traverse the spaces of various well-defined problems (e.g., the Tower of Hanoi,

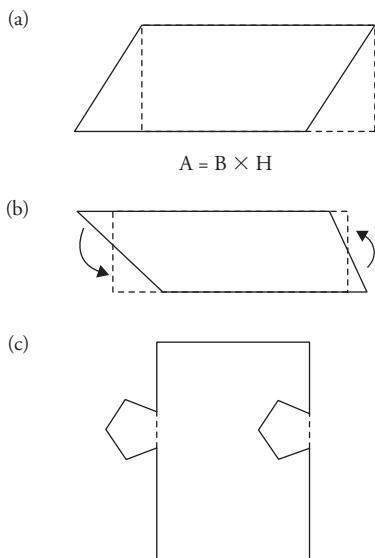

Fig. 21.5 Finding the area of (a) a parallelogram, (b) a quadrilateral, and (c) an irregularly shaped geometric figure. The solid lines indicate the geometric figures whose areas are desired. The dashed lines show how to convert the given figures into rectangles (i.e., they show solutions with understanding).

Hobbits and Orcs). They discovered that solvers' search is guided by a number of shortcut strategies, or *heuristics*, which are likely to get the solver to the goal state without an extensive amount of search. Heuristics are often contrasted with *algorithms*—methods that are guaranteed to yield the correct solution. For example, one could try every possible move in the three-disk Tower of Hanoi problem and, eventually, find the correct solution. Although such an exhaustive search is a valid algorithm for this problem, for many problems its application is very time consuming and impractical (e.g., consider the game of chess).

In their attempts to identify people's search heuristics, Newell and Simon (1972) relied on two primary methodologies: think-aloud protocols and computer simulations. Their use of think-aloud protocols brought a high degree of scientific rigor to the methodology used by Duncker (1945; see Ericsson & Simon, 1980). Solvers were required to say out loud everything they were thinking as they solved the problem, that is, everything that went through their verbal working memory. Subjects' verbalizations—their think-aloud protocols—were tape-recorded and then transcribed verbatim for analysis. This method is extremely time consuming (e.g., a transcript of one person's solution to the cryptarithmetic problem DONALD + GERALD = ROBERT, with D = 5, generated a 17-page transcript), but it provides a detailed record of the solver's ongoing solution process.
