An important caveat to keep in mind while interpreting a subject's verbalizations is that "a protocol is relatively reliable only for what it positively contains, but not for that which it omits" (Duncker, 1945, p. 11). Ericsson and Simon (1980) provided an in-depth discussion of the conditions under which this method is valid (but see Russo, Johnson, & Stephens, 1989, for an alternative perspective). To test their interpretation of a subject's problem solution, inferred from the subject's verbal protocol, Newell and Simon (1972) created a computer simulation program and examined whether it solved the problem the same way the subject did. To the extent that the computer simulation provided a close approximation of the solver's step-by-step solution process, it lent credence to the researcher's interpretation of the verbal protocol.

Newell and Simon's (1972) most famous simulation was the General Problem Solver or GPS (Ernst & Newell, 1969). GPS successfully modeled human solutions to problems as different as the Tower of

Hanoi and the construction of logic proofs using a single general-purpose heuristic: *means-ends analysis*. This heuristic captures people's tendency to devise a solution plan by setting *subgoals* that could help them achieve their final goal. It consists of the following steps: (1) Identify a difference between the current state and the goal (or *subgoal*) state; (2) Find an operator that will remove (or reduce) the difference; (3a) If the operator can be directly applied, do so, or (3b) If the operator cannot be directly applied, set a subgoal to remove the obstacle that is preventing execution of the desired operator; (4) Repeat steps 1–3 until the problem is solved. Next, we illustrate the implementation of this heuristic for the Tower of Hanoi problem, using the problem space in Figure 21.3.

As can be seen in Figure 21.3, a key difference between the initial state and the goal state is that the large disk is on the wrong peg (step 1). To remove this difference (step 2), one needs to apply the operator "move-large-disk." However, this operator cannot be applied because of the presence of the medium and small disks on top of the large disk. Therefore, the solver may set a subgoal to move that two-disk tower to the middle peg (step 3b), leaving the rightmost peg free for the large disk. A key difference between the initial state and this new subgoal state is that the medium disk is on the wrong peg. Because application of the move-medium-disk operator is blocked, the solver sets another subgoal to move the small disk to the right peg. This subgoal can be satisfied immediately by applying the move-small-disk operator (step 3a), generating State #3. The solver then returns to the previous subgoal—moving the tower consisting of the small and medium disks to the middle peg. The differences between the current state (#3) and the subgoal state (#9) can be removed by first applying the move-medium-disk operator (yielding State #5) and then the move-small-disk operator (yielding State #9). Finally, the move-large-disk operator is no longer blocked. Hence, the solver moves the large disk to the right peg, yielding State #11.

Notice that the subgoals are stacked up in the order in which they are generated, so that they pop up in the order of last in first out. Given the first subgoal in our example, repeated application of the means-ends analysis heuristic will yield the shortest-path solution, indicated by the large gray arrows. In general, subgoals provide direction to the search and allow solvers to plan several moves ahead. By assessing progress toward a required subgoal rather

than the final goal, solvers may be able to make moves that otherwise seem unwise. To take a concrete example, consider the transition from State #1 to State #3 in Figure 21.3. Comparing the initial state to the goal state, this move seems unwise because it places the small disk on the bottom of the right peg, whereas it ultimately needs to be at the top of the tower on that peg. But comparing the initial state to the solver-generated subgoal state of having the medium disk on the middle peg, this is exactly where the small disk needs to go.

Means-ends analysis and various other heuristics (e.g., the *hill-climbing* heuristic that exploits the similarity, or distance, between the state generated by the next operator and the goal state; *working backward* from the goal state to the initial state) are flexible strategies that people often use to successfully solve a large variety of problems. However, the generality of these heuristics comes at a cost: They are relatively weak and fallible (e.g., in the means-ends solution to the problem of fixing a hole in a bucket, “Dear Liza” leads “Dear Henry” in a loop that ends back at the initial state; the lyrics of this famous song can be readily found on the Web). Hence, although people use general-purpose heuristics when they encounter novel problems, they replace them as soon as they acquire experience with and sufficient knowledge about the particular problem space (e.g., Anzai & Simon, 1979).

Despite the fruitfulness of this research agenda, it soon became evident that a fundamental weakness was that it minimized the importance of people’s background knowledge. Of course, Newell and Simon (1972) were aware that problem solutions require relevant knowledge (e.g., the rules of logical proofs, or rules for stacking disks). Hence, in programming GPS, they supplemented every problem they modeled with the necessary background knowledge. This practice highlighted the generality and flexibility of means-ends analysis but failed to capture how people’s background knowledge affects their solutions. As we discussed in the previous section, domain knowledge is likely to affect how people represent problems and, therefore, how they generate problem solutions. Moreover, as people gain experience solving problems in a particular knowledge domain (e.g., math, physics), they change their representations of these problems (e.g., Chi, Feltovich, & Glaser, 1981; Haverty, Koedinger, Klahr, & Alibali, 2000; Schoenfeld & Herrmann, 1982) and learn domain-specific heuristics (e.g., Polya, 1957; Schoenfeld, 1979) that trump the general-purpose strategies.

It is perhaps inevitable that the two traditions in problem-solving research—one emphasizing representation and the other emphasizing search strategies—would eventually come together. In the next section we review developments that led to this integration.

The Two Legacies Converge

Because Newell and Simon (1972) aimed to discover the strategies people use in searching for a solution, they investigated problems that minimized the impact of factors that tend to evoke differences in problem representations, of the sort documented by the Gestalt psychologists. In subsequent work, however, Simon and his collaborators showed that such factors are highly relevant to people’s solutions of well-defined problems, and Simon (1986) incorporated these findings into the theoretical framework that views problem solving as search in a problem space.

In this section, we first describe illustrative examples of this work. We then describe research on insight solutions that incorporates ideas from the two legacies described in the previous sections.

Relevance of the Gestalt Ideas to the Solution of Search Problems

In this subsection we describe two lines of research by Simon and his colleagues, and by other researchers, that document the importance of perception and of background knowledge to the way people search for a problem solution. The first line of research used variants of relatively well-defined riddle problems that had the same structure (i.e., “problem isomorphs”) and, therefore, supposedly the same problem space. It documented that people’s search depended on various perceptual and conceptual inferences they tended to draw from a specific instantiation of the problem’s structure. The second line of research documented that people’s search strategies crucially depend on their domain knowledge and on their prior experience with related problems.

PROBLEM ISOMORPHS

Hayes and Simon (1977) used two variants of the Tower of Hanoi problem that, instead of disks and pegs, involved monsters and globes that differed in size (small, medium, and large). In both variants, the initial state had the small monster holding the large globe, the medium-sized monster holding the small globe, and the large monster holding the medium-sized globe. Moreover, in both variants the

goal was for each monster to hold a globe proportionate to its own size. The only difference between the problems concerned the description of the operators. In one variant (“transfer”), subjects were told that the monsters could transfer the globes from one to another as long as they followed a set of rules, adapted from the rules in the original Tower of Hanoi problem (e.g., only one globe may be transferred at a time). In the other variant (“change”), subjects were told that the monsters could shrink and expand themselves according to a set of rules, which corresponded to the rules in the transfer version of the problem (e.g., only one monster may change its size at a time). Despite the isomorphism of the two variants, subjects conducted their search in two qualitatively different problem spaces, which led to solution times for the change variant being almost twice as long as those for the transfer variant. This difference arose because subjects could more readily envision and track an object that was changing its location with every move than one that was changing its size.

Recent work by Patsenko and Altmann (2010) found that, even in the standard Tower of Hanoi problem, people’s solutions involve object-bound routines that depend on perception and selective attention. The subjects in their study solved various Tower of Hanoi problems on a computer. During the solution of a particular “critical” problem, the computer screen changed at various points without subjects’ awareness (e.g., a disk was added, such that a subject who started with a five-disc tower ended with a six-disc tower). Patsenko and Altmann found that subjects’ moves were guided by the configurations of the objects on the screen rather than by solution plans they had stored in memory (e.g., the next subgoal).

The Gestalt psychologists highlighted the role of perceptual factors in the formation of problem representations (e.g., Maier’s, 1930, nine-dot problem) but were generally silent about the corresponding implications for how the problem was solved (although they did note effects on solution accuracy). An important contribution of the work on people’s solutions of the Tower of Hanoi problem and its variants was to show the relevance of perceptual factors to the application of various operators during search for a problem solution—that is, to the *how* of problem solving. In the next section, we describe recent work that documents the involvement of perceptual factors in how people understand and use equations and diagrams in the context of solving math and science problems.

Kotovsky, Hayes, and Simon (1985) further investigated factors that affect people’s representation and search in isomorphs of the Tower of Hanoi problem. In one of their isomorphs, three disks were stacked on top of each other to form an inverted pyramid, with the smallest disc on the bottom and the largest on top. Subjects’ solutions of the inverted pyramid version were similar to their solutions of the standard version that has the largest disc on the bottom and the smallest on top. However, the two versions were solved very differently when subjects were told that the discs represent acrobats. Subjects readily solved the version in which they had to place a small acrobat on the shoulders of a large one, but they refrained from letting a large acrobat stand on the shoulders of a small one. In other words, object-based inferences that draw on people’s semantic knowledge affected the solution of search problems, much as they affect the solution of the ill-defined problems investigated by the Gestalt psychologists (e.g., Duncker’s, 1945, candles problem). In the next section, we describe more recent work that shows similar effects in people’s solutions to mathematical word problems.

The work on differences in the representation and solution of problem isomorphs is highly relevant to research on analogical problem solving (or analogical transfer), which examines when and how people realize that two problems that differ in their cover stories have a similar structure (or a similar problem space) and, therefore, can be solved in a similar way. This research shows that minor differences between example problems, such as the use of X-rays versus ultrasound waves to fuse a broken filament of a light bulb, can elicit different problem representations that significantly affect the likelihood of subsequent transfer to novel problem analogs (Holyoak & Koh, 1987). Analogical transfer has played a central role in research on human problem solving, in part because it can shed light on people’s understanding of a given problem and its solution and in part because it is believed to provide a window onto understanding and investigating creativity (see Smith & Ward, Chapter 23). We briefly mention some findings from the analogy literature in the next subsection on expertise, but we do not discuss analogical transfer in detail because this topic is covered elsewhere in this volume (Holyoak, Chapter 13).

EXPERTISE AND ITS DEVELOPMENT

In another line of research, Simon and his colleagues examined how people solve ecologically valid

problems from various rule-governed and knowledge-rich domains. They found that people's level of expertise in such domains, be it in chess (Chase & Simon, 1973; Gobet & Simon, 1996), mathematics (Hinsley, Hayes, & Simon, 1977; Paige & Simon, 1966), or physics (Larkin, McDermott, Simon, & Simon, 1980; Simon & Simon, 1978), plays a crucial role in how they represent problems and search for solutions. This work, and the work of numerous other researchers, led to the discovery (and rediscovery, see Duncker, 1945) of important differences between experts and novices, and between "good" and "poor" students.

One difference between experts and novices pertains to pattern recognition. Experts' attention is quickly captured by familiar configurations within a problem situation (e.g., a familiar configuration of pieces in a chess game). In contrast, novices' attention is focused on isolated components of the problem (e.g., individual chess pieces). This difference, which has been found in numerous domains, indicates that experts have stored in memory many meaningful groups (chunks) of information: for example, chess (Chase & Simon, 1973), circuit diagrams (Egan & Schwartz, 1979), computer programs (McKeithen, Reitman, Rueter, & Hirtle, 1981), medicine (Coughlin & Patel, 1987; Myles-Worsley, Johnston, & Simons, 1988), basketball and field hockey (Allard & Starkes, 1991), and figure skating (Deakin & Allard, 1991).

The perceptual configurations that domain experts readily recognize are associated with stored solution plans and/or compiled procedures (Anderson, 1982). As a result, experts' solutions are much faster than, and often qualitatively different from, the piece-meal solutions that novice solvers tend to construct (e.g., Larkin et al., 1980). In effect, experts often see the solutions that novices have yet to compute (e.g., Chase & Simon, 1973; Novick & Sherman, 2003, 2008). These findings have led to the design of various successful instructional interventions (e.g., Catrambone, 1998; Kellman et al., 2008). For example, Catrambone (1998) perceptually isolated the subgoals of a statistics problem. This perceptual chunking of meaningful components of the problem prompted novice students to self-explain the meaning of the chunks, leading to a conceptual understanding of the learned solution. In the next section, we describe some recent work that shows the beneficial effects of perceptual pattern recognition on the solution of familiar mathematics problems, as well as the potentially detrimental effects

of familiar perceptual chunks to understanding and reasoning with diagrams depicting evolutionary relationships among taxa.

Another difference between experts and novices pertains to their understanding of the solution-relevant problem structure. Experts' knowledge is highly organized around domain principles, and their problem representations tend to reflect this principled understanding. In particular, they can extract the solution-relevant structure of the problems they encounter (e.g., meaningful causal relations among the objects in the problem; see Cheng & Buehner, Chapter 12). In contrast, novices' representations tend to be bound to surface features of the problems that may be irrelevant to solution (e.g., the particular objects in a problem). For example, Chi, Feltovich, and Glaser (1981) examined how students with different levels of physics expertise group mechanics word problems. They found that advanced graduate students grouped the problems based on the physics principles relevant to the problems' solutions (e.g., conservation of energy, Newton's second law). In contrast, undergraduates who had successfully completed an introductory course in mechanics grouped the problems based on the specific objects involved (e.g., pulley problems, inclined plane problems). Other researchers have found similar results in the domains of biology, chemistry, computer programming, and math (Adelson, 1981; Kindfield, 1993/1994; Kozma & Russell, 1997; McKeithen et al., 1981; Silver, 1979, 1981; Weiser & Shertz, 1983).

The level of domain expertise and the corresponding representational differences are, of course, a matter of degree. With increasing expertise, there is a gradual change in people's focus of attention from aspects that are not relevant to solution to those that are (e.g., Deakin & Allard, 1991; Hardiman, Dufresne, & Mestre, 1989; McKeithen et al., 1981; Myles-Worsley et al., 1988; Schoenfeld & Herrmann, 1982; Silver, 1981). Interestingly, Chi, Bassok, Lewis, Reimann, and Glaser (1989) found similar differences in focus on structural versus surface features among a group of novices who studied worked-out examples of mechanics problems. These differences, which echo Wertheimer's (1959) observations of individual differences in students' learning about the area of parallelograms, suggest that individual differences in people's interests and natural abilities may affect whether, or how quickly, they acquire domain expertise.

An important benefit of experts' ability to focus their attention on solution-relevant aspects of problems is that they are more likely than novices to recognize analogous problems that involve different objects and cover stories (e.g., Chi et al., 1989; Novick, 1988; Novick & Holyoak, 1991; Wertheimer, 1959) or that come from other knowledge domains (e.g., Bassok & Holyoak, 1989; Dunbar, 2001; Goldstone & Sakamoto, 2003). For example, Bassok and Holyoak (1989) found that, after learning to solve arithmetic-progression problems in algebra, subjects spontaneously applied these algebraic solutions to analogous physics problems that dealt with constantly accelerated motion. Note, however, that experts and good students do not simply ignore the surface features of problems. Rather, as was the case in the problem isomorphs we described earlier (Kotovsky et al., 1985), they tend to use such features to infer what the problem's structure could be (e.g., Alibali, Bassok, Solomon, Syc, & Goldin-Meadow, 1999; Blessing & Ross, 1996). For example, Hinsley et al. (1977) found that, after reading no more than the first few words of an algebra word problem, expert solvers classified the problem into a likely problem category (e.g., a work problem, a distance problem) and could predict what questions they might be asked and the equations they likely would need to use.

Surface-based problem categorization has a heuristic value (Medin & Ross, 1989): It does not ensure a correct categorization (Blessing & Ross, 1996), but it does allow solvers to retrieve potentially appropriate solutions from memory and to use them, possibly with some adaptation, to solve a variety of novel problems. Indeed, although experts exploit surface-structure correlations to save cognitive effort, they have the capability to realize that a particular surface cue is misleading (Hegarty, Mayer, & Green, 1992; Lewis & Mayer, 1987; Martin & Bassok, 2005; Novick 1988, 1995; Novick & Holyoak, 1991). It is not surprising, therefore, that experts may revert to novice-like heuristic methods when solving problems under pressure (e.g., Beilock, 2008) or in sub-domains in which they have general but not specific expertise (e.g., Patel, Groen, & Arocha, 1990).

Relevance of Search to Insight Solutions

We introduced the notion of insight in our discussion of the nine-dot problem in the section on the Gestalt tradition. The Gestalt view (e.g., Duncker, 1945; Maier, 1931; see Ohlsson, 1984, for a review) was that insight problem solving is characterized

by an initial work period during which no progress toward solution is made (i.e., an impasse), a sudden restructuring of one's problem representation to a more suitable form, followed immediately by the sudden appearance of the solution. Thus, solving problems by insight was believed to be all about representation, with essentially no role for a step-by-step solution process (i.e., search). Subsequent and contemporary researchers have generally concurred with the Gestalt view that getting the right representation is crucial. However, research has shown that insight solutions do not necessarily arise suddenly or full blown after restructuring (e.g., Weisberg & Alba, 1981); and even when they do, the underlying solution process (in this case outside of awareness) may reflect incremental progress toward the goal (Bowden & Jung-Beeman, 2003; Durso, Rea, & Dayton, 1994; Novick & Sherman, 2003).

"Demystifying insight," to borrow a phrase from Bowden, Jung-Beeman, Fleck, and Kounios (2005), requires explaining (1) why solvers initially reach an impasse in solving a problem for which they have the necessary knowledge to generate the solution, (2) how the restructuring occurred, and (3) how it led to the solution. A detailed discussion of these topics appears elsewhere in this volume (van Steenburgh et al., Chapter 24). Here, we describe briefly three recent theories that have attempted to account for various aspects of these phenomena: Knoblich, Ohlsson, Haider, and Rhenius's (1999) representational change theory, MacGregor, Ormerod, and Chronicle's (2001) progress monitoring theory, and Bowden et al.'s (2005) neurological model. We then propose the need for an integrated approach to demystifying insight that considers both representation and search.

According to Knoblich et al.'s (1999) representational change theory, problems that are solved with insight are highly likely to evoke initial representations in which solvers place inappropriate constraints on their solution attempts, leading to an impasse. An impasse can be resolved by revising one's representation of the problem. Knoblich and his colleagues tested this theory using Roman numeral matchstick arithmetic problems in which solvers must move one stick to a new location to change a false numerical statement (e.g., $I = II + II$) into a statement that is true. According to representational change theory, re-representation may occur through either constraint relaxation or chunk decomposition. (The solution to the example problem is to change $II +$ to $III -$, which requires both

methods of re-representation, yielding $I = III - II$). Good support for this theory has been found based on measures of solution rate, solution time, and eye fixation (Knoblich et al., 1999; Knoblich, Ohlsson, & Raney, 2001; Öllinger, Jones, & Knoblich, 2008).

Progress monitoring theory (MacGregor et al., 2001) was proposed to account for subjects' difficulty in solving the nine-dot problem, which has traditionally been classified as an insight problem. According to this theory, solvers use the hill-climbing search heuristic to solve this problem, just as they do for traditional search problems (e.g., Hobbits and Orcs). In particular, solvers are hypothesized to monitor their progress toward solution using a criterion generated from the problem's current state. If solvers reach criterion failure, they seek alternative solutions by trying to relax one or more problem constraints. MacGregor et al. found support for this theory using several variants of the nine-dot problem (also see Ormerod, MacGregor, & Chronicle, 2002). Jones (2003) suggested that progress monitoring theory provides an account of the solution process up to the point an impasse is reached and representational change is sought, at which point representational change theory picks up and explains how insight may be achieved. Hence, it appears that a complete account of insight may require an integration of concepts from the Gestalt (representation) and Newell and Simon's (search) legacies.

Bowden et al.'s (2005) neurological model emphasizes the overlap between problem solving and language comprehension, and it hinges on differential processing in the right and left hemispheres. They proposed that an impasse is reached because initial processing of the problem produces strong activation of information irrelevant to solution in the left hemisphere. At the same time, weak semantic activation of alternative semantic interpretations, critical for solution, occurs in the right hemisphere. Insight arises when the weakly activated concepts reinforce each other, eventually rising above the threshold required for conscious awareness. Several studies of problem solving using compound remote associates problems, involving both behavioral and neuroimaging data, have found support for this model (Bowden & Jung-Beeman, 1998, 2003; Jung-Beeman & Bowden, 2000; Jung-Beeman et al., 2004; also see Moss, Kotovsky, & Cagan, 2011).

Note that these three views of insight have received support using three quite distinct types of

problems (Roman numeral matchstick arithmetic problems, the nine-dot problem, and compound remote associates problems, respectively). It remains to be established, therefore, whether these accounts can be generalized across problems. Kershaw and Ohlsson (2004) argued that insight problems are difficult because the key behavior required for solution may be hindered by perceptual factors (the Gestalt view), background knowledge (so expertise may be important; e.g., see Novick & Sherman, 2003, 2008), and/or process factors (e.g., those affecting search). From this perspective, solving visual problems (e.g., the nine-dot problem) with insight may call upon more general visual processes, whereas solving verbal problems (e.g., anagrams, compound remote associates) with insight may call upon general verbal/semantic processes.

Summary

The work we reviewed in this section shows the relevance of problem representation (the Gestalt legacy) to the way people search the problem space (the legacy of Newell and Simon), and the relevance of search to the solution of insight problems that require a representational change. In addition to this inevitable integration of the two legacies, the work we described here underscores the fact that problem solving crucially depends on perceptual factors and on the solvers' background knowledge. In the next section, we describe some recent work that shows the involvement of these factors in the solution of problems in math and science.

Effects of Perception and Knowledge in Problem Solving in Academic Disciplines

Although the use of puzzle problems continues in research on problem solving, especially in investigations of insight, many contemporary researchers tackle problem solving in knowledge-rich domains, often in academic disciplines (e.g., mathematics, biology, physics, chemistry, meteorology). In this section, we provide a sampling of this research that highlights the importance of visual perception and background knowledge for successful problem solving.

The Role of Visual Perception

We stated at the outset that a problem representation (e.g., the problem space) is a model of the problem constructed by solvers to summarize their understanding of the problem's essential nature. This informal definition refers to the *internal*

representations people construct and hold in working memory. Of course, people may also construct various *external representations* (Markman, 1999) and even manipulate those representations to aid in solution (see Hegarty & Stull, Chapter 31). For example, solvers often use paper and pencil to write notes or draw diagrams, especially when solving problems from formal domains (e.g., Cox, 1999; Kindfield, 1993/1994; S. Schwartz, 1971). In problems that provide solvers with external representation, such as the Tower of Hanoi problem, people's planning and memory of the current state is guided by the actual configurations of disks on pegs (Garber & Goldin-Meadow, 2002) or by the displays they see on a computer screen (Chen & Holyoak, 2010; Patsenko & Altmann, 2010).

In STEM (science, technology, engineering, and mathematics) disciplines, it is common for problems to be accompanied by diagrams or other external representations (e.g., equations) to be used in determining the solution. Larkin and Simon (1987) examined whether isomorphic sentential and diagrammatic representations are interchangeable in terms of facilitating solution. They argued that although the two formats may be equivalent in the sense that all of the information in each format can be inferred from the other format (informational equivalence), the ease or speed of making inferences from the two formats might differ (lack of computational equivalence). Based on their analysis of several problems in physics and math, Larkin and Simon further argued for the general superiority of diagrammatic representations (but see Mayer & Gallini, 1990, for constraints on this general conclusion).

Novick and Hurley (2001, p. 221) succinctly summarized the reasons for the general superiority of diagrams (especially abstract or schematic diagrams) over verbal representations: They "(a) simplify complex situations by discarding unnecessary details (e.g., Lynch, 1990; Winn, 1989), (b) make abstract concepts more concrete by mapping them onto spatial layouts with familiar interpretational conventions (e.g., Winn, 1989), and (c) substitute easier perceptual inferences for more computationally intensive search processes and sentential deductive inferences (Barwise & Etchemendy, 1991; Larkin & Simon, 1987)." Despite these benefits of diagrammatic representations, there is an important caveat, noted by Larkin and Simon (1987, p. 99) at the very end of their paper: "Although every diagram supports some easy perceptual inferences,

nothing ensures that these inferences must be useful in the problem-solving process." We will see evidence of this in several of the studies reviewed in this section.

Next we describe recent work on perceptual factors that are involved in people's use of two types of external representations that are provided as part of the problem in two STEM disciplines: equations in algebra and diagrams in evolutionary biology. Although we focus here on effects of perceptual factors per se, it is important to note that such factors only influence performance when subjects have background knowledge that supports differential interpretation of the alternative diagrammatic depictions presented (Hegarty, Canham, & Fabricant, 2010).

EQUATIONS

In the previous section, we described the work of Patsenko and Altmann (2010) that shows direct involvement of visual attention and perception in the sequential application of move operators during the solution of the Tower of Hanoi problem. A related body of work documents similar effects in tasks that require the interpretation and use of mathematical equations (Goldstone, Landy, & Son, 2010; Landy & Goldstone, 2007a, b). For example, Landy and Goldstone (2007b) varied the spatial proximity of arguments to the addition (+) and multiplication (*) operators in algebraic equations, such that the spatial layout of the equation was either consistent or inconsistent with the order-of-operations rule that multiplication precedes addition. In *consistent equations*, the space was narrower around multiplication than around addition (e.g., $g*m + r*w = m*g + w*r$), whereas in *inconsistent equations* this relative spacing was reversed (e.g., $s * n + e * c = n * s + c * e$). Subjects' judgments of the validity of such equations (i.e., whether the expressions on the two sides of the equal sign are equivalent) were significantly faster and more accurate for consistent than inconsistent equations.

In discussing these findings and related work with other external representations, Goldstone et al. (2010) proposed that experience with solving domain-specific problems leads people to "rig up" their perceptual system such that it allows them to look at the problem in a way that is consistent with the correct rules. Similar logic guides the Perceptual Learning Modules developed by Kellman and his collaborators to help students interpret and use algebraic equations and graphs (Kellman et al., 2008;

Kellman, Massey, & Son, 2009). These authors argued and showed that, consistent with the previously reviewed work on expertise, perceptual training with particular external representations supports the development of perceptual fluency. This fluency, in turn, supports students' subsequent use of these external representations for problem solving.

This research suggests that extensive experience with particular equations or graphs may lead to perceptual fluency that could replace the more mindful application of domain-specific rules. Fisher, Borchert, and Bassok (2011) reported results from algebraic-modeling tasks that are consistent with this hypothesis. For example, college students were asked to represent verbal statements with algebraic equations, a task that typically elicits systematic errors (e.g., Clement, Lochhead, & Monk, 1981). Fisher et al. found that such errors were very common when subjects were asked to construct "standard form" equations ($y = ax$), which support fluent left-to-right translation of words to equations, but were relatively rare when subjects were asked to construct nonstandard division-format equations ($x = y/a$) that do not afford such translation fluency.

In part because of the left-to-right order in which people process equations, which mirrors the linear order in which they process text, equations have traditionally been viewed as sentential representations. However, Landy and Goldstone (2007a) have proposed that equations also share some properties with diagrammatic displays and that, in fact, in some ways they are processed like diagrams. That is, spatial information is used to represent and to support inferences about syntactic structure. This hypothesis received support from Landy and Goldstone's (2007b) results, described earlier, in which subjects' judgments of the validity of equations were affected by the Gestalt principle of grouping: Subjects did better when the grouping was consistent rather than inconsistent with the underlying structure of the problem (order of operations). Moreover, Landy and Goldstone (2007a) found that when subjects wrote their own equations they grouped numbers and operators (+, *, =) in a way that reflected the hierarchical structure imposed by the order-of-operations rule.

DIAGRAMS

In a recent line of research, Novick and Catley (2007; Novick, Catley, & Funk, 2010; Novick, Shade, & Catley, 2011) have examined effects of

the spatial layout of diagrams depicting the evolutionary history of a set of taxa on people's ability to reason about patterns of relationship among those taxa. We consider here their work that investigates the role of another Gestalt perceptual principle—good continuation—in guiding students' reasoning. According to this principle, a continuous line is perceived as a single entity (Kellman, 2000). Consider the diagrams shown in Figure 21.6. Each is a cladogram, a diagram that depicts nested sets of taxa that are related in terms of levels of most recent common ancestry. For example, chimpanzees and starfish are more closely related to each other than either is to spiders. The supporting evidence for their close relationship is their most recent common ancestor, which evolved the novel character of having radial cleavage. Spiders do not share this ancestor and thus do not have this character.

Cladograms are typically drawn in two isomorphic formats, which Novick and Catley (2007) referred to as trees and ladders. Although these formats are informationally equivalent (Larkin & Simon, 1987), Novick and Catley's (2007) research shows that they are not computationally equivalent (Larkin & Simon, 1987). Imagine that you are given evolutionary relationships in the ladder format, such as in Figure 21.6a (but without the four characters—hydrostatic skeleton, bilateral symmetry, radial cleavage, and trocophore larvae—and associated short lines indicating their locations on the cladogram), and your task is to translate that diagram to the tree format. A correct translation is shown in Figure 21.6b. Novick and Catley (2007) found that college students were much more likely to get such problems correct when the presented cladogram was in the nested circles (e.g., Figure 21.6d) rather than the ladder format. Because the Gestalt principle of good continuation makes the long slanted line at the base of the ladder appear to represent a single hierarchical level, a common translation error for the ladder to tree problems was to draw a diagram such as that shown in Figure 21.6c.

The difficulty that good continuation presents for interpreting relationships depicted in the ladder format extends to answering reasoning questions as well. Novick and Catley (unpublished data) asked comparable questions about relationships depicted in the ladder and tree formats. For example, using the cladograms depicted in Figures 21.6a and 21.6b, consider the following questions: (a) Which taxon—jellyfish or earthworm—is the closest evolutionary relation to starfish, and what evidence

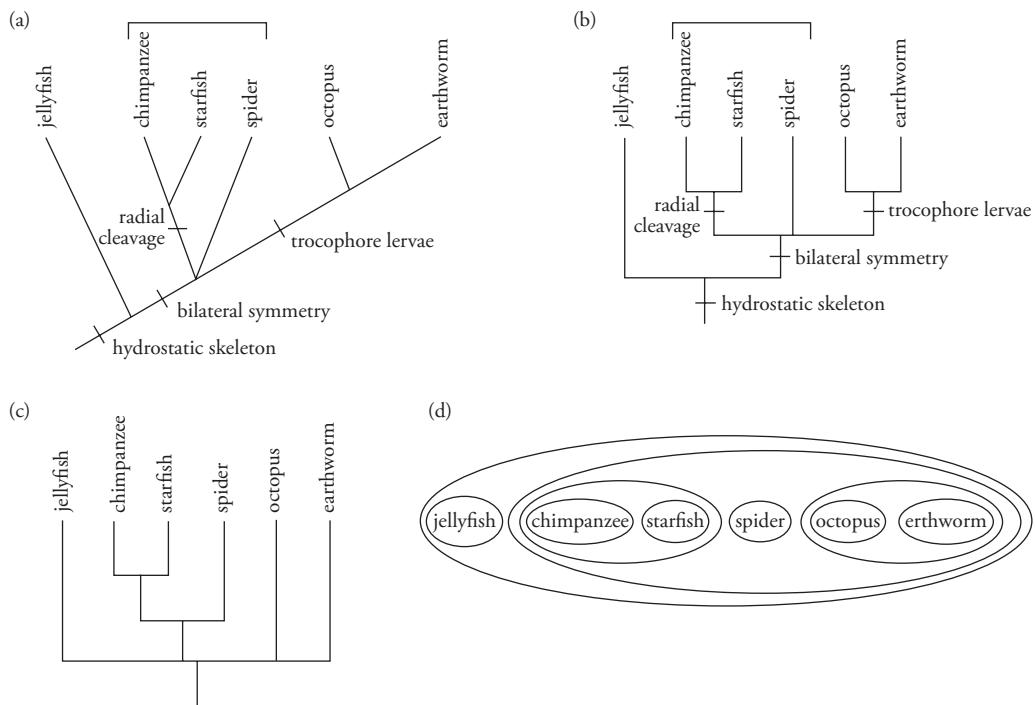

Fig. 21.6 Four cladograms depicting evolutionary relationships among six animal taxa. Cladogram (a) is in the ladder format, cladograms (b) and (c) are in the tree format, and cladogram (d) is in the nested circles format. Cladograms (a), (b), and (d) are isomorphic.

supports your answer? (b) Do the bracketed taxa comprise a clade (a set of taxa consisting of the most recent common ancestor and all of its descendants), and what evidence supports your answer? For both such questions, students had higher accuracy and evidence quality composite scores when the relationships were depicted in the tree than the ladder format.

If the difficulty in extracting the hierarchical structure of the ladder format is due to good continuation (which leads problem solvers to interpret continuous lines that depict multiple hierarchical levels as depicting only a single level), then a manipulation that breaks good continuation at the points where a new hierarchical level occurs should improve understanding. Novick et al. (2010) tested this hypothesis using a translation task by manipulating whether characters that are the markers for the most recent common ancestor of each nested set of taxa were included on the ladders. Figure 21.6a shows a ladder with such characters. As predicted, translation accuracy increased dramatically simply by adding these characters to the ladders, despite the additional information subjects had to account for in their translations.

The Role of Background Knowledge

As we mentioned earlier, the specific entities in the problems people encounter evoke inferences that affect how people represent these problems (e.g., the candle problem; Duncker, 1945) and how they apply the operators in searching for the solution (e.g., the disks vs. acrobats versions of the Tower of Hanoi problem; Kotovsky et al., 1985). Such object-based inferences draw on people's knowledge about the properties of the objects (e.g., a box is a container, an acrobat is a person who can be hurt). Here, we describe the work of Bassok and her colleagues, who found that similar inferences affect how people select mathematical procedures to solve problems in various formal domains. This work shows that the objects in the texts of mathematical word problems affect how people represent the problem situation (i.e., the *situation model* they construct; Kintsch & Greeno, 1985) and, in turn, lead them to select mathematical models that have a corresponding structure. To illustrate, a word problem that describes constant change in the rate at which ice is melting off a glacier evokes a model of continuous change, whereas a word problem that describes constant change in the rate at which ice is

delivered to a restaurant evokes a model of discrete change. These distinct situation models lead subjects to select corresponding visual representations (e.g., Bassok & Olseth, 1995) and solutions methods, such as calculating the average change over time versus adding the consecutive changes (e.g., Alibali et al., 1999).

In a similar manner, people draw on their general knowledge to infer how the objects in a given problem are related to each other and construct mathematical solutions that correspond to these inferred object relations. For example, a word problem that involves doctors from two hospitals elicits a situation model in which the two sets of doctors play symmetric roles (e.g., work with each other), whereas a mathematically isomorphic problem that involves mechanics and cars elicits a situation model in which the sets play asymmetric roles (e.g., mechanics fix cars). The mathematical solutions people construct to such problems reflect this difference in symmetry (Bassok, Wu, & Olseth, 1995). In general, people tend to add objects that belong to the same taxonomic category (e.g., doctors + doctors) but divide functionally related objects (e.g., cars + mechanics). People establish this correspondence by a process of analogical alignment between semantic and arithmetic relations, which Bassok and her colleagues refer to as “semantic alignment” (Bassok, Chase, & Martin, 1998; Doumas, Bassok, Guthormsen, & Hummel, 2006; Fisher, Bassok, & Osterhout, 2010).

Semantic alignment occurs very early in the solution process and can prime arithmetic facts that are potentially relevant to the problem solution (Bassok, Pedigo, & Oskarsson, 2008). Although such alignments can lead to erroneous solutions, they have a high heuristic value because, in most textbook problems, object relations indeed correspond to analogous mathematical relations (Bassok et al., 1998). Interestingly, unlike in the case of reliance on specific surface-structure correlations (e.g., the keyword “more” typically appears in word problems that require addition; Lewis & Mayer, 1987), people are more likely to exploit semantic alignment when they have more, rather than less modeling experience. For example, Martin and Bassok (2005) found very strong semantic-alignment effects when subjects solved simple division word problems, but not when they constructed algebraic equations to represent the relational statements that appeared in the problems. Of course, these subjects had significantly more experience with solving numerical word

problems than with constructing algebraic models of relational statements. In a subsequent study, Fisher and Bassok (2009) found semantic-alignment effects for subjects who constructed correct algebraic models, but not for those who committed modeling errors.

Conclusions and Future Directions

In this chapter, we examined two broad components of the problem-solving process: representation (the Gestalt legacy) and search (the legacy of Newell and Simon). Although many researchers choose to focus their investigation on one or the other of these components, both Duncker (1945) and Simon (1986) underscored the necessity to investigate their interaction, as the representation one constructs for a problem determines (or at least constrains) how one goes about trying to generate a solution, and searching the problem space may lead to a change in problem representation. Indeed, Duncker’s (1945) initial account of one subject’s solution to the radiation problem was followed up by extensive and experimentally sophisticated work by Simon and his colleagues and by other researchers, documenting the involvement of visual perception and background knowledge in how people represent problems and search for problem solutions.

The relevance of perception and background knowledge to problem solving illustrates the fact that, when people attempt to find or devise ways to reach their goals, they draw on a variety of cognitive resources and engage in a host of cognitive activities. According to Duncker (1945), such goal-directed activities may include (a) placing objects into categories and making inferences based on category membership, (b) making inductive inferences from multiple instances, (c) reasoning by analogy, (d) identifying the causes of events, (e) deducing logical implications of given information, (f) making legal judgments, and (g) diagnosing medical conditions from historical and laboratory data. As this list suggests, many of the chapters in the present volume describe research that is highly relevant to the understanding of problem-solving behavior. We believe that important advancements in problem-solving research would emerge by integrating it with research in other areas of thinking and reasoning, and that research in these other areas could be similarly advanced by incorporating the insights gained from research on what has more traditionally been identified as problem solving.

As we have described in this chapter, many of the important findings in the field have been established by a careful investigation of various riddle problems. Although there are good methodological reasons for using such problems, many researchers choose to investigate problem solving using ecologically valid educational materials. This choice, which is increasingly common in contemporary research, provides researchers with the opportunity to apply their basic understanding of problem solving to benefit the design of instruction and, at the same time, allows them to gain a better understanding of the processes by which domain knowledge and educational conventions affect the solution process. We believe that the trend of conducting educationally relevant research is likely to continue, and we expect a significant expansion of research on people's understanding and use of dynamic and technologically rich external representations (e.g., Kellman et al., 2008; Mayer, Griffith, Jurkowitz, & Rothman, 2008; Richland & McDonough, 2010; Son & Goldstone, 2009). Such investigations are likely to yield both practical and theoretical payoffs.

On the Distinction Between Rationality and Intelligence: Implications for Understanding Individual Differences in Reasoning

Keith E. Stanovich

Abstract

A concern for individual differences has been missing from the Great Rationality Debate in cognitive science—the debate about how much irrationality to attribute to human cognition. There are individual differences in rational thinking that are less than perfectly correlated with individual differences in intelligence because intelligence and rationality occupy different conceptual locations in models of cognition. A tripartite extension of currently popular dual-process theories is presented in this chapter that illustrates how intelligence and rationality are theoretically separate concepts. The chapter concludes by showing how this tripartite model of mind, taken in the context of studies of individual differences, can help to resolve the Great Rationality Debate.

Key Words: rationality, intelligence, reasoning, individual differences

Introduction

In psychology and among the lay public alike, assessments of intelligence and tests of cognitive ability are taken to be the sine qua non of good thinking. Critics of these instruments often point out that IQ tests fail to assess many domains of psychological functioning that are essential. For example, many largely noncognitive domains such as socioemotional abilities, creativity (Smith & Ward, Chapter 23), empathy, and interpersonal skills are almost entirely unassessed by tests of cognitive ability. However, even these common critiques of intelligence tests often contain the unstated assumption that although intelligence tests miss certain key noncognitive areas, they encompass most of what is important cognitively. In this chapter, I will challenge this tacit assumption by arguing that certain very important classes of individual differences in thinking are ignored if only intelligence-related variance is the focus. Many of these classes of individual differences that are missing from IQ tests are those relating to rational thought (Chater & Oaksford,

Chapter 2). In this chapter, I will illustrate how a comprehensive assessment of individual differences in reasoning skills will necessitate the theoretical and empirical differentiation of the concepts of intelligence and rational thinking.

The discussion in this chapter will begin by showing how differing definitions of rationality frame what is known as the Great Rationality Debate in cognitive science. That debate concerns how much irrationality to attribute to human cognition. I will argue that a concern for individual differences has been missing from this debate because we failed to appreciate that there are individual differences in rational thought as well as intelligence. This is easier to appreciate when we realize that intelligence and rationality occupy somewhat different conceptual locations within most models of cognition. Thus, I present a generic model of the mind that is an extension of currently popular dual-process theories (Evans, Chapter 8), and I situate both intelligence and rationality within this model and show how they dissociate, both conceptually and empirically.

I conclude the chapter by showing how this tripartite model of mind, taking in the context of studies of individual differences, can help to resolve the Great Rationality Debate.

The Concept of Rational Thought in Cognitive Science and Philosophy

The term *rationality* has a strong and a weak sense. The strong sense of the term is the one used in cognitive science, and it will be the one used throughout this chapter. However, a weaker sense of the term has sometimes influenced—and hence confused—arguments in the so-called Great Rationality Debate in cognitive science. The influence of the weak sense of the term has also impeded investigation into individual differences in rational thought.

Dictionary definitions of rationality tend to be of the weak sort—often seeming quite lame and unspecific (“the state or quality of being in accord with reason”). The meaning of rationality in modern cognitive science (the strong sense) is, in contrast, much more specific and prescriptive than this. The weak definitions of rationality derive from a categorical notion of rationality tracing to Aristotle (humans as the only animals who base actions on reason). As de Sousa (2007) has pointed out, such a notion of rationality as “based on reason” has as its opposite not irrationality but *arationality* (outside the domain of reason). Aristotle’s characterization is categorical—the behavior of entities is either based on thought or it is not. Animals are either rational or arational. In this conception, humans are rational, but other animals are not. There is no room for individual differences in rational thinking *among* humans in this view.

In its stronger sense (the sense employed in most of cognitive science and in this chapter) rational thought is a normative notion (Chater & Oaksford, Chapter 2; Griffiths, Tenenbaum, & Kemp, Chapter 3). Its opposite is irrationality, not arationality. Normative models of optimal judgment and decision making define perfect rationality in the noncategorical view employed in cognitive science. Rationality (and irrationality) comes in degrees defined by the distance of the thought or behavior from the optimum defined by a normative model. De Sousa (2007) points out that the notion of rationality in Aristotle’s sense cannot be normative, but in the strong sense of cognitive science, it is. Other animals may be arational, but only humans can be irrational. As de Sousa (2007) puts it, “if human beings can indeed be described as rational animals, it is precisely in virtue of the fact

that humans, of all the animals, are the only ones capable of irrational thoughts and actions” (p. 7).

Hurley and Nudds (2006) make a similar point when they argue that, for a strong sense of the term: “ironically, rationality requires the possibility that the animal might err. It can’t be automatically right, no matter what it does.... when we say that an agent has acted rationally, we imply that it would have been a mistake in some sense to have acted in certain different ways. It can’t be the case that anything the agent might do would count as rational. This is normativity in a quite weak sense” (p. 2). The weak sense they are referring to is an Aristotelian (categorical) sense, and no cognitive scientist is using rationality in this sense when claiming that an experiment has demonstrated human irrationality.

When a cognitive scientist terms a behavior irrational, he or she means that the behavior departs from the optimum prescribed by a particular normative model. The scientist is not implying that no thought or reason was behind the behavior. Some of the hostility that has been engendered by experimental claims of human irrationality no doubt derive from a (perhaps tacit) influence of the Aristotelian view—the thought that cognitive psychologists are saying that certain people are somehow less than human when they are said to behave irrationally. But in using the strong sense of the term *rationality*, most cognitive scientists are saying no such thing.¹

Some of the heat in the Great Rationality Debate is no doubt caused by reactions to the term *irrationality* being applied to humans. As mentioned, lingering associations with the Aristotelian categorical view make charges of irrationality sound more cutting than they actually are when in the context of cognitive science research. When we find a behavioral pattern that is less than optimally rational, we could easily say that it is “less than perfectly rational” rather than that it is irrational—with no loss of meaning. Perhaps if this had been the habit in the literature, the rationality debate in cognitive science would not have become so heated. Such an emphasis also highlights the theme of this chapter—that there are indeed individual differences in rational thought and that understanding the nature of these differences might have important theoretical implications.

Cognitive scientists recognize two types of rationality: epistemic and instrumental. *Epistemic rationality* concerns how well beliefs map onto the actual structure of the world. It is sometimes called theoretical rationality or evidential rationality (see

Audi, 1993, 2001; Foley, 1987; Harman, 1995; Manktelow, 2004; Over, 2004).

The simplest definition of *instrumental rationality* is as follows: behaving in the world so that you get exactly what you most want, given the resources (physical and mental) available to you. Somewhat more technically, we could characterize instrumental rationality as the optimization of the individual's goal fulfillment. Economists and cognitive scientists have refined the notion of optimization of goal fulfillment into the technical notion of expected utility. The model of rational judgment used by decision scientists (Chater & Oaksford, Chapter 2; LeBoeuf & Shafir, Chapter 16) is one in which a person chooses options based on which option has the largest expected utility² (see Baron, 2008; Dawes, 1998; Hastie & Dawes, 2010; Wu, Zhang, & Gonzalez, 2004). One of the fundamental advances in the history of modern decision science was the demonstration that if people's preferences follow certain patterns (the so-called axioms of choice—things like transitivity and freedom from certain kinds of context effects), then they are behaving as if they are maximizing utility; they are acting to get what they most want (Edwards, 1954; Gilboa, 2010; Jeffrey, 1983; Luce & Raiffa, 1957; Savage, 1954; von Neumann & Morgenstern, 1944). This is what makes people's degrees of rationality measurable by the experimental methods of cognitive science. Although it is difficult to assess utility directly, it is much easier to assess whether one of the axioms of rational choice is being violated. This is much like our judgments at a sporting event, where, for example, it might be difficult to discern whether a quarterback has put the ball perfectly on the money, but it is not difficult at all to detect a bad throw.

In fact, in many domains of life this is often the case as well. It is often difficult to specify what the very *best* response might be, but performance *errors* are much easier to spot. Essayist Neil Postman (1988) has argued, for instance, that educators and other advocates of good thinking might adopt a stance more similar to that of physicians or attorneys. He points out that doctors would find it hard to define "perfect health" but, despite this, they are quite good at spotting disease. Likewise, lawyers are much better at spotting injustice and lack of citizenship than defining "perfect justice" or ideal citizenship. Postman argues that, like physicians and attorneys, educators might best focus on instances of poor thinking which are much easier to identify as opposed to trying to define ideal thinking. The

literature on the psychology of rationality has followed this logic in that the empirical literature has focused on identifying thinking errors, just as physicians focus on disease. Degrees of rationality can be assessed in terms of the number and severity of such cognitive biases that individuals display. Conversely, *failure* to display a cognitive bias becomes a measure of rational thought.

The Great Rationality Debate in Cognitive Science

A substantial research literature—one comprising literally hundreds of empirical studies conducted over several decades—has firmly established that people's responses sometimes deviate from the performance considered normative on many reasoning tasks. For example, people assess probabilities incorrectly, they test hypotheses inefficiently, they violate the axioms of utility theory, they do not properly calibrate degrees of belief, their choices are affected by irrelevant context, they ignore the alternative hypothesis when evaluating data, and they display numerous other information processing biases (Baron, 2008; Bazerman & Moore, 2008; Evans, 2007; Gilovich, Griffin, & Kahneman, 2002; Kahneman & Tversky, 2000; Shafir & LeBoeuf, 2002; Stanovich, 2009b, 2011). Demonstrating that descriptive accounts of human behavior diverged from normative models was a main theme of the heuristics and biases research program inaugurated by Kahneman and Tversky in the early 1970s (Kahneman & Tversky, 1972, 1973; Tversky & Kahneman, 1974).

Researchers working in the heuristics and biases tradition tend to be so-called Meliorists (see Bishop & Trout, 2005; Doherty, 2003; Larrick, 2004; Stanovich, 1999, 2004). They assume that human reasoning is not as good as it could be, and that thinking could be improved. The dictionary definition of *meliorism* is "the doctrine that the world tends to become better or may be made better by human effort." Thus, a Meliorist is one who feels that education and the provision of information could help make people more rational—could help them more efficiently further their goals and to bring their beliefs more in line with the actual state of the world.³ Stated this way, Meliorism seems to be an optimistic doctrine, and in one sense it is. But this optimistic part of the Meliorist message derives from the fact that Meliorists see a large gap between normative models of rational responding and descriptive models of what people actually do. Emphasizing the gap, of course, entails that

Meliorists will be attributing a good deal of irrationality to human cognition.

Over the last two decades, an alternative interpretation of the findings from the heuristics and biases research program has been championed. Contributing to this alternative interpretation have been evolutionary psychologists, adaptationist modelers, and ecological theorists (Anderson, 1990; Cosmides & Tooby, 1996; Gigerenzer, 2007; Marewski, Gaissmaier, & Gigerenzer, 2010; Oaksford & Chater, 2007). They have reinterpreted the modal response in most of the classic heuristics and biases experiments as indicating an optimal information processing adaptation on the part of the subjects. It is argued by these investigators that the research in the heuristics and biases tradition has not demonstrated human irrationality at all. This group of theorists—who argue that an assumption of maximal human rationality is the proper default position to take—have been termed the Panglossians (Stanovich, 1999). This position posits no difference between descriptive and normative models of performance because human performance is actually normative.

The contrasting positions of the Panglossians and Meliorists define the differing poles in what has been termed the Great Rationality Debate in cognitive science—the debate about how much irrationality to attribute to human cognition. This debate has generated a very substantial literature of often heated arguments (Cohen, 1981; Doherty, 2003; Edwards & von Winterfeldt, 1986; Evans & Over, 1996, 2010; Gigerenzer, 1996; Jungermann, 1986; Kahneman & Tversky, 1983, 1996; Koehler, 1996; Koehler & James, 2009, 2010; Krueger & Funder, 2004; Kuhberger, 2002; Lee, 2006; Samuels & Stich, 2004; Stanovich, 1999, 2004, 2010; Stanovich & West, 2000; Stein, 1996; Stich, 1990; Vranas, 2000). Tetlock and Mellers (2002) have noted that “the debate over human rationality is a high-stakes controversy that mixes primordial political and psychological prejudices in combustible combinations” (p. 97). The great debate about human rationality is a “high-stakes controversy” because it involves nothing less than the models of human nature that underlie economics, moral philosophy, and the personal theories (folk theories) we use to understand the behavior of other humans. For example, a very influential part of the Panglossian camp is represented by the mainstream of the discipline of economics, which is notable for using strong rationality assumptions as fundamental tools.

Evolution Does Not Guarantee Human Rationality

An Aristotelian view of rationality has no room for individual differences in rational thinking *between* humans. In this view, humans are the unique animals who act based on reason. Thus, all humans are rational—and all are equally so. However, once we move from this view to the normative conception of rationality, we open up room for individual differences. The maximizing notions of rational thought and action in decision science potentially array individuals on a continuum based on the distance of their behavior from the normative model.

We might ask, however, whether—aside from holding an Aristotelian view—there is any other reason to be a Panglossian. One assumption that often draws people to a Panglossian view of human rationality is the thought that evolution would have guaranteed that our cognition is fully rational. This is a mistaken view. There are a number of reasons why evolution would not be expected to guarantee perfect human rationality. One reason is that rationality is defined in terms of maximization (for example, in the case of instrumental rationality, maximizing the expected utility of actions). In contrast to maximization, natural selection works on a “better than” principle. As Dawkins puts it, “Natural selection chooses the better of present available alternatives.... The animal that results is not the most perfect design conceivable, nor is it merely good enough to scrape by. It is the product of a historical sequence of changes, each one of which represented, at best, the better of the alternatives that happened to be around at the time” (p. 46, 1982). In short, the variation and selective retention logic of evolution “designs” (Dennett, 1995) for the reproductive advantage of one organism over the next, not for the optimality of any one characteristic (including rationality). It has been said that evolution should be described as the survival of the *fitter* rather than as the survival of the fittest.

Evolution proceeds to increase the reproductive fitness of genes, not to increase the rationality of humans (Stanovich, 2004; Stanovich & West, 2003). Increases in fitness do not always entail increases in rationality. Take, for example, the domain of beliefs. Beliefs need not always track the world with maximum accuracy in order for fitness to increase (Stich, 1990). Thus, evolution does not guarantee perfect epistemic rationality. For example, evolution might fail to select out epistemic mechanisms of high accuracy when they are costly

in terms of organismic resources (for example, in terms of memory, energy, or attention). An additional reason that belief-forming mechanisms might not be maximally truth preserving is that:

a very cautious, risk-aversive inferential strategy—one that leaps to the conclusion that danger is present on very slight evidence—will typically lead to false beliefs more often, and true ones less often, than a less hair-trigger one that waits for more evidence before rendering a judgment. Nonetheless, the unreliable, error-prone, risk-aversive strategy may well be favored by natural selection. For natural selection does not care about truth; it cares only about reproductive success. (p. 62, Stich, 1990)

It is likewise in the domain of goals and desires. As has become clear from recent research on the topic of affective forecasting, people are remarkably bad at making choices that make themselves happy (Gilbert, 2006; Kahneman et al., 2006; Wilson & Gilbert, 2005). This should be no surprise. The reason we have pleasure circuits in our brains is to encourage us to do things (survive and reproduce, help kin) that propagate our genes. The pleasure centers were not designed to maximize the amount of time we are happy.

The instrumental rationality of humans is not guaranteed by evolution for two further reasons. First, many genetic goals that have been lodged in our brain no longer serve our ends because the environment has changed (Richerson & Boyd, 2005). For example, thousands of years ago, humans needed as much fat as they could get in order to survive. More fat meant longer survival and because few humans survived beyond their reproductive years, longevity translated directly into more opportunities for gene replication. In short, our mechanisms for storing and utilizing energy evolved in times when fat preservation was efficacious. These mechanisms no longer serve the goals of people in our modern technological society where there is a McDonald's on practically every corner—the goals underlying these mechanisms have become detached from their evolutionary context.

Finally, rational standards for assessing human behavior are social and cultural products that are preserved and stored independently of the genes. The development of probability theory, concepts of empiricism, logic, and scientific thinking throughout the centuries have provided humans with conceptual tools to aid in the formation and revision of belief and in their reasoning about action (Chater & Oaksford, Chapter 2; Griffiths et al.,

Chapter 3; Dunbar & Klahr, Chapter 35). They represent the cultural achievements that foster greater human rationality (Thagard & Nisbett, 1983). As societies evolve, they produce more of the cultural tools of rationality and these tools become more widespread in the population. Thus, the cultural evolution of rational standards (Thagard & Nisbett, 1983) is apt to occur at a pace markedly faster than that of human evolution—providing ample opportunity for mental strategies of utility maximization to dissociate from local genetic fitness maximization. In summary, a consideration of our evolutionary history should not lead one to a Panglossian view of human rationality.

A reconciliation of the views of the Panglossians and Meliorists is possible, however, if we take three scientific steps. First, we must consider data patterns long ignored in the heuristics and biases literature—individual differences on rational thinking tasks. Second, we must understand the empirical patterns obtained through the lens of a modified dual-process theory (Evans, Chapter 8) and of evolutionary theory. Thirdly, we must distinguish the concepts of rationality and intelligence in cognitive theory. Subsequent sections of this chapter develop each of these points.

Individual Differences in the Great Rationality Debate

Dozens of empirical studies have shown that there are few tasks in the heuristics and biases literature where all untutored laypersons give the same response. What has largely been ignored is that—although the average person in the classic heuristics and biases experiments might well display an overconfidence effect, underutilize base rates, ignore P(D/-H), violate the axioms of utility theory, choose P and Q in the selection task, commit the conjunction fallacy, and so on—on each of these tasks, *some people give the standard normative response* (Bruine de Bruin, Parker, & Fischhoff, 2007; Cokely & Kelley, 2009; Del Missier, Mantyla, & Bruine de Bruin, 2010; Dohmen et al., 2009; Finucane & Gullion, 2010; Frederick, 2005; Klaczynski, 2001; Oechssler, Roider, & Schmitz, 2009; Stanovich & West, 1998b, 1998c, 1999, 2000, 2008b; West et al., 2008). What has been ignored in the Great Rationality Debate is individual differences. For example, in knowledge calibration studies, although the mean performance level of the entire sample may be represented by a calibration curve that indicates overconfidence, almost always some

people do display near perfect calibration. Likewise, in probabilistic assessment, while the majority of subjects might well ignore the noncausal base-rate evidence, a minority of subjects often makes use of this information in exactly the way prescribed by Bayes' theorem. A few people even respond correctly on the notoriously difficult abstract selection task (Evans, Newstead, & Byrne, 1993; Stanovich & West, 1998a, 2008b).

In short, some people give the response traditionally considered normative, and others do not. There is variability in responding on all of these tasks. So when Panglossians and heuristics and biases researchers argue about the normative appropriateness of a particular response, whoever eventually prevails in the dispute—both sides have been guilty of glossing over individual differences. In short, it is incorrect to imply that people uniformly display a particular rational or irrational response pattern. A particular experiment might instead be said to show that the average person, or perhaps the modal person, displays optimal or suboptimal thinking. Other people, often a minority to be sure, display the opposite style of thinking.

In light of these empirical data, it is puzzling that Panglossians would presumably accept the existence of individual differences in intelligence but not rationality. This is possible, however, if intelligence and rationality are two different things conceptually. In the remainder of this chapter, I will show that the Panglossians are correct in one of their assumptions but incorrect in another. Conceptually, intelligence and rational thinking are indeed two different things. But—contra Panglossian assumptions—the latter as well as the former displays substantial individual differences.

Discussions of intelligence often go off the rails at the very beginning by failing to set the concept within a general context of cognitive functioning—thus inviting the default assumption that intelligence is the central feature of the mind. I will try to preclude this natural default by outlining a model of the mind and then placing intelligence within it. The generic models of the mind developed by cognitive scientists often give short shrift to a question that the public is intensely interested in: How and why do people *differ* from each other in their thinking? In an attempt to answer that question, I am going to present a gross model of the mind that is true to modern cognitive science but that emphasizes individual differences in ways that are somewhat new. The model builds on a current consensus

view of cognition termed dual-process theory (see Evans, Chapter 8, for a more detailed discussion).

From Dual-Process Theory to a Tripartite Model of Mind

The idea that the brain is composed of many different subsystems (see Aunger & Curtis, 2008) has recurred in conceptualizations in many different disciplines—from the society of minds view in artificial intelligence (Minsky, 1985); to Freudian analogies (Ainslie, 1982); to discussions of the concept of multiple selves in philosophy, economics, and decision science (Ainslie, 2001; Schelling, 1984). In fact, the notion of many different systems in the brain is by no means new. Plato (1945) argued that “we may call that part of the soul whereby it reflects, rational; and the other, with which it feels hunger and thirst and is distracted by sexual passion and all the other desires, we will call irrational appetite, associated with pleasure in the replenishment of certain wants” (p. 137).

What is new, however, is that cognitive scientists are beginning to understand the biology and cognitive structure of these systems (Evans & Frankish, 2009; see Morrison & Knowlton, Chapter 6; Green & Dunbar, Chapter 7) and are beginning to posit some testable speculations about their evolutionary and experiential origins. I will build on the current consensus that the functioning of the brain can be characterized by two different types of cognition having somewhat different functions and different strengths and weaknesses. There is a wide variety of evidence that has converged on the conclusion that some type of dual-process notion is needed in a diverse set of specialty areas not limited to cognitive psychology, social psychology, naturalistic philosophy, decision theory, and clinical psychology (Evans, 2003, 2008, 2010; Frankish, 2004; Lieberman, 2007, 2009; Schneider & Chein, 2003; Sloman, 1996, 2002; Smith & Decoster, 2000; Stanovich, 1999). Evolutionary theorizing and neurophysiological work also have supported a dual-process conception (Camerer, Loewenstein, & Prelec, 2005; Frank, Cohen, & Sanfey, 2009; Lieberman, 2009; McClure, Laibson, Loewenstein, & Cohen, 2004; Prado & Noveck, 2007; Reber, 1993; Toates, 2005, 2006). In fact, a dual-process view was implicit within the early writings in the groundbreaking heuristics and biases research program. As Kahneman (2000) notes, “Tversky and I always thought of the heuristics and biases approach as a two-process theory” (p. 682).

Just how ubiquitous are dual-process models in psychology and related fields is illustrated in

Table 22.1, which lists a variety of such theories that have appeared during the last couple of decades. Some common terms for the dual processes are listed in Table 22.1. My purpose here is not to adjudicate the differences among these models. Instead, I will gloss over differences and instead start with

a model that emphasizes the family resemblances. Evans (Chapter 8) provides a much more nuanced discussion.

The family resemblances extend to the names for the two classes of process. The terms *heuristic* and *analytic* are two of the oldest and most popular (see

Table 22.1 Some Alternative Terms for Type 1 and Type 2 Processing Used by Various Theorists

Theorist	Type 1	Type 2
Bargh & Chartrand (1999)	Automatic processing	Conscious processing
Bazerman, Tenbrunsel, & Wade-Benzoni, (1998)	Want self	Should self
Bickerton (1995)	Online thinking	Offline thinking
Brainerd & Reyna (2001)	Gist processing	Analytic processing
Chaiken et al. (1989)	Heuristic processing	Systematic processing
Evans (1984, 1989)	Heuristic processing	Analytic processing
Evans & Over (1996)	Tacit thought processes	Explicit thought processes
Evans & Wason (1976); Wason & Evans (1975)	Type 1 processes	Type 2 processes
Fodor (1983)	Modular processes	Central processes
Gawronski & Bodenhausen (2006)	Associative processes	Propositional processes
Haidt (2001)	Intuitive system	Reasoning system
Johnson-Laird (1983)	Implicit inferences	Explicit inferences
Kahneman & Frederick (2002, 2005)	Intuition	Reasoning
Lieberman (2003)	Reflexive system	Reflective system
Loewenstein (1996)	Visceral factors	Tastes
Metcalfe & Mischel (1999)	Hot system	Cool system
Norman & Shallice (1986)	Contention scheduling	Supervisory attentional system
Pollock (1991)	Quick and inflexible modules	Intellection
Posner & Snyder (1975)	Automatic activation	Conscious processing
Reber (1993)	Implicit cognition	Explicit learning
Shiffrin & Schneider (1977)	Automatic processing	Controlled processing
Sloman (1996)	Associative system	Rule-based system
Smith & DeCoster (2000)	Associative processing	Rule-based processing
Strack & Deutsch (2004)	Impulsive system	Reflective system
Thaler & Shefrin (1981)	Doer	Planner
Toates (2006)	Stimulus-bound	Higher order
Wilson (2002)	Adaptive unconscious	Conscious

Evans, 1984, 1989). However, to attenuate the proliferation of nearly identical theories, I suggested the more generic terms System 1 and System 2 in a previous book (Stanovich, 1999). Although these terms have become popular, there is an infelicitousness to the System 1/System 2 terminology. Such terminology seems to connote that the two processes in dual-process theory map explicitly to two distinct brain systems. This is a stronger assumption than most theorists wish to make. Additionally, both Evans (2008, 2009, 2010; Chapter 8, this volume) and Stanovich (2004, 2011) have discussed how terms such as *System 1* or *heuristic system* are really misnomers because they imply that what is being referred to is a singular system. In actuality, the term used should be plural because it refers to a *set* of systems in the brain that operate autonomously in response to their own triggering stimuli and are not under higher level cognitive control. I have suggested (Stanovich, 2004) the acronym TASS (standing for The Autonomous Set of Systems) to describe what is in actuality a heterogeneous set.

Using the acronym TASS was a step forward in clearing up some of the confusion surrounding autonomous processes. For similar reasons, Evans (2008, 2009, Chapter 8; see also Samuels, 2009) has suggested a terminology of Type 1 processing versus Type 2 processing. The Type 1/Type 2 terminology captures better than previous terminology that a dual-*process* theory is not necessarily a dual-*system* theory (see Evans, 2008, 2009, for an extensive discussion). For these reasons, I will rely most heavily on the Type 1/Type 2 terminology. An even earlier terminology due to Evans (1984, 1989)—heuristic versus analytic processing—will also be employed on occasions when it is felicitous.

The defining feature of Type 1 processing is its autonomy—the execution of Type 1 processes is mandatory when their triggering stimuli are encountered, and they are not dependent on input from high-level control systems. Autonomous processes have other correlated features—their execution is rapid, they do not put a heavy load on central processing capacity, they tend to operate in parallel without interfering with themselves or with Type 2 processing—but these other correlated features are not defining. Autonomous processes would include behavioral regulation by the emotions; the encapsulated modules for solving specific adaptive problems that have been posited by evolutionary psychologists; processes of implicit learning; and the automatic firing of overlearned associations. Type 1

processes conjoin the properties of automaticity, quasi-modularity, and heuristic processing as these constructs have been variously discussed in cognitive science (Barrett & Kurzban, 2006; Carruthers, 2006; Coltheart, 1999; Evans, 2008, 2009; Moors & De Houwer, 2006; Samuels, 2005, 2009; Shiffrin & Schneider, 1977; Sperber, 1994).

It is important to emphasize that Type 1 processing is not limited to modular subprocesses that meet all of the classic Fodorian (1983) criteria. Type 1 processing encompasses processes of unconscious implicit learning and conditioning. Also, many rules, stimulus discriminations, and decision-making principles that have been practiced to automaticity (e.g., Kahneman & Klein, 2009; Shiffrin & Schneider, 1977) are processed in a Type 1 manner. This learned information can sometimes be just as much a threat to rational behavior as are evolutionary modules that fire inappropriately in a modern environment. Rules learned to automaticity can be overgeneralized—they can autonomously trigger behavior when the situation is an exception to the class of events they are meant to cover (Arkes & Ayton, 1999; Hsee & Hastie, 2006).

Type 2 processing is nonautonomous. Type 2 processing contrasts with Type 1 processing on each of the correlated properties that define the latter. It is relatively slow and computationally expensive. Many Type 1 processes can operate at once in parallel, but Type 2 processing is largely serial. Type 2 processing is often language based, but it is not necessarily so. One of the most critical functions of Type 2 processing is to override Type 1 processing. This is sometimes necessary because autonomous processing has heuristic qualities. It is designed to get the response into the right ballpark when solving a problem or making a decision, but it is not designed for the type of fine-grained analysis called for in situations of unusual importance (financial decisions, fairness judgments, employment decisions, legal judgments, etc.). Heuristics depend on benign environments. In hostile environments, they can be costly (see Hilton, 2003; Over, 2000; Stanovich, 2004, 2009b). A benign environment means one that contains useful (that is, diagnostic) cues that can be exploited by various heuristics (for example, affect-triggering cues, vivid and salient stimulus components, convenient and accurate anchors). Additionally, for an environment to be classified as benign, it also must contain no other individuals who will adjust their behavior to exploit those relying only on heuristics. In contrast,

a hostile environment for heuristics is one in which there are few cues that are usable by heuristic processes or there are misleading cues (Kahneman & Klein, 2009). Another way that an environment can turn hostile for a heuristic processor is if other agents discern the simple cues that are being used and the other agents start to arrange the cues for their own advantage (for example, advertisements, or the deliberate design of supermarket floor space to maximize revenue).

All of the different kinds of Type 1 processing (processes of emotional regulation, Darwinian modules, associative and implicit learning processes) can produce responses that are irrational in a particular context if not overridden. For example, often humans act as cognitive misers (see Stanovich, 2009b) by engaging in attribute substitution (Kahneman & Frederick, 2002)—the substitution of an easy-to-evaluate characteristic for a harder one, even if the easier one is less accurate. For example, the cognitive miser will substitute the less effortful attributes of vividness or affect for the more effortful retrieval of relevant facts (Kahneman, 2003; Li & Chapman, 2009; Slovic & Peters, 2006; Wang, 2009). But when we are evaluating important risks—such as the risk of certain activities and environments for our children—we do not want to substitute vividness for careful thought about the situation. In such situations, we want to employ Type 2 override processing to block the attribute substitution of the cognitive miser.

To override Type 1 processing, Type 2 processing must display at least two related capabilities. One is the capability of interrupting Type 1 processing and suppressing its response tendencies. Type 2 processing thus involves inhibitory mechanisms of the type that have been the focus of work on executive functioning (Aron, 2008; Best, Miller, & Jones, 2009; Hasher, Lustig, & Zacks, 2007; Miyake et al., 2000; Zelazo, 2004). But the ability to suppress Type 1 processing gets the job only half done. Suppressing one response is not helpful unless there is a better response available to substitute for it. Where do these better responses come from? One answer is that they come from processes of hypothetical reasoning and cognitive simulation that are a unique aspect of Type 2 processing (Johnson-Laird, Chapter 9). When we reason hypothetically, we create temporary models of the world and test out actions (or alternative causes) in that simulated world. To reason hypothetically we must, however, have one critical cognitive capability—we must be

able to prevent our representations of the real world from becoming confused with representations of imaginary situations. The so-called cognitive decoupling operations are the central feature of Type 2 processing that make this possible, and they have implications for how we conceptualize both intelligence and rationality.

In a much-cited article, Leslie (1987) modeled pretense by positing a so-called secondary representation (see Perner, 1991) that was a copy of the primary representation but that was decoupled from the world so that it could be manipulated—that is, be a mechanism for simulation. The important issue for our purposes is that decoupling secondary representations from the world and then maintaining the decoupling while simulation is carried out is a Type 2 processing operation. It is computationally taxing and greatly restricts the ability to conduct any other Type 2 operation simultaneously. In fact, decoupling operations might well be a major contributor to a distinctive Type 2 property: its seriality.

Figure 22.1 represents a preliminary model of mind, based on what has been outlined thus far, with one important addition. The addition stems from the fact that instructions to initiate override of Type 1 processing (and to initiate simulation activities) must be controlled by cognitive machinery at a higher level than the decoupling machinery itself. Type 2 processing needs to be understood in terms of two levels of cognitive control—what are termed in Figure 22.1 the algorithmic level and the reflective level. There I have presented the tripartite proposal in the spirit of Dan Dennett's (1996) book *Kinds of Minds* where he used that title to suggest that within the brain of humans are control systems of very different types—different kinds of minds. I have labeled the traditional source of Type 1 processing as the autonomous mind but differentiated Type 2 processing into the algorithmic mind and the reflective mind. The autonomous mind can be overridden by algorithmic-level mechanisms; but override itself is initiated by higher level control. That is, the algorithmic level is conceptualized as subordinate to the higher level goal states and epistemic thinking dispositions of the reflective mind.

Individual Differences Within the Tripartite Model of Mind

Psychometricians have long distinguished typical performance situations from optimal (sometimes termed *maximal*) performance situations (see Ackerman, 1994, 1996; Ackerman & Heggestad,

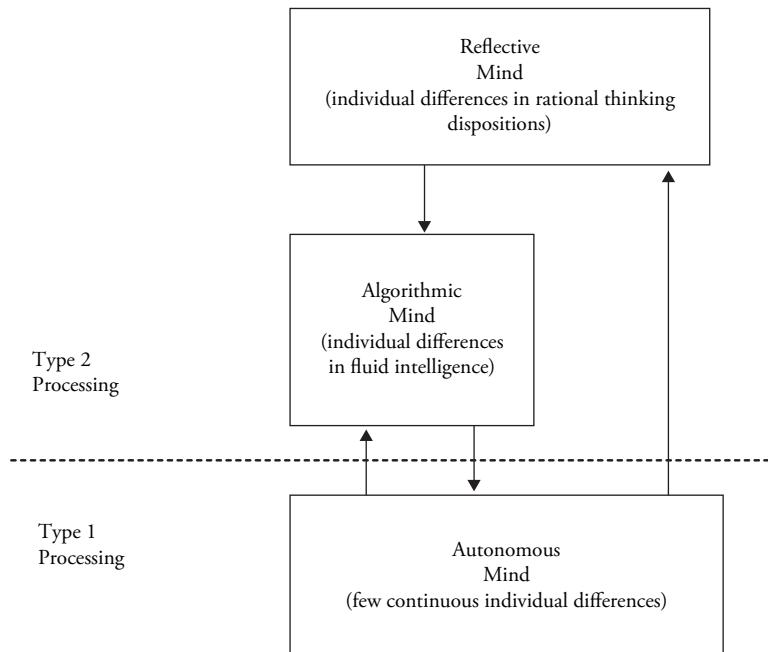

Fig. 22.1 The tripartite structure and the locus of individual differences.

1997; Ackerman & Kanfer, 2004; see also Cronbach, 1949; Matthews, Zeidner, & Roberts, 2002; Sternberg, Grigorenko, & Zhang, 2008). Typical performance situations are unconstrained in that no overt instructions to maximize performance are given, and the task interpretation is determined to some extent by the participant. The goals to be pursued in the task are left somewhat open. The issue is what a person would typically do in such a situation, given few constraints. Typical performance measures are measures of the reflective mind—they assess in part goal prioritization and epistemic regulation. In contrast, optimal performance situations are those where the task interpretation is determined externally. The person performing the task is instructed to maximize performance. Thus, optimal performance measures examine questions of the efficiency of goal pursuit—they capture the processing efficiency of the algorithmic mind. All tests of intelligence or cognitive aptitude are optimal performance assessments, whereas measures of critical or rational thinking are often assessed under typical performance conditions.

The difference between the algorithmic mind and the reflective mind is captured in another well-established distinction in the measurement of individual differences: the distinction between cognitive ability and thinking dispositions. The former are,

as just mentioned, measures of the efficiency of the algorithmic mind. The latter travel under a variety of names in psychology—*thinking dispositions* or *cognitive styles* being the two most popular. Many thinking dispositions concern beliefs, belief structure and, importantly, attitudes toward forming and changing beliefs. Other thinking dispositions that have been identified concern a person's goals and goal hierarchy. Examples of some thinking dispositions that have been investigated by psychologists are actively open-minded thinking, need for cognition (the tendency to think a lot), consideration of future consequences, need for closure, superstitious thinking, and dogmatism (Cacioppo et al., 1996; Kruglanski & Webster, 1996; Norris & Ennis, 1989; Schommer-Aikins, 2004; Stanovich, 1999, 2009b; Sternberg, 2003; Sternberg & Grigorenko, 1997; Strathman et al., 1994).

The types of cognitive propensities that these thinking disposition measures reflect are the tendency to collect information before making up one's mind, the tendency to seek various points of view before coming to a conclusion, the disposition to think extensively about a problem before responding, the tendency to calibrate the degree of strength of one's opinion to the degree of evidence available, the tendency to think about future consequences before taking action, the tendency to explicitly weigh pluses

and minuses of situations before making a decision, and the tendency to seek nuance and avoid absolutism. In short, individual differences in thinking dispositions are assessing variation in people's goal management, epistemic values, and epistemic self-regulation—differences in the operation of reflective mind. They are psychological characteristics that underpin rational thought and action.

The cognitive abilities assessed on intelligence tests are not of this type. They are not about high-level personal goals and their regulation, or about the tendency to change beliefs in the face of contrary evidence, or about how knowledge acquisition is internally regulated when not externally directed. People have indeed come up with *definitions* of intelligence that encompass such things. Theorists often define intelligence in ways that encompass rational action and belief but, nevertheless, *the actual measures of intelligence in use assess only algorithmic-level cognitive capacity*. No current intelligence test that is even moderately used in practice assesses rational thought or behavior (Stanovich, 2002, 2009b).

Figure 22.1 represents the classification of individual differences in the tripartite view. The broken horizontal line represents the location of the key distinction in older, dual-process views. Whereas the reflective and algorithmic minds are characterized by continuous individual differences and substantial variability, there are fewer continuous individual differences in the autonomous mind and less variability (see Kaufman et al., 2010, for a different view). Disruptions to the autonomous mind often reflect damage to cognitive modules that result in very discontinuous cognitive dysfunction such as autism or the agnosias and alexias (Anderson, 2005; Bermudez, 2001; Murphy & Stich, 2000).

Figure 22.1 identifies variation in fluid intelligence (Gf) with individual differences in the efficiency of processing of the algorithmic mind. Fluid intelligence is one component in the Cattell/Horn/Carroll (CHC) theory of intelligence (Carroll, 1993; Cattell, 1963, 1998; Horn & Cattell, 1967). Sometimes called the theory of fluid and crystallized intelligence (symbolized Gf/Gc theory), this theory posits that tests of mental ability tap, in addition to a general factor, a small number of broad factors, of which two are dominant (Geary, 2005; Horn & Noll, 1997; Taub & McGrew, 2004). Fluid intelligence (Gf) reflects reasoning abilities operating across a variety of domains—in particular, novel ones. It is measured by tasks of abstract reasoning

such as figural analogies, Raven matrices, and series completion. Crystallized intelligence (Gc) reflects declarative knowledge acquired from acculturated learning experiences. It is measured by vocabulary tasks, verbal comprehension, and general knowledge measures. Ackerman (1996) discusses how the two dominant factors in the CHC theory reflect a long history of considering two aspects of intelligence: intelligence-as-process (Gf) and intelligence-as-knowledge (Gc).

I have argued that individual differences in fluid intelligence are a key indicator of the variability across individuals in the ability to sustain decoupling operations (Stanovich, 2001, 2009b). Increasingly it is becoming apparent that one of the critical mental operations being tapped by measures of fluid intelligence is the cognitive decoupling operation I have discussed in this chapter. This is becoming clear from converging work on executive function and working memory. Most measures of executive function and working memory are direct or indirect indicators of a person's ability to sustain decoupling operations (Duncan et al., 2008; Engle, 2002; Gray, Chabris, & Braver, 2003; Hasher, Lustig, & Zacks, 2007; Kane, 2003; Lepine, Barrouillet, & Camos, 2005; Salthouse, Atkinson, & Berish, 2003; Salthouse & Pink, 2008; Stanovich, 2011).

Figure 22.1 highlights an important sense in which rationality is a more encompassing construct than intelligence. As previously discussed, to be rational, a person must have well-calibrated beliefs and must act appropriately on those beliefs to achieve goals—both properties of the reflective mind. The person must, of course, have the algorithmic-level machinery that enables him or her to carry out the actions and to process the environment in a way that enables the correct beliefs to be fixed and the correct actions to be taken. Thus, individual differences in rational thought and action can arise because of individual differences in fluid intelligence (the algorithmic mind) or because of individual differences in thinking dispositions (the reflective mind).

The conceptualization in Figure 22.1 has several advantages. First, it conceptualizes intelligence in terms of what intelligence tests actually measure. IQ tests do not attempt to measure directly an aspect of epistemic or instrumental rationality, nor do they examine any thinking dispositions that relate to rationality. It is also clear from Figure 22.1 why rationality and intelligence can become dissociated. Rational thinking depends on thinking dispositions

as well as algorithmic efficiency. Thus, as long as variation in thinking dispositions is not perfectly correlated with fluid intelligence, there is the statistical possibility of dissociations between rationality and intelligence.

In fact, substantial empirical evidence indicates that individual differences in thinking dispositions and intelligence are far from perfectly correlated. Many different studies involving thousands of subjects (e.g., Ackerman & Heggestad, 1997; Austin & Deary, 2002; Baron, 1982; Bates & Shieles, 2003; Cacioppo et al., 1996; Eysenck, 1994; Goff & Ackerman, 1992; Kanazawa, 2004; Kokis et al., 2002; Zeidner & Matthews, 2000) have indicated that measures of intelligence display only moderate to weak correlations (usually less than .30) with some thinking dispositions (e.g., actively open-minded thinking, need for cognition) and near-zero correlations with others (e.g., conscientiousness, curiosity, diligence). Other important evidence supports the conceptual distinction made here between algorithmic cognitive capacity and thinking dispositions. For example, across a variety of tasks from the heuristics and biases literature, it has consistently been found that rational thinking dispositions will predict variance after the effects of general intelligence have been controlled.⁴

The functions of the different levels of control are illustrated more completely in Figure 22.2. There, it is clear that the override capacity itself is a property of the algorithmic mind and it is indicated by the arrow labeled A. However, previous dual-process theories have tended to ignore the higher level cognitive function that initiates the override function in the first place. This is a dispositional property of the reflective mind that is related to rationality. In the model in Figure 22.2, it corresponds to arrow B, which represents (in machine intelligence terms) the call to the algorithmic mind to override the Type 1 response by taking it offline. This is a different mental function than the override function itself (arrow A), and there, the evidence cited earlier indicates that the two functions are indexed by different types of individual differences.

Figure 22.2 represents another aspect of cognition somewhat neglected by previous dual-process theories. Specifically, the override function has loomed large in dual-process theory but less so the simulation process that computes the alternative response that makes the override worthwhile. Figure 22.2 explicitly represents the simulation function as well as the fact that the call to initiate simulation originates in the reflective mind. The decoupling

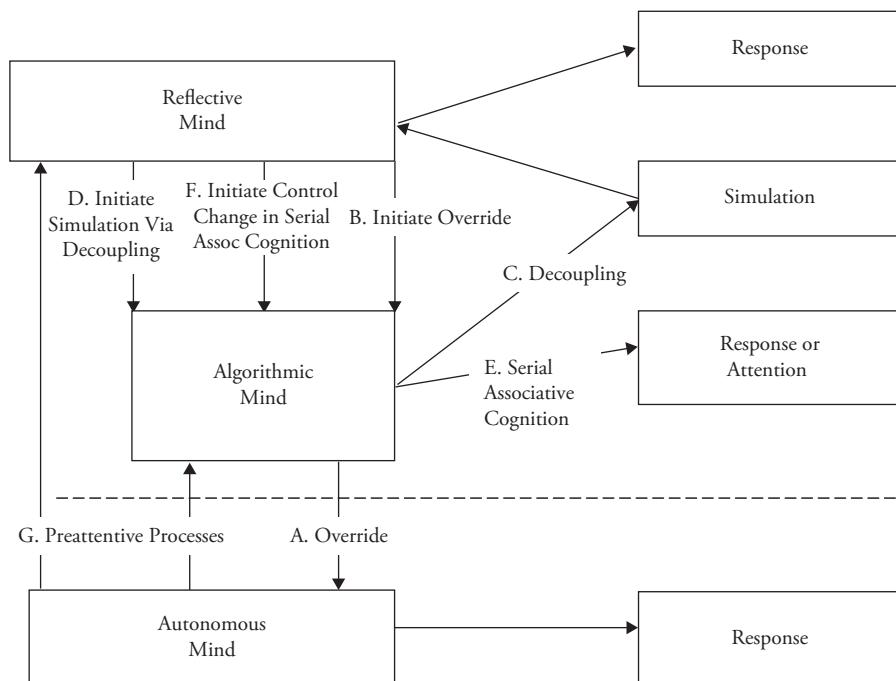

Fig. 22.2 A more complete model of the tripartite structure.

operation (indicated by arrow C) itself is carried out by the algorithmic mind and the call to initiate simulation (indicated by arrow D) by the reflective mind. Again, two different types of individual differences are associated with the initiation call and the decoupling operator—specifically, rational thinking dispositions with the former and fluid intelligence with the latter. Also represented is the fact that the higher levels of control receive inputs from the computations of the autonomous mind (arrow G) via so-called preattentive processes (Evans, 2006, 2007, 2008, 2009). The arrows labeled E and F reflect the decoupling and higher level control of a kind of Type 2 processing (serial associative cognition) that does not involve fully explicit cognitive simulation (see Stanovich, 2011).

Mindware in the Tripartite Model

Knowledge bases, both innate and derived from experience, also importantly bear on rationality. The term *mindware* was coined by Perkins (1995) to refer to the rules, knowledge, procedures, and strategies that a person can retrieve from memory in order to aid decision making and problem solving. Each of the levels in the tripartite model of mind has to access knowledge to carry out its operations,

as illustrated in Figure 22.3. As the Figure indicates, the reflective mind not only accesses general knowledge structures (G_c) but, importantly, accesses the person's opinions, beliefs, and reflectively acquired goal structure. The algorithmic mind accesses microstrategies for cognitive operations and production system rules for sequencing behaviors and thoughts. Finally, the autonomous mind accesses not only knowledge bases that are evolutionary adaptations, but it also retrieves information that has become tightly compiled and available to the autonomous mind due to overlearning and practice.

It is important to note that what is displayed in Figure 22.3 are the knowledge bases that are *unique* to each mind. Algorithmic- and reflective-level processes also receive inputs from the computations of the autonomous mind (see arrow G in Figure 22.2). The mindware available for retrieval, particularly that available to the reflective mind, is in part the product of past learning experiences. The knowledge structures available for retrieval by the reflective mind represent G_c , crystallized intelligence. Recall that G_f , fluid intelligence (intelligence-as-process), is already represented in the Figure 22.2. It is the general computational power of the algorithmic

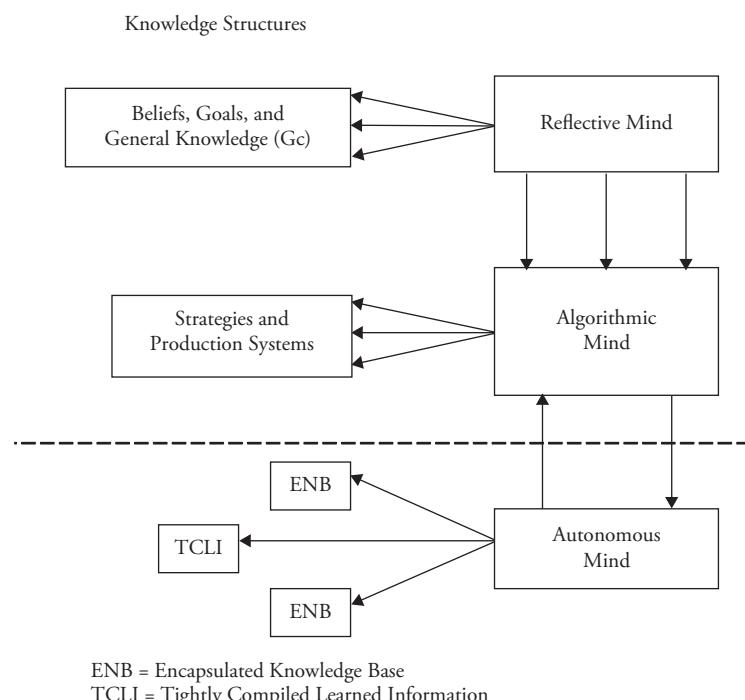

Fig. 22.3 Knowledge structures in the tripartite framework.

mind—importantly exemplified by the ability to sustain cognitive decoupling.

It is important to see how both of the major components of Gf/Gc theory miss critical aspects of rational thought. Fluid intelligence will, of course, have some relation to rationality because it indexes the computational power of the algorithmic mind to sustain decoupling. Because override and simulation are important operations for rational thought, Gf will definitely facilitate rational action in some situations. Nevertheless, the tendency to initiate override (arrow B in Fig. 22.2) and to initiate simulation activities (arrow D in Fig. 22.2) are both aspects of the reflective mind unassessed by intelligence tests, so the tests will miss these components of rationality.

The situation with respect to Gc is a little different. It is true that much of the mindware of rational thought would be classified as crystallized intelligence in the abstract. But is it the kind of crystallized knowledge that is specifically assessed on the tests? The answer is no. The mindware of rational thought is somewhat specialized mindware (see Stanovich, 2009b). It clusters in the domains of probabilistic reasoning (see Griffiths et al., Chapter 3), causal reasoning (see Cheng & Buehner, Chapter 12), and scientific reasoning (see Dunbar & Klahr, Chapter 35). In contrast, the crystallized knowledge assessed on IQ tests is deliberately designed to be nonspecialized. The designers of the tests, in order to make sure the sampling of Gc is fair and unbiased, explicitly attempt to *broadly* sample vocabulary, verbal comprehension domains, and general knowledge. The broad sampling ensures unbiasedness in the test, but it inevitably means that the specific knowledge bases critical to rationality will go unassessed. In short, Gc, as traditionally measured, does not assess individual differences in rationality, and Gf will do so only indirectly and to a mild extent. In short, as measures of rational thinking, IQ tests are radically incomplete.

The Requirements of Rational Thinking and Their Relation to Intelligence

Within the tripartite framework, rationality requires mental characteristics of three different types. Problems in rational thinking arise when cognitive capacity is insufficient to sustain autonomous system override, when the necessity of override is not recognized, or when simulation processes do not have access to the mindware necessary for the synthesis of a better response. The source of these

problems, and their relation to intelligence, help to explain one data trend that has been uncovered—that some rational thinking problems show surprising degrees of dissociation from cognitive ability (Stanovich, 2009b, 2011; Stanovich & West, 2007, 2008a, 2008b; West, Toplak, & Stanovich, 2008). Myside bias, for example, is virtually independent of intelligence (Macpherson & Stanovich, 2007; Sá, Kelley, Ho, & Stanovich, 2005; Stanovich & West, 2007, 2008a, 2008b; Toplak & Stanovich, 2003). Individuals with higher IQs in a university sample are no less likely to process information from an egocentric perspective than are individuals with relatively lower IQs.

Irrational behavior can occur because the right mindware (cognitive rules, strategies, knowledge, and belief systems) is not available to use in decision making. We would expect to see a correlation with intelligence here because mindware gaps most often arise from lack of education or experience. Nevertheless, while it is true that more intelligent individuals learn more things than less intelligent individuals, much knowledge (and many thinking dispositions) relevant to rationality are picked up rather late in life. Explicit teaching of this mindware is not uniform in the school curriculum at any level. That such principles are taught very inconsistently means that some intelligent people may fail to learn these important aspects of critical thinking. In university samples, correlations with cognitive ability have been found to be roughly (in absolute magnitude) in the range of .20–.35 for probabilistic reasoning tasks and scientific reasoning tasks measuring a variety of rational principles (Bruine de Bruin, Parker, & Fischhoff, 2007; Kokis et al., 2002; Parker & Fischhoff, 2005; Sá, West, & Stanovich, 1999; Stanovich & West, 1998b, 1998c, 1998d, 1999, 2000, 2008b; Toplak & Stanovich, 2002). This is again a magnitude of correlation that allows for substantial discrepancies between intelligence and rationality. Intelligence is thus no inoculation against many of the sources of irrational thought. None of these sources are directly assessed on intelligence tests, and the processes that *are* tapped by IQ tests are not highly overlapping with the processes and knowledge that explain variation in rational thinking ability.

Conclusions and Future Directions

The many studies of individual differences on heuristics and biases tasks falsify the most explicit versions of the Panglossian view. People are not all

identically rational. There are individual differences on all of these tasks and the individual differences are not the result of random performance errors (see Stanovich, 1999; Stein, 1996). Instead, they are systematic. If there are such systematic individual differences, it means that at least some people, some of the time, are irrational. Extreme Panglossianism cannot be sustained. However, there is another position in the debate that, like Panglossianism, serves to minimize the attribution of irrationality. Termed the Apologist position (Stanovich, 1999), this view takes very seriously the idea that humans have computational limitations that keep them from being fully rational.

Like the Meliorist, the Apologist accepts the empirical reality and nonspuriousness of normative/descriptive gaps, but the Apologist is much more hesitant to term them instances of irrationality. This is because the Apologist takes the position that to characterize a suboptimal behavior as irrational, it must be the case that the normative model is computable by the individual. If there are computational limitations affecting task performance, then the normative model may not be prescriptive, at least for individuals of low algorithmic capacity. Prescriptive models are usually viewed as specifying how processes of belief formation and decision making should be carried out, given the limitations of the human cognitive apparatus and the situational constraints (e.g., time pressure) with which the decision maker must deal (Baron, 2008). From the Apologist's perspective, the descriptive model is quite close to the prescriptive model and the descriptive/normative gap is attributed to a computational limitation. Although the Apologist admits that performance is suboptimal from the standpoint of the normative model, it is not irrational because there is no prescriptive/descriptive gap.

However, as demonstrated in some of the data patterns I have described in this chapter, the Apologist stratagem will not work for all of the irrational tendencies that have been uncovered in the heuristics and biases literature. This is because many biases are not very strongly correlated with measures of intelligence (algorithmic capacity). Additionally, there is reliable variance in rational thinking found even after cognitive ability is controlled, and that reliable variance is associated with thinking dispositions in theoretically predictable ways. These thinking dispositions reflect control features of the reflective mind that can lead to responses that are more or less rational. They are one of the main sources of

the individual differences in rational thought that I have been exploring in this chapter. Such thinking dispositions vary systematically from individual to individual, and they are the source of what Meliorists consider the variance in the irrationalities in human cognition. Unlike the Panglossian (who assumes uniform rationality) or the Apologist (who minimizes such variability while not entirely denying it), the Meliorist is very accepting of the idea of variability in rational thought.

The Panglossian position in the Great Rationality Debate has obscured the existence of individual differences in rational thought and its underlying components. In particular, Panglossian philosophers have obscured the importance of the reflective mind. Philosophical treatments of rationality by Panglossians tend to have a common structure (see Cohen, 1981, for example). Such treatments tend to stress the importance of the competence/performance distinction and then proceed to allocate all of the truly important psychological mechanisms to the competence side of the dichotomy.

For example, Rescher (1988) argues that "to construe the data of these interesting experimental studies [of probabilistic reasoning] to mean that people are systematically programmed to fallacious processes of reasoning—rather than merely that they are inclined to a variety of (occasionally questionable) substantive suppositions—is a very questionable step.... While all (normal) people are to be credited with the capacity to reason, they frequently do not exercise it well" (p. 196). There are two parts to Rescher's (1988) point here: the "systematically programmed" part and the "inclination toward questionable suppositions" part (or, as Rips (1994, p. 394) puts it, whether incorrect reasoning is "systematically programmed or just a peccadillo"). Rescher's (1988) focus—like that of many who have dealt with the philosophical implications of the idea of human irrationality—is on the issue of how humans are "systematically programmed." "Inclinations toward questionable suppositions" are only of interest to those in the philosophical debates as mechanisms that allow one to drive a wedge between competence and performance—thus maintaining a theory of near-optimal human rational competence in the face of a host of responses that seemingly defy explanation in terms of standard normative models.

Analogously to Rescher, Cohen (1982) argues that there really are only two factors affecting performance on rational thinking tasks: "normatively

correct mechanisms on the one side, and adventitious causes of error on the other” (p. 252). Not surprisingly given such a conceptualization, the processes contributing to error (“adventitious causes”) are of little interest to Cohen (1981, 1982). In his view, human performance arises from an intrinsic human competence that is impeccably rational, but responses occasionally deviate from normative correctness due to inattention, memory lapses, lack of motivation, and other fluctuating but basically unimportant causes (in Cohen’s view). There is nothing in such a conception that would motivate any interest in patterns of errors or individual differences in such errors.

One of the goals of this chapter is to reverse the figure and ground in the rationality debate, which has tended to be dominated by the particular way that philosophers frame the competence/performance distinction. From a psychological standpoint, there may be important implications in precisely the aspects of performance that have been backgrounded in this controversy (“adventitious causes,” “peccadillos”). That is, whatever the outcome of the disputes about how humans are “systematically programmed,” variation in the “inclination toward questionable suppositions” is of psychological interest as a topic of study in its own right. The research discussed in this chapter provides at least tentative indications that the “inclination toward questionable suppositions” has some degree of domain generality and that it is predicted by thinking dispositions that concern the epistemic and pragmatic goals of the individual and that are part of the reflective mind.

Johnson-Laird and Byrne (1993; see Johnson-Laird, 2006) articulate a view of rational thought that parses the competence/performance distinction much differently from that of Cohen (1981, 1982, 1986). It is a view that highlights the importance of the reflective mind and leaves room for individual differences in important components of cognition. At the heart of the rational competence that Johnson-Laird and Byrne (1993) attribute to humans is not perfect rationality but instead just one meta-principle: People are programmed to accept inferences as valid provided that they have constructed no mental model of the premises that contradict the inference (see Johnson-Laird, Chapter 9). Inferences are categorized as false when a mental model is discovered that is contradictory. However, the search for contradictory models is “not governed by any systematic or comprehensive principles” (p. 178).

The key point in Johnson-Laird and Byrne’s (1993) account is that once an individual constructs a mental model from the premises, once the individual draws a new conclusion from the model, and once the individual begins the search for an alternative model of the premises that contradicts the conclusion, the individual “lacks any systematic method to make this search for counter-examples” (p. 205). Here is where Johnson-Laird and Byrne’s (1993) model could be modified to allow for the influence of thinking styles in ways that the impeccable competence view of Cohen (1981) does not. In this passage, Johnson-Laird and Byrne seem to be arguing that there are no systematic control features of the search process. But epistemically related thinking dispositions may in fact be reflecting just such control features.

Individual differences in the extensiveness of the search for contradictory models could arise from a variety of cognitive factors that, although they may not be completely systematic, may be far from “adventitious”—factors such as dispositions toward premature closure, cognitive confidence, reflectivity, dispositions toward confirmation bias, and ideational generativity. The decontextualizing requirement of many heuristics and biases tasks is a feature that is emphasized by many critics of that literature who, nevertheless, fail to see it as implying a research program for differential psychology. For example, I have argued that to contextualize a problem is such a ubiquitous reasoning style for human beings that it constitutes one of a very few so-called fundamental computational biases of information processing (Stanovich, 2003, 2004). Thus, it is not surprising that many people respond incorrectly when attempting a psychological task that is explicitly designed to require a decontextualized reasoning style (contrary-to-fact syllogisms, argument evaluation, etc.). But recall the empirically demonstrated variability on all of these tasks. The fact that some people *do* give the decontextualized response means that at least some people have available a larger repertoire of reasoning styles, allowing them to reason flexibly reason so as to override fundamental computational biases if the situation requires.

Another way of stressing the importance of individual differences in understanding the nature of rational thought is in terms of Dennett’s (1987) so-called intentional stance, which he marries to an assumption of idealized rationality. Dennett (1988) argues that we use the intentional stance for humans and dogs but not for lecterns because for the latter

“there is no predictive leverage gained by adopting the intentional stance” (p. 496). However, in several experiments discussed in this chapter, it has been shown that there is additional predictive leverage to be gained by relaxing the idealized rationality assumption of Dennett’s (1987, 1988) intentional stance and by positing measurable and systematic variation in intentional-level psychologies (that is, in the reflective mind). Knowledge about such individual differences in people’s intentional-level psychologies can be used to predict variance in the normative/descriptive gap displayed on many reasoning tasks. Consistent with the Meliorist conclusion that there can be individual differences in human rationality, the results show that there is variability in reasoning that cannot be accommodated within a model of perfect rational competence operating in the presence of performance errors and computational limitations.

Acknowledgments

This research was supported by grants from the Social Sciences and Humanities Research Council of Canada and the Canada Research Chairs program to Keith E. Stanovich. Laura Noveck and Keith Holyoak are thanked for their insightful comments on an earlier version of this chapter.

Notes

1. It should also be noted that in the view of rationality taken in this chapter, rationality is an intentional-level personal entity and not an algorithmic-level subpersonal one (Bermudez, 2001; Davies, 2000; Frankish, 2009; Stanovich, 1999, 2009a). A memory system in the human brain is not rational or irrational—it is merely efficient or inefficient (or of high or low capacity). Thus, subprocesses of the brain do not display rational or irrational properties per se, although they may contribute in one way or another to personal decisions or beliefs that could be characterized as such. Rationality concerns the actions of an entity in its environment that serve its goals. One of course could extrapolate the notion of environment to include the interior of the brain itself and then talk of a submodule that chose strategies rationally or not. This move creates two problems. First, what are the goals of this subpersonal entity—what are its interests that its rationality is trying to serve? This is unclear in the case of a subpersonal entity. Second, such a move regresses all the way down. We would need to talk of a neuron firing being either rational or irrational. As Oaksford and Chater (1998) put it, “the fact that a model is optimizing something does not mean that the model is a rational model. Optimality is not the same as rationality....Stomachs may be well or poorly adapted to their function (digestion), but they have no beliefs, desires or knowledge, and hence the question of their rationality does not arise” (pp. 4 and 5).

2. The principle of maximizing expected value says that the action that a rational person should choose is the one with the highest expected value. Expected value is calculated by taking the objective value of each outcome and multiplying it by the probability of that outcome and then summing those products over all of the possible outcomes. Symbolically, the formula is

as follows: Expected value = $\sum p_i v_i$; where p_i is the probability of each outcome and v_i is the value of each outcome. The symbol Σ is the summation sign, and simply means “add up all of the terms that follow.” The term *utility* refers to subjective value. Thus, the calculation of expected utility involves identical mathematics except that a subjective estimate of utility is substituted for the measure of objective value.

3. It is important to note that the Meliorist recognizes two different ways in which human decision-making performance might be improved. These might be termed *cognitive change* and *environmental change*. First, it might be possible to teach people better reasoning strategies and to have them learn rules of decision making that are helpful (see Stanovich, 2009b). These would represent instances of cognitive change. Additionally, however, research has shown that it is possible to change the environment so that natural human reasoning strategies will not lead to error (Gigerenzer, 2002; Milkman, Chugh, & Bazerman, 2009; Thaler & Sunstein, 2008). For example, choosing the right default values for a decision would be an example of an environmental change. In short, environmental alterations (as well as cognitive changes) can prevent rational thinking problems. Thus, in cases where teaching people the correct reasoning strategies might be difficult, it may well be easier to change the environment so that decision-making errors are less likely to occur.

4. Such empirical studies indicate that cognitive capacity and thinking dispositions measures are tapping separable variance. The converging evidence on the existence of this separable variance is growing (Bruine de Bruin, Parker, & Fischhoff, 2007; Finucane & Gullion, 2010; Klaczynski, Gordon, & Fauth, 1997; Klaczynski & Lavalée, 2005; Klaczynski & Robinson, 2000; Kokis et al., 2002; Macpherson & Stanovich, 2007; Newstead, Handley, Harley, Wright, & Farrelly, 2004; Parker & Fischhoff, 2005; Sá & Stanovich, 2001; Stanovich & West, 1997, 1998c, 2000; Toplak, Liu, Macpherson, Toneatto, & Stanovich, 2007; Toplak & Stanovich, 2002).

Cognition and the Creation of Ideas

Steven M. Smith and Thomas B. Ward

Abstract

The cognition that gives rise to creative thinking is not a singular process or operation; rather, it consists of many different cognitive structures and processes that can collaborate in a variety of ways to construct different types of creative products. Cognition that is often relevant to creativity includes remote association, conceptual combination, visualization, retrieving and mapping analogies, reasoning, insight problem solving, implicit and explicit cognition, abstraction, and mental models.

Key Words: creativity, cognition, insight, imagination, emergence

How do our minds produce creative ideas? Clearly, there can be no formulaic answer to this enormous question. Part of the problem is that a consensual definition of creativity is difficult to construct. There are many domains of creative endeavor, such as art, engineering, literature, business, or athletics, and creativity might systematically differ for different domains. Furthermore, even within a single domain there are usually many different ways that creative ideas come into being. Even a single individual can be creative in different ways at different times. To know how our minds produce creative ideas, we undoubtedly need to understand the many factors that affect creativity, and there are multiple approaches to understanding those factors. For example, motivational factors, emotional factors, individual differences, environmental factors, and historical factors can strongly influence creativity. One of those factors, clearly, must be cognition: Creativity is at least in part influenced or even determined by cognition. In this chapter we focus on the question of how cognition supports or gives rise to creative work—the *creative cognition* approach.

The creative cognition approach begins with the rather obvious assumption that cognitive processes

play a critical role when people get creative ideas. Creative ideas are ones that are novel and potentially of value. There are similarities among cases in which people have had historically influential ideas, or ideas that are consensually judged as creative. Research in creative cognition is based upon the premise that similar experiences can be evoked in laboratory experiments. Metrics of creativity that emerge from these studies measure aspects of creativity but generally not how creative the ultimate product is. Most who use this creative cognition approach endorse the notion that there is no singular cognitive process or mental operation that we could call *the creative process*. Rather, we manage our cognitive resources in various ways to try to produce ideas with novelty and potential value, and the way those cognitive resources are managed may differ for different domains, different individuals, and different situations. In the course of pursuing creative ideas, people often experience certain phenomena or use certain heuristics to make creative ideas more likely.

We also endorse the notion that the cognition involved in creative activities resembles the cognition

that operates in other areas of cognition that are not commonly considered creative. For example, false memories are created by the same processes that affect creative ideation, analogies are mapped in creative and noncreative cognition, we create language when we speak, and we create mental models of our environments. Novel and useful outcomes emerge in many domains of cognition. What is special about creative cognition is that the insights and ideas produced are usually unexpected (e.g., Metcalfe, 1986).

The less surprising the product, the less creative it seems to be; nonobviousness is a requirement of all U.S. patents (Smith, 2008). Furthermore, unexpected insights and ideas that have value prompt the experience of delight. Although it engages the same basic cognitive mechanisms involved in domains such as memory, concept formation, problem solving, decision making, and metacognition, creative cognition is not limited to generating planned or deliberately intended products. Truly creative cognition can bring into being unexpected products of delight.

Domains of Cognition Involved in Creative Thinking

There are multiple domains of cognition that are involved in creative thinking, essentially, the same that are involved in noncreative cognition. The most noteworthy of these domains include conceptualization, visualization, memory, problem solving, language, decision making, and several areas of implicit cognition.

Concepts and Categories: The Structures of Imagination

Ward's (1994) structured imagination theory centers on the notion that the ideas imagined by creating minds are based, at least in part, on the conceptual cognitive structures that must be used, extended, and combined during the course of creative cognition. Understanding the ways that concepts are flexibly constructed and tailored for different contexts, how they are combined, and what guides the way that people extend categories in order to recognize or generate new instances of those concepts is essential to this structured imagination view.

Humans acquire vast storehouses of knowledge as a result of their experiences in the world. Because of the centrality of this type of knowledge to what it means to be human, considerable research has been devoted to the nature and structure of our concepts and categories, how they are acquired, and how they guide our actions and thought (Barsalou,

1985; Murphy & Medin, 1985; Rosch, 1973, 1975; Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976; see Rips et al., Chapter 11). Rather than being randomly organized collections of separate pieces of information, concept representations are highly organized and, at least from a functional perspective, hierarchical (e.g., Bower, Clark, Winzenz, & Lesgold, 1969). Both of these properties have implications for understanding the role of cognition in creativity.

Before considering the structured and hierarchical aspects of concepts, it is worth noting that the formation of concepts is itself a kind of creative, or at the very least generative, activity. This is because experiences with entities in the world are discrete, and the structures that tie those experiences together must be generated by the learner. Consider the child who ultimately learns the category "dog" from experiences with the family pet, others seen from the window, in the park, in books, or other places. Each of the experiences occurs at a separate time point, and the "glue" holding them together must be generated by the child. At a more extreme level, even the conclusion that the family pet is really the same entity across multiple discrete exposures is a kind of construction, not given directly by the input. Although this type of construction of conceptual structures is much simpler than those typically thought of when considering creativity, views of creativity are broadening to include a wider range of phenomenon. For example, Kaufman and Beghetto (2009) introduced the *four C* model of creativity to deal with the perceived inadequacy of early suggestions regarding the split between small-c (everyday) and Big-C (eminent) creativity. The latter split does not really allow a distinction between, for example, the songwriting of an amateur amusing himself with simple creations and a professional making her living writing songs, both of which would be small-c creativity, in contrast to the lasting, Big-C works of acknowledged master composers, such as Mozart. Nor does the small-c versus Big-C split allow the type of personally constructed understandings that are developed by individuals as they attempt to make sense of their world to be thought of as creativity, because they may not result in observable products that a qualified audience would judge to be novel and useful. Yet those understandings are clearly an instance of generative thinking. To deal with the latter problem, Kaufman and Beghetto (2009, see also Beghetto & Kaufman, 2007) introduced mini-c creativity to capture the

notion that such personal understandings are a kind of creative construction. By extension, the conceptual structures people generate in service of organizing and understanding experiences can be thought of as instances of creativity, albeit at a very simple level. Thus, Kaufman's four Cs include mini-c (personal realizations), small-c (everyday insights), pro-c (advanced enough to be making a career of some creative domain), and Big-C (eminent contributions to chosen domain).

The fact that our conceptual knowledge is organized and structured into identifiable groupings also relates to another aspect of creativity, namely, the degree to which it is domain general versus domain specific (e.g., Finke et al., 1992). This issue is concerned with the question of whether creative capacity is better thought of as a general ability that could be applied to a wide range of domains or a more specialized ability that would facilitate performance in a single domain. Whether people possess a more general or more specific creativity capacity, the fact is that they create within domains that can be described at various levels of breadth, such as written communication, fiction writing, novel writing, romance novel writing, and so on. To the extent that people possess differing amounts of knowledge and differently structured knowledge about a given domain, a consideration of conceptual structure would seem to favor a domain-specific view of creativity. Certainly, as noted later, domain knowledge will influence the form of newly created ideas with a domain. Alternatively, since some of the basic processes by which concepts are retrieved, combined, and used might represent general cognitive tendencies, a focus on conceptual processing could be readily compatible with a more domain-general view of creativity.

Our organized knowledge structures allow us to function effectively in the world and communicate with others. At a most fundamental level they allow us to identify and correctly classify new entities rather than have to treat each newly encountered object as something novel to be learned about (see Rips et al., Chapter 11). We can readily classify a furry, four-legged, barking, tail-wagging creature with floppy ears dangling from the sides of its head as a dog even if we have never seen it or even another of its breed before because of the stored information we have acquired about previously encountered dogs. Although this capacity for rapid, efficient classification serves us well in most circumstances, it can also underlie our tendency to miss potentially

creative solutions to even the simplest of problems. One classic example of this is the two-string problem, in which would-be solvers must find a way to tie together two strings suspended from the ceiling that are too far apart to be grasped simultaneously (Maier, 1931). Even though a pair of pliers is present that could serve as a pendulum weight for swinging the distant string closer to the one the solver is grasping, most do not readily see that possibility, due at least in part to the efficient tendency to categorize them as pliers rather than as a heavy object. Glucksberg and Weisberg (1966) showed that this so-called functional fixedness effect was prevented somewhat if participants verbally labeled the critical incidental stimulus, adding evidence that categorization can powerfully impact fixation.

The hierarchical aspect of conceptual structure is also important in considering creativity from a cognitive perspective. To illustrate, the same entity could be thought of as a tabby, a cat, a feline, a mammal, a living thing, and so on. Classic research established that, rather than all levels being equally prominent, the basic level, intermediate between the most general and the most specific, tends to predominate in initial classification, labeling and reasoning about a given entity (Rosch, 1973; Rosch et al., 1976; Rosch, 1975). In the example given here, "cat" would be the basic level. The importance of this phenomenon for creativity is that, as described more fully in a later section, the basic level also plays a powerful role in the generation of new ideas within a domain (Rosch, 1973; Rosch et al., 1976; Rosch, 1975).

Our concepts also allow us to go beyond simple classification and to reason and draw inferences about known and novel category instances (Gelman, 1988; Heit, 2000; Osherson, Smith, Wilkie, López & Shafir, 1990; Rips, 1975). Conceptual knowledge includes considerably more information than just that which might be used to classify objects. It also includes known or assumed properties that we can generalize to new instances. Even without seeing the entity described in the previous paragraph, on being told that it is a dog, we would make certain inferences with varying degrees of certainty, including the likelihood that it possessed those identifying properties, as well as a number of others including that it might have a heart, lungs, or a stomach, be someone's pet, go for walks in the park with its owner, eat and drink from bowls, and be susceptible to fleas and heartworms. The extent to which each of those inferences is warranted could be debated, and

considerable research has been devoted to understanding the factors that influence the tendency of people to draw inferences (e.g., Heit, 2000). But such tendencies are also direct determinants of the novelty or unusualness of newly generated products. As noted earlier, people tend to create within domains, and they show a striking tendency to incorporate properties of known domain instances into the novel items they generate (e.g., Bredart, Ward, & Marczewski, 1998; Ward, 1994; Ward, Dodds, Saunders, & Sifonis, 2000; Ward, Patterson, Sifonis, Dodds, & Saunders, 2002) (see Fig. 23.1).

According to the path-of-least-resistance theory (Ward, 1994, 1995), when people develop new ideas, such as designing imaginary life forms, they tend to begin by retrieving highly representative exemplars of creatures, such as a dog, a fish, or a bird. Next, they project the properties of those specific instances onto the novel ideas they are developing. Taking this path of least resistance leads to less original ideas and thwarts more flexible uses of conceptual knowledge. Abstraction can help one avoid this reliance on representative instances, making one more likely to produce creative ideas (Ward & Sifonis, 1997).

Memory

The link between memory and creativity may seem counterintuitive, because memory seems designed to converge upon real events of the past, whereas creativity seems more divergent, dealing with imaginative possibilities. In fact, memory and creativity have much in common, even if the products of memory processes are often quite different from the products of creative cognition. Both creativity and memory involve both conscious and implicit processes, both are sensitive to recent and frequent experiences, both show blocking and recovery effects, and both involve constructive cognitive processes.

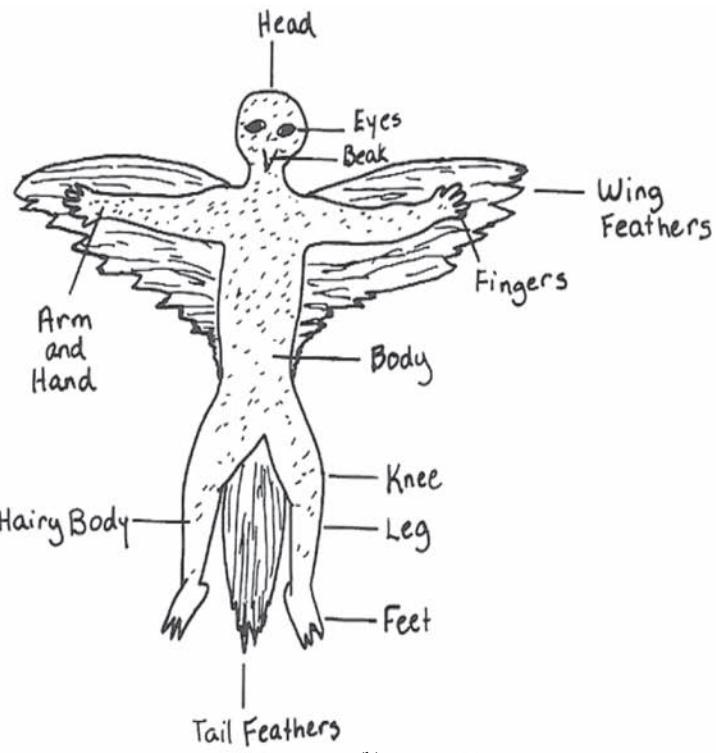

Implicit memory is a cognitive resource that supports conscious operations in many ways (see Evans, Chapter 8). For example, in automatization, a repetitious set of operations is offloaded from the explicit system to an automatic, implicit set of processes; this offloading frees up cognitive resources for other attention-demanding activities. Unfortunately, when implicit memory makes inappropriate material too accessible, it can block access to more appropriate information. Worse, this type of block happens without conscious awareness, so it is difficult for one to detect one's own implicit memory blocks. Smith

and Tindell (1997) showed that reading a word (e.g., ANALOGY) that is orthographically similar to the correct completion of a word fragment (e.g., A_L__GY) can cause an implicit memory block for the solution (ALLERGY) (see Fig. 23.2).

Participants who were warned that previously seen blocker words were incorrect solutions still remain susceptible to these implicit memory blocks. Similarly, in creative invention tasks, designers automatically incorporate features of previously seen examples, even when those features are problematic and explicitly forbidden in the instructions (Jansson & Smith, 1991; Landau & Lehr, 2004; Smith, Ward, & Schumacher, 1993). Only when the specific reasons that negative features are problematic are clearly explained to participants is this design fixation effect mitigated (Chrysikou & Weisberg, 2005). Thus, implicit memory of inappropriate material appears to block creative design (see Figs. 23.3 and 23.4).

Another area in which memory and creative cognition share a great deal of overlap involves recovery from blocks. Two mysterious phenomena, *reminiscence* (and the related phenomenon *hypermnesia*) in memory, and *incubation* effects in creative problem solving, have been linked to the same underlying cognitive mechanisms. Reminiscence refers to a phenomenon in which memories that are initially inaccessible are subsequently retrieved without re-exposure to the to-be-remembered material. Hypermnesia, a closely related phenomenon, is a net increase in recall from one recall attempt to the next (e.g., Erdelyi & Becker, 1974). These memory phenomena fly in the face of the long-established rule that memory gets *worse* as the retention interval increases, because time elapses from one test to the next. The mystery of incubation effects is that key ideas for difficult problems sometimes occur when one takes a break from the problem, rather than working on it uninterrupted (e.g., Smith & Blankenship, 1989, 1991). These key ideas are not predictable by the people who experience the moments of insight (e.g., Metcalfe & Weibe, 1987), and they may result from cognitive operations that operate outside of awareness (e.g., Schooler & Melcher, 1995).

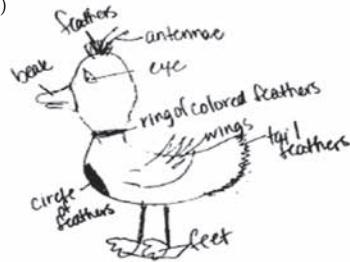

Although there are multiple explanations of reminiscence and of incubation effects, and these phenomena may be multiply caused, a single theory has been proposed to explain both. The *forgetting fixation* theory (e.g., Kohn & Smith, 2009; Smith & Blankenship, 1989, 1991) states that both reminiscence and incubation effects can be caused by recovery from initial blocks (i.e., fixation) when

Fig 23.2 Word fragments, their correct solutions, and blocker words used to show an implicit memory blocking effect (Smith & Tindell, 1997).

blocking responses are put out of mind. In the case of incubation effects, many puzzles or insight problems initially may promote ideas or ways of thinking that are ultimately found to be inappropriate solutions—blockers—for those problems. The forgetting fixation hypothesis states that getting blockers out of mind can benefit creative problem solving. The same hypothesis explains reminiscence by focusing on *output interference* that occurs on the initial recall test; as items are recalled from a memory set, their subsequent probability of being retrieved again is increased. This results in a biased retrieval set in which initially recalled (and strengthened) items block recall of other items in the same memory set. The forgetting fixation hypothesis explains reminiscence as a decrease (after a time lag) in the blocking effect exerted by initially retrieved items in the same memory set, thereby allowing initially blocked items to be retrieved (e.g., Smith, 1995a).

Empirical tests of the forgetting fixation hypothesis in reminiscence and incubation show clear support for the hypothesis. Reminiscence, defined as recalling on a second test items not recalled on an earlier test, can be explained by the incremental hypothesis as the result of continued retrieval efforts, and since more attempts will eventually find initially unrecalled items, those items might be recalled on a second test (Roediger & Thorpe, 1978). What if a second (unexpected) recall test is given after a delay during which participants are kept busy? The incremental hypothesis predicts that reminiscence should drop if the retest is delayed because initially unretrieved items are even harder to retrieve after a delay. The forgetting fixation hypothesis, however, predicts that a delay permits

weakening of initial output interference, resulting in greater reminiscence on a delayed test. Smith and Vela (1991) showed *incubated reminiscence* effects, consistent with the forgetting fixation prediction: More initially unretrieved items were recalled if a retest was delayed.

A similar pattern of results has been found in creative problem solving, using puzzle problems (Smith & Blankenship, 1989) and Remote Associates Test problems (Kohn & Smith, 2009; Smith & Blankenship, 1991; Vul & Pashler, 2007) (see Fig 23.5). To ensure that initial fixation occurs, some participants in these studies were exposed to misleading hints before their first attempt at solving these problems, so initial fixation was experimentally introduced, and its effect verified by poorer initial performance relative to control group conditions. Retesting immediately versus after a delay yields consistent incubation effects; that is, problems not initially solved are more likely to be solved after a delay, as compared to immediate retesting conditions. Furthermore, these incubation effects are more robust when fixation is experimentally introduced. Thus, the forgetting fixation hypothesis, which explains reminiscence effects, also explains incubation effects in creative problem solving (Fig 23.6).

Incubation effects in tip-of-the-tongue (TOT) resolution have also been reported. When a name or word that could not be retrieved initially is later remembered, it often seems to happen in the absence of the initial TOT experience. Because TOT states have sometimes been attributed to momentary memory blocks (e.g., Jones, 1989; Jones & Langford, 1987; Reason & Lucas, 1983), these TOT recovery experiences may reflect the same underlying cognitive processes that give rise to incubation effects. Choi and Smith (2005) asked participants to name eight capital cities, each cued by the names of the country, eight names of diseases cued by disease descriptions, eight names of celebrities cued by their photographs, and so on, asking for graded TOT judgments whenever a name or word could not be remembered. Resolution of TOT states (i.e., successful recall of initially unrealled items) was greater if retesting followed an incubation period than if retesting was not delayed, and this TOT incubation effect was greater for TOT states that had been judged stronger. It was assumed that some of these TOTs were caused by blocking because not one, but eight questions were given for each category, a procedure known to cause output interference (e.g., Brown & Hall, 1979). On the other hand, Kornell and Metcalfe (2006), who

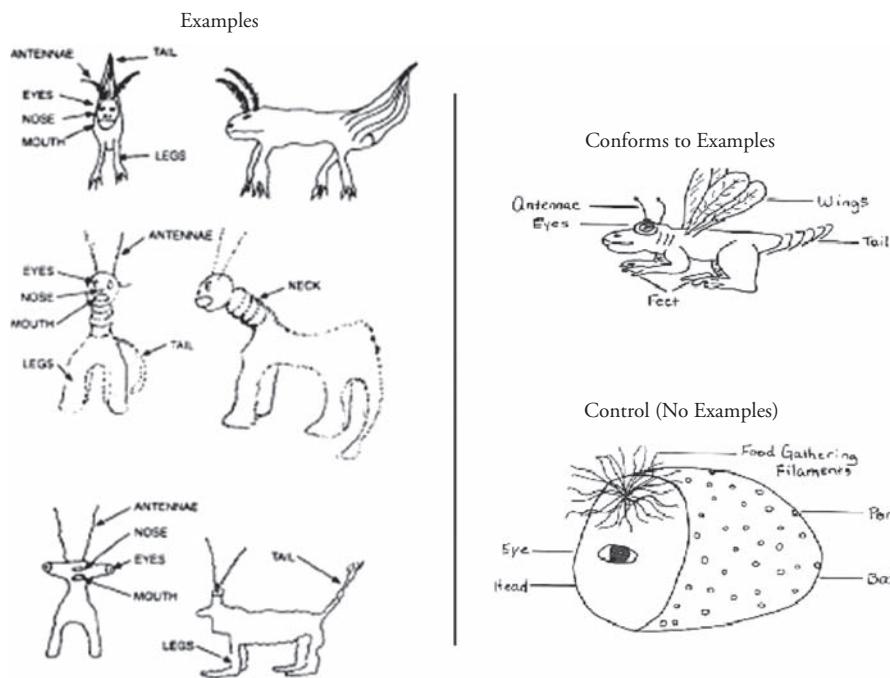

Fig. 23.3 The left panel shows examples seen by half the participants, who all tried to create life forms that might evolve on an imaginary planet similar to Earth. The top right shows an idea from a participant who saw the three examples; this sketch contains all three of the exemplified features (four legs, antennae, tail), a conformity effect that is found even when participants are asked to design ideas that are as different as possible from the examples. The bottom right shows an idea with none of those features, sketched by a participant who saw no examples (Smith et al., 1993).

also found incubation effects in TOT resolution, found that incubation did not interact with initial blocking self-reports, and reminding participants of their reported blockers at retest did not affect TOT resolution, casting doubt on the forgetting fixation hypothesis of TOT resolution. In that study, blocking was not directly manipulated but rather defined in terms of metacognitive reports of blocker experiences. Thus, whether incubated TOT resolution can be explained by forgetting blockers remains in question, probably due to the likelihood that TOTs have multiple causes, such as partial activation, memory blocking, and experiment demand characteristics.

Problem Solving

Creative and noncreative problem solving can be distinguished. Using known algorithms or heuristics to solve a problem, or simply retrieving a known solution from memory, would be considered noncreative problem solving, whereas creative problem solving involves solving new problems or solving old problems in new ways. Not all creative thinking can be described as creative problem solving, but much creative cognition research frames the activity that way.

One distinction that separates creative and noncreative problem solving is the concept of *well-defined*

versus *ill-defined* problems. A problem is considered well defined (and not creative) if its beginning state and goal state are thoroughly specified, in addition to the operations to be used in getting from the beginning to the goal (Reitman, 1965). Creative problems are considered ill defined, primarily because multiple hypothetical solutions might satisfy the goals of the problem. Another approach distinguishes *divergent* from *convergent problem solving*. Whereas a convergent problem has a single correct answer, divergent problems have many possible solutions (e.g., Finke, Ward, & Smith, 1992). Divergent problem solving will be discussed in the next section.

The topic of insight (e.g., Dominowski & Jenrick, 1972; see also van Steenburgh et al., Chapter 24) often has been studied as a type of creative problem solving. It is important to distinguish the concepts of insight, insight problems, and insight experiences. Whereas *insight* refers to a clear and/or deep understanding, *insight experiences* (also known as *aha!* experiences) are insights that are experienced suddenly and unpredictably. *Insight problems* are puzzle problems that are typically (but not necessarily) solved by insight experiences (Finke et al., 1992; Smith, 1995a). Insight problem solving, as discussed earlier, often has been described as accompanied by a perceptual-like restructuring of

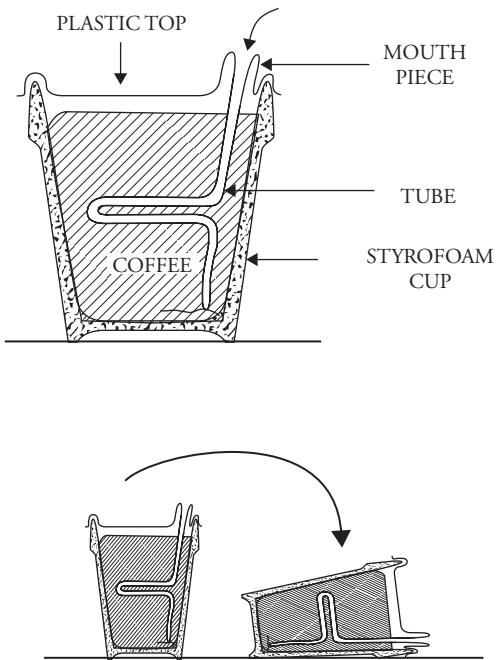

Fig. 23.4 Example spill-proof coffee cup given to some participants in Jansson and Smith (1991). Although the example uses a straw and a mouthpiece (which could lead to scalded mouths), these features were explicitly disallowed for designs sketched by participants. Nonetheless, design students who saw this example were far more likely to include straws and mouthpieces in the designs they sketched, as compared with students who did not see the example.

the problem, that is, discovering a new or different way to frame a problem in a manner similar to the way that an alternative interpretation of an ambiguous figure might be discovered (e.g., Dominowski, 1981; Duncker, 1945; Ellen, 1982; Maier, 1930; Metcalfe, 1986) (see Fig. 23.7). Initial attempts to solve insight problems often result in fixation, impediments caused by retrieval of inappropriate prepotent responses or methods. Recent research suggests that inhibition of prepotent responses may facilitate insight problem solving by providing a means by which to overcome fixation (Storm & Angello, 2010).

Implicit Cognition

Cognitive processes that occur without explicit awareness or deliberate intention can be described as *implicit cognition*. Implicit or unconscious cognition has long been considered to play a critically important role in the creative process. The idea that insights or solutions to problems can be arrived at via unconscious processes has been long endorsed as the reason that creative solutions seem to appear unbidden, and often occur outside of the typical problem-solving context, even when conscious work has been put aside. On the one hand, no evidence indicates that unconscious cognitive processes, like conscious processes, are capable autonomously of carrying out sequences of knowledge states, with each step using the products of previous states. On the other hand, there has been evidence that unconscious processes similar to spreading activation might be responsible for intuitive hunches (e.g., Bowers, Farvolden, & Mermigis, 1995), that impending solutions to insight problems cannot be predicted more in advance than about 10 seconds (Metcalfe, 1986), and that inventors and students in creative fields are often subject to involuntary conformity effects (e.g., Smith, Ward, & Schumacher, 1993).

The type of implicit cognition most often referred to in reference to creative thinking is spreading activation that occurs below the level of conscious awareness. Below-threshold activation has been the mechanism for a theory that implicit cognition can lead incrementally, but below the level of conscious awareness, toward an insight, and the final step in the process that completes an idea is simply the product of numerous incremental steps, not a cognitive restructuring (e.g., Weisberg, 1992). Yaniv and Meyer (1987) found that answers to general knowledge questions were responded to faster in a lexical decision task even if a participant could not consciously retrieve the answer, and furthermore, the stronger the feeling-of-knowing report accompanying the initial retrieval failure, the clearer the lexical decision advantage. They attributed this

Remote Associates Test Problems			Blockers	Solutions

ARM	COAL	STOP	rest	pit

Fig. 23.5 Remote Associates Test (RAT) problems, along with examples of blockers (related to two but not all three test words) and solutions (a single word related to each of the three test words).

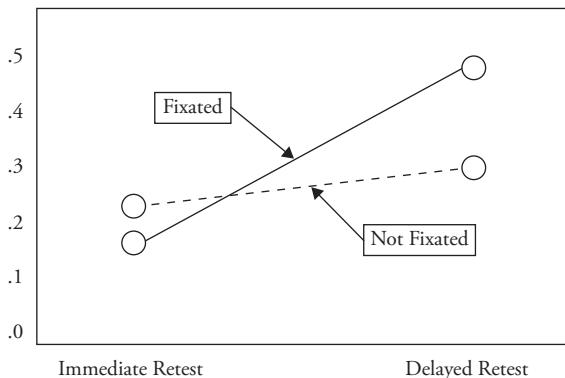

Fig. 23.6 Proportion of initially failed problems that were resolved on a retest that was given either immediately, or after a 5-minute delay. Problems with no misleading “hints” on the original test (Not Fixated) did not show an incubation effect (defined as better resolution on the delayed retest), but those with misleading hints (Fixated) showed a clear incubation effect (from Experiment 1 of Smith & Blankenship, 1991).

priming effect to below-threshold activation of target items, caused by the unsuccessful retrieval attempts. Although Connor, Balota, and Neely (1992) later challenged the interpretation of their results, Yaniv and Meyer claimed that such activation could be the mechanism underlying incubation effects. Seifert et al. (1994) expanded upon this idea, arguing that “failure indices” may become attached to initially unsuccessful retrieval attempts, and chance encounters with related stimuli are more likely to trigger insights or *aha!* experiences. This “opportunistic assimilation” theory, based on unconscious activation of concepts, has been offered as a theory of incubation effects.

Another feature of creative thinking, *intuition*, has been treated as below-threshold activation by Bowers and colleagues (Bowers et al., 1990, 1995). In contrast with insight, an idea one becomes consciously aware of, intuition is treated as a “hunch” by Bowers and colleagues. According to this view, intuitive guiding, rising from unconscious activation, can lead one toward more coherent solutions. A similar aspect of implicit cognition has been examined in terms of predicting insight experiences in problem solving (Metcalfe, 1986; Metcalfe & Weibe, 1987). These studies introduced a metacognitive definition of insight experiences, based on repeated subjective reports known as *warmth ratings*. Because intuition is defined as a hunch, or an ineffable “gut feeling,” warmth ratings might be considered estimates of intuition. For noninsight problems, this metacognitive measure shows regular increases over time until a solution is reached. For insight problems, however, increasing warmth ratings did not predict impending solutions; rather, they predicted impending failures. Metcalfe’s research shows that intuition may not be a good predictor of insight.

Implicit memory in the form of involuntary retrieval of recently encountered stimuli has been

linked to fixation and conformity effects in creative invention and problem solving (e.g., Smith, 1995b, 2003). Smith and Tindell (1997) used word fragment completion to induce implicit memory blocks, priming with words orthographically similar to test fragments, but that could not correctly complete the fragments. The resulting implicit memory blocks (e.g., Kinoshita & Towgood, 2001; Leynes, Rass, & Landau, 2008; Logan & Balota, 2003; Lustig & Hasher, 2001) are not eliminated when participants are explicitly warned not to think about read words while they were completing the test fragments. Parallel results have been reported, showing that similar warnings do not mitigate conformity effects in creative idea generation (Smith et al., 1993) or fixation in creative design (Jansson & Smith, 1991).

Creative Operations, Procedures, and Activities

Although no fixed set of cognitive operations or procedures is common for all creative activities, there are, nonetheless, some that often are encountered and considered in the research literature on creative thinking. These operations include the practice of generating lists of ideas (also known as idea generation, or ideation) and combining ideas.

Combination

One of the challenges people confront as a result of relying heavily on existing knowledge in performing creative tasks is generating something new, something that goes beyond what is already known. Indeed, this requirement also represents a challenge for researchers attempting to explain creativity. How are we to account for the appearance of something new if all people have to work with is their existing knowledge? One process that can help with both challenges is *conceptual combination*, in which people merge together two concepts that were previously

Change from A to B in 3 moves.

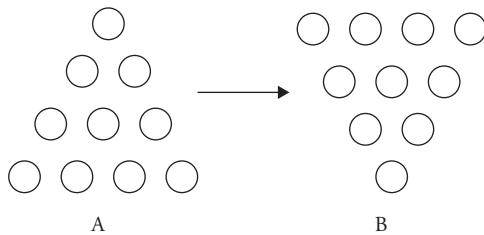

Fig. 23.7 An insight problem, one whose solution tends to be realized suddenly (e.g., Metcalfe, 1986).

completely separate or are otherwise discrepant or dissimilar (e.g., Medin & Shoben, 1988; Shoben & Gagné, 1997; Sifonis & Ward, 1998; Wisniewski, 1997). One of the reasons conceptual combination can be effective in provoking or explaining the origins of novelty is that it can result in the emergence of properties that are not strongly associated with either of the parent concepts in the combination. The creative potential inherent in those *emergent properties* can then serve as the basis for a new ideas or products. A classic example of emergence is seen in the interpretation of the somewhat unusual combination "Harvard-educated carpenter," which might be perceived as being nonmaterialistic, a property not necessarily strongly associated with Harvard-educated people or carpenters in general (e.g., Kunda, Miller, & Claire, 1990). Research is consistent with the idea that the more discrepant the separate concepts are, the more likely it is that emergent properties will be observed (e.g., Estes & Ward, 2002; Hampton, 1987; Wilkenfeld & Ward, 2001), possibly because discrepancy forces people to attempt to resolve the contradiction between the component terms (Hampton, 1997; Kunda et al., 1990).

Ideation

Divergent thinking, the search for many varied and imaginative possible problem solutions, has been contrasted with *convergent thinking*, a type of problem solving or reasoning in which cognitive operations are intended to converge upon the single correct answer to a problem. In divergent thinking tasks, people begin with an ill-defined or open-ended problem, such as finding alternative uses for a common object (e.g., Finke et al., 1992). Performing a divergent thinking task resembles the task of listing members of categories; in both cases, the subject brings all of the required knowledge to the task. There is a tendency to think of these two activities as fundamentally different. Whereas responses in category

generation tasks are often seen as passively residing in a memory repository, ideas for an idea generation task seem to be created on the spot. However, both of these assumptions are flawed. Most categories (e.g., *birds*) have a graded structure, with some members perceived as better members (e.g., *robin*) and others as poorer (e.g., *phoenix*), and ad hoc categories (e.g., *heavy things*), in particular, clearly demand on-the-spot imagination (e.g., *a sumo wrestler's lunchbox*; see Barsalou, 1982, 1985). Divergent thinking, like category generation, requires both retrieval of material from memory and imagination.

When done as a collaborative group, ideation is usually referred to as *brainstorming* (e.g., Osborn, 1957). There are other collaborative methods intended to enhance ideation, but generating and combining ideas is the basic goal of such activities.

Creative Cognition Theories

It is not easy to demarcate theories of creative cognition from theories of cognition. For example, Gentner's structural mapping theory (e.g., Gentner, 1987; Gentner & Markman, 1994; see Holyoak, Chapter 13) deals with analogical reasoning and is relevant to important issues in creative cognition, yet we would not call it a creative cognition theory; rather, it is a theory of cognition that we use to describe aspects of creative thinking. In comparison, Ward's (1994) structured imagination theory was specifically designed to address certain aspects of creative thinking, and it is couched in terms of cognitive theory; therefore, it qualifies as a theory of creative cognition. Here we briefly review theories that were intended to capture important aspects of creative cognition.

Remote Association

The theory of *remote association* (e.g., Mednick, 1962; Mednick, Mednick, & Mednick, 1964), inspired by studies of associative responses given by schizophrenic patients (e.g., Mednick, 1962), took a narrow view of creative thinking as a single associative process. The idea is that the process of accessing or retrieving a remote associate of a stimulus, rather than a common or prepotent response, is a cognitive event at the heart of all truly creative thinking. This process, accessing a remote association, should be useful in the tricky sort of creative problem solving in which the prepotent ("sucker") initial response implicitly includes unnoticed assumptions that prevent successful problem solving. The ability to access a more remote association allows the creative problem solver to go beyond the initial fixation

caused by the prepotent response. Furthermore, remote access allows a person to combine more distantly related ideas or concepts; such unusual combinations might produce novel emergent properties, a hallmark of many creative ideas.

Martindale (1981, 1989, 1995) elaborated and extended the theory of remote association, adding mechanisms such as attentional defocusing (or narrowing) that can impact the gradient of associative hierarchies. A steep associative hierarchical gradient (where prepotent responses are far more likely than other associates to be accessed) can shift to a flatter gradient, in which remote associates are more accessible (Martindale, 1995). Flattening of this associative gradient via defocused attention, according to Martindale, should be directly related to sympathetic arousal levels, because lower arousal acts to increase the randomicity (temperature) function in Martindale's connectionist model, facilitating escape from local minima.

Darwinian Model

A Darwinian model of creativity is one that embraces the notion of random variation and selection at the level of ideas (e.g., Simonton, 1999; see Simonton, Chapter 25). That is, one must continue to produce variations of ideas until, by chance, an idea turns out to be creative and valuable. Key to this theory is the idea that creativity is a stochastic process, rather than a deterministic one. That is, one cannot produce creative products by virtue of a preplanned step-by-step process. Rather, creativity is seen as a lucky accident. Therefore, increasing the chances of a providential accident can be accomplished by increasing the number of ideas that are generated and considered in the course of creative ideation.

This Darwinian theory of creative ideation does not really specify the cognitive mechanisms that determine variations in the quantity of ideas that can be generated and, in fact, does not depend upon the empirical validity of any cognitive mechanisms, except for those that might contribute to the quantity of ideas that are produced. Indeed, the quantity of ideas, often measured as fluency, is one of the most common measures of creative productivity. Most experimental studies of brainstorming, for example, have relied upon measures of the quantity of ideas produced in various conditions. Shah et al. (2003) referred to quantity as a *process* measure, rather than an *outcome* measure of creativity. That is, more ideas might increase the chances that a highly creative

idea will be produced (the Darwinian principle), but quantity is not a necessary outcome if someone only thinks of that single most creative idea.

Opportunistic Assimilation

The "prepared mind" theory, based on Pasteur's notion that "Chance favors the prepared mind," is another cognitive model of aspects of creative thinking. Encompassing the principle of the prepared mind is the *opportunistic assimilation* theory of Seifert and colleagues (e.g., Patalano & Seifert, 1997; Seifert et al., 1994; Seifert & Patalano, 2001). This theory explains insight experiences with a combination of several cognitive mechanisms, including (unconscious) spreading activation, failure indices encoded with unsolved problems, and serendipitous environmental triggers. The theory states that recognizing opportunities to fulfill pending goals is improved by predictively encoding one's goal, which allows people to take advantage of unforeseen opportunities to achieve those goals. When attempts to solve a problem result in initial failures, these episodes can be encoded in memory as associations between pending goals and stimulus features that might potentially solve the failed problem. Unsolved problems that are encoded in association with these "failure indices" may be remembered when stimuli with features related to those indices are serendipitously encountered. Furthermore, unconscious semantic activation of failed problems primes the encoded representations of unsolved problems, making them more likely to be remembered when such chance encounters occur (e.g., Yaniv & Meyer, 1987).

According to the opportunistic assimilation theory, this combination of encoded failure indices and unconscious spreading activation describes the prepared mind, because it prepares the problem solver to be able to use relevant cues without requiring the examination of every object in the environment to consider its relevance to the unsolved problem. Encoding more abstract versions of failure indices, according to this view, is more advantageous than specific or concrete encodings because abstract problem needs might be satisfied by an entire class of objects, rather than requiring a specific object. This opportunistic assimilation was designed to explain incubation effects in creative problem solving: When one initially fails to solve a problem, and the problem is put aside, a serendipitously encountered object in one's environment can provide a relevant clue, triggering an insight.

Idea Roadmaps

Smith's roadmaps theory (Smith, 1995a) provides a theoretical basis for a generative search of one's knowledge, a search for information that could potentially address one's goals and problem solutions. The theory does not assume that goals or problem solutions are necessarily stored in their final form, but rather that goals are achieved via an incremental construction process that can combine preexisting knowledge with new ideas constructed from combinations of existing knowledge. The theory can be applied to creative problem solving, design, or other similar constructive activities.

The multidimensional space in which ideas are constructed, according to an extension of this theory (Smith, 1995b), is determined and bounded by the *plan* adopted to guide thinking. This type of plan includes a set of operations for manipulating the content of ideas that are under construction; these operations, combined with the content that serves as a problem's initial representation, determine an idea space that can be constructed and navigated as the idea is developed. If this idea space is arranged hierarchically, with each location defined in terms of the idea's specified content, then this idea roadmap can be oriented with the least specific content at the top of the roadmap and the most specified ideas at the bottom of the hierarchy. Typical problem solving, according to this theory, tends to begin at or near the top of a roadmap and proceed incrementally toward the bottom of the roadmap, where specific solutions are represented. During creative idea construction, each successive representation of an idea on a roadmap tends to be a precursor for a more specific representation, so there may be a tendency to include each represented set of elements automatically on subsequent problem-solving steps. Thus, representations on the roadmap of ideas tend to encode implicit knowledge, memories, or assumptions about problem solutions.

Fixation, according to this theory, corresponds to taking a dead-end branch in the path that is constructed in the course of creative problem solving. If a problem solution or a creative insight is not located on a projected idea map, and we assume only downward movement within the idea space, this provides a way to view fixation in creative thinking. "Upward" movement on an idea roadmap involves removing elements from idea representations, which can be especially difficult for elements that have become implicitly included components of a representation. Incubation, in this theory, allows one

to escape from dead-end fixated paths. If a break or context shift enables a new idea representation that does not include fixating elements, then fixation may be resolved—an incubation effect, due to restructuring of the problem.

This roadmaps theory blends well with Ward's ideas about structured imagination and his path-of-least-resistance theory, as described earlier. That is, a hierarchically structured conceptual map forms the basis of imagination in both cases. In the structured imagination view, beginning ideation with a representation that is too concretely specified can limit the breadth of one's search for ideas. In the roadmaps view, fixation and conformity due to recent experience can likewise limit the breadth of idea generation.

Metrics of Creativity

How can we recognize creativity when we see it? How can we measure creativity? The same basic questions have been asked about other cognitive domains, such as memory. Cued recall and word stem completion are two different measures commonly used to measure memory; which is a better measure of the construct? Most cognitive psychologists understand the absurdity of this question, because the answer begins with "It depends on what you want to measure." There is no "single" or "best" measure of memory, because memory involves many complex interacting systems. The same can be said about creativity. What is the best measure of creativity? It depends on what aspect of creative thinking you want to measure. Studies of creative thinking often focus on specific aspects of creative cognition, such as creative problem solving, idea generation, conceptual combination, or visualization.

Although many studies have looked at performance on insight problems to measure creative problem solving (e.g., Maier, 1931; Metcalfe, 1986; Smith & Blankenship, 1989, 1991), studies of creative thinking must go beyond puzzles to connect cognition with creative products. In these cases, the most typical metrics used to measure creative output are the *quantity*, *quality*, *variety*, and *novelty* of responses or products. For example, in a divergent thinking task in which one is asked to list the alternative uses of empty 2-liter soda bottles, the number of ideas listed is the quantity, the number of categories of ideas (e.g., construction, weapon, things that float) is the variety, and the statistical infrequency of each idea, as measured by a norm, is the novelty. Quality is usually subjectively judged. Shah et al. (2000) distinguished *process metrics* from

outcome metrics of creative ideation, stating that the novelty and quality are important for judging the outcome or end product of creative work, whereas quantity and variety are important only for judging aspects of the creative process. These four metrics, and variants of them, have proven useful in different ideation contexts, such as divergent thinking tasks (e.g., Guilford, 1967), brainstorming (e.g., Kohn & Smith, 2010), and engineering design (e.g., Vargas-Hernandez, Shah, & Smith, 2010). Nonetheless, there are important limitations of these creativity metrics. One limitation has to do with domain differences and idiosyncrasies (e.g., engineering design may have many important creative needs that differ from those of music composition, business, and science).

Some relatively new metrics of creative cognition have been identified, including measures of conformity, emergence, and abstraction. Smith et al. (1993) defined *conformity* as using features of examples one has seen in one's own creative ideas. They and others (e.g., Dahl & Moreau, 2002; Jansson & Smith, 1991; Vargas-Hernandez et al., 2010) have shown that conformity may not be overcome by instructions to avoid using features of examples. Kohn and Smith (2010) showed that brainstorming participants tend to conform to the ideas of others in their brainstorming group. Although the term "conformity" typically is used pejoratively, it is clearly the case that conforming to useful examples in education and training is quite useful and important. When examples block or unnecessarily limit creative thinking, however, conformity is a problem. *Emergence* has been measured as a property seen in creative thinking in which combinations of ideas can produce concepts with qualities that are not seen in the component concepts (e.g., Estes & Ward, 2002; Wilkenfeld & Ward, 2001), and it has been used as a measure of creative cognition (e.g., Kerne, Smith, Koh, Choi, & Graeber, 2008a). Another metric of creative thinking is *abstraction*, that is, progressing from relatively concrete representations to more general levels, which potentially enables a broader variety of ideas. Abstraction can circumvent fixation and overly structured imagination (e.g., Ward et al., 2004), and it may promote access to remote associations and analogies.

Impediments and Aids to Creative Thinking

There are several known impediments and aids to creative thinking that relate directly to patterns

of cognition. Here, we briefly review some of these impediments and aids.

Impediments

INADEQUATE KNOWLEDGE

Perhaps the most common impediment to creative thinking is a lack of knowledge and resources (e.g., Weisberg, 1992, 2006). Both everyday creativity and extraordinary creativity (see Simonton, Chapter 25) require prior knowledge and experience. A myth of creativity is that one needs no expertise, and that an active imagination is all one needs to create great things; such notions are nonsense. A creative imagination is necessarily structured according to one's prior knowledge (e.g., Ward, 1994), and the value of serendipitous discoveries can only be noticed or realized by those with some level of expertise in a domain.

IMPLICIT ASSUMPTIONS

Although knowledge and experience are necessary for creative thinking, they are not sufficient in many identifiable cases. Inappropriate ideas or approaches to a problem can impede creative thinking via fixation (e.g., Smith & Blankenship, 1989, 1991; Wiley, 1998) and the implicit use of inappropriate assumptions (e.g., Smith, 1994). Findings that show fixation and implicit assumptions (e.g., Luchins & Luchins, 1959) can block creative cognition and demonstrate that prior experience can, at times, have negative consequences (see Fig 23.8). What is insidious about the implicit assumptions that can cause fixation is that such impediments are hidden from one's conscious mind, making them difficult to detect and remedy.

COGNITIVE ILLUSIONS

Cognitive illusions, such as false memories (e.g., Roediger & McDermott, 1995), memory misattributions (e.g., Jacoby, 1991), or misapplied availability heuristics (e.g., Tversky & Kahneman, 1974), cause predictable, systematic cognitive errors. One cognitive illusion that can impede creative thinking is *hindsight bias*. The sense that retrospective views of ideas make them seem more obvious can impede certain aspects of creativity (e.g., Fischhoff, 1975). A good example of hindsight bias can be seen in the patent process. A U.S. patent can be granted only for inventions that are "nonobvious" to practitioners of a profession. This nonobviousness criterion may lead to denial of patents for creative ideas that, in retrospect, might seem obvious to patent examiners (e.g., Seifert, 2008; Smith, 2008).

Problem #	Jar A	Jar B	Jar C	Goal Amount	Solution
1	64	100	6	24	B - A - 2C
2	21	73	5	42	
3	6	28	7	8	
4	35	94	21	17	
5	22	49	12	3	
6	7	56	8	33	
7	15	39	3	18	
8	28	76	3	25	

Fig. 23.8 Luchins' water jar problem: Using only the jars A, B, and C as measuring devices, measure out the desired amount for each problem. The mental set B – A – 2C, learned early in the problem sequence, may become mindlessly reapplied on each successive problem. This fixation effect, that is, blind use of a mental set, leads to use of a complicated solution (B – A – 2C) where a simple one should be apparent on Problem 7 (A + C), and it leads to the use of an incorrect solution (B – A – 2C) on Problem 8, even though a simple correct solution (A – C) should be readily apparent.

PREMATURE CONCEPTUALIZATION

One may begin creative work on an idea with a relatively specific or concrete representation, or one may reach such a representation early on in the process. Taking the path of least resistance, one may thereafter implicitly include all of those prematurely specified features in subsequently developed versions of a creative idea, never considering ideas that lack those features.

Aids

Creativity can be aided in many ways, such as gaining knowledge and expertise, using analogies, combining ideas, thinking abstractly, redefining problems that are fixated, and noticing ways in which a new idea could have important implications.

COMBINATION

Ever since people have tried to encourage creative thinking, the notion has flourished that combinations of existing ideas can form the basis of creative ideas (e.g., Osborn, 1957). As more interpretations of a conceptual combination are generated, the interpretations increase in their normative originality, and they tend to be based more on idiosyncratic knowledge of the components of the combination. One of the main goals in creative conceptual combination is to discover new and potentially useful emergent properties: that is, properties not commonly seen in the component concepts, but that emerge only in combinations (e.g., Estes & Ward, 2002).

ANALOGY

Because analogies link conceptual domains that are similar, they can provide vehicles for constructing creative solutions that cannot be found within the domain of a problem (e.g., Gick & Holyoak, 1980; see Holyoak, Chapter 13). Typically, the most useful analogies will be those that are based on the similarity of deeper meaningful levels of problem topics and solution vehicles, as opposed to similarity of superficial features of topic and vehicle domains. Local analogies are those that are conceptually closer to a problem topic domain than are remote analogies. Like remote associations, remote analogies appear to be more useful than local analogies for creative design (e.g., Christensen & Schunn, 2007), whereas Dunbar (e.g., 1997) found the reverse for a group of scientists engaged in scientific problem solving (also see Dunbar & Klahr, Chapter 35).

ABSTRACTION

Because imagination is structured according to underlying concepts in memory (e.g., Ward, 1994), beginning creative idea development at a convenient basic level and then taking the path of least resistance can lead to premature conceptualization. Abstract thinking, particularly early on in the ideation process, can lead one to explore a greater range of ideas, effectively expanding the conceptual space under consideration.

NOTICING

Stumbling across a key clue is not sufficient; one must *notice* the implications of that clue and realize its implications in terms of creative products or unsolved problems. No mind can be prepared to notice such clues without sufficient expert knowledge. Noticing may be facilitated by frustration from initial failures, which potentiates unsolved problems, helping them come to mind when relevant clues appear (e.g., Patalano & Seifert, 1997; Seifert et al., 1994).

KNOWLEDGE

Ideally, an expert always knows the correct approach for any given problem. Even experts, however, are susceptible to fixation and conformity effects in inventive design tasks (e.g., Jansson & Smith, 1991; Linsey et al., 2009). Redefinition of a problem or goal can sometimes provide a key insight, a restructuring of the problem, particularly when problems cannot be solved using expert

heuristics. One way to aid redefinition is via perspective shifts: thinking about problems in new contexts, ones that may not be associated with fixated approaches. Another aid to redefinition is analogy (e.g., Linsey, Wood, & Markman, 2008).

SUPPORT TECHNOLOGIES

Although there are many physical tools and technologies that aid the cognitive structures and operations that give rise to creativity, sketching is one of the oldest and most universal of these external aids (see Hegarty & Stull, Chapter 31). Sketching provides a particularly good medium for expressing and sharing spaces, schemas, and mental models (Tversky & Hard, 2001), freeing up cognitive resources, and extending our visualization abilities in ways that are particularly conducive to creative cognition (Tversky, 2001, 2005). Because sketches can be reexamined and reconsidered, they can support restructuring and discovery of unanticipated relations (Goel, 1995; Goldschmidt, 1994; Suwa & Tversky, 2001; Tversky & Suwa, 2009).

Conclusions

Creative thinking involves all of the cognitive systems. There is no single creative process; rather, there are many different types of creative ideas, and many ways in which ideas can be generated, constructed, and developed. Many of these pathways to creativity can be described and explained in terms of the cognition that underlies the creation of ideas. As in most other areas of cognitive psychology, the creative cognition approach has used empirical science to study the nature and functioning of cognitive processes and structures that underlie creative thinking. Cognitive operations that often are involved in creative cognition include divergent idea generation, the formation of conceptual combinations, retrieval and mapping of analogies, abstraction, visualization, and conceptual restructuring. Common impediments to creative cognition include inadequate prior knowledge, implicit assumptions, cognitive illusions, and premature conceptualization in the development of creative ideas. Methods and tools that can support creative cognition must be based on the cognitive operations and structures that give rise to creative ideas.

Future Directions

Cognitive Neuroscience

The role of the brain and nervous system in creative cognition is beginning to be explored by some

cognitive neuroscientists, and there are many ways in which neuroscientific mechanisms might contribute to creative thinking. Martindale, for example, linked access to remote associates with the effects that low physiological arousal have on neural communication (e.g., Martindale, 1981, 1995). Another excellent example is the work of Jung-Beeman, Kounios, and others who have developed a theory of insight and comprehension based on functional magnetic resonance imaging (fMRI) and electroencephalography (EEG) studies of participants solving insight problems (e.g., Jung-Beeman, 2005; Jung-Beeman et al., 2004; Kounios et al., 2006; Kounios et al., 2008). These studies have found, for example, activity in the right anterior superior temporal gyrus linked with awareness of a solution to an insight problem (e.g., Jung-Beeman et al., 2004; see van Steenburgh et al., Chapter 24). Future research on the neuroscience of creative cognition must blend neuroscience with cognitive mechanisms that are well known for their link to creative thinking, as the aforementioned studies have already begun to do.

Collaborative Cognition

Much of the cognition involved in real-world creativity is done collaboratively, using multiple types of media. Many studies have documented brainstorming deficits when participants are in groups: More ideas are produced when the individuals brainstorm individually (e.g., Diehl & Stroebe, 1987, 1991; Kohn & Smith, 2010; Nijstad et al., 2003; Nijstad & Stroebe, 2006). Cognitive mechanisms such as fixation and conformity to the ideas of others have been shown to limit the number and the novelty of ideas of brainstorming participants (Kohn & Smith, 2010). Parallel findings of collaborative inhibition in memory recall show that more is recalled when participants recall events individually (e.g., Weldon & Bellinger, 1997). Future research must pursue questions about the cognition that occurs in groups and how that cognition affects creativity. Particularly relevant to questions about collaborative creativity is the increasing role of the Internet in customer-driven design, and virtual teams (e.g., Maher, 2010; Ward, Guerdat, & Roskos, 2010).

Digital Tools

Digital tools that can aid creativity can be considered extensions of the types of human cognition that participate in creative cognition (Smith, Kerne, Koh, & Shah, 2009) (see Fig. 23.9). These digital tools can promote, for example, analogical

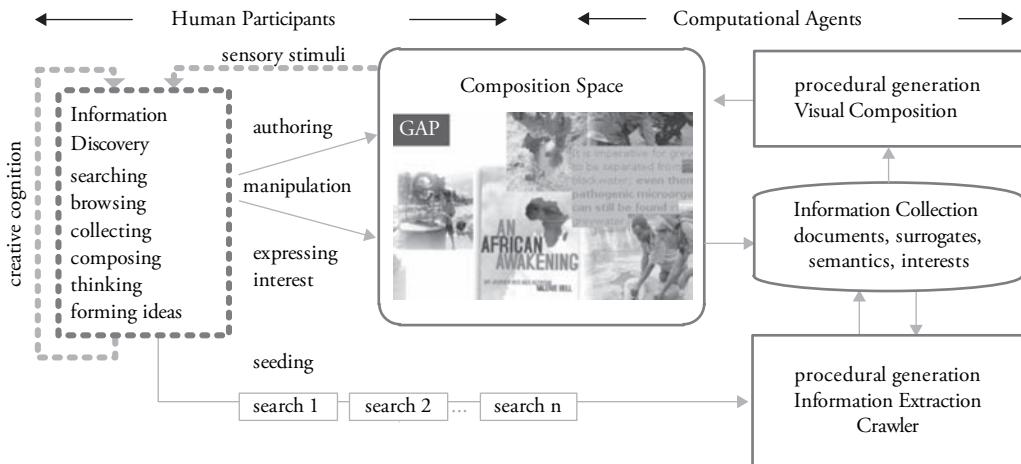

Fig. 23.9 Computational agents support human participants in the combinFormation digital tool for information discovery, which involves browsing through collections returned by search engines and forming navigable compositions of relevant results (Kerne, Koh, Smith, Webb, & Dworaczyk, 2008b). Problems are iteratively reformulated, representations are manipulated, and solutions constructed, often involving integration of multiple information resources (Kerne & Smith, 2004). See color figure.

reasoning (Markman, Wood, Linsey, Murphy, & Laux, 2009), conceptual combination of remote associates (Kerne et al., 2008a), or abstract thinking (Ward, 2009). Future research in creative cognition should examine this fundamental link between cognition and digital tools designed to support and enhance creativity.

Creative Expertise

Do some people gain creative expertise; that is, do they become expert at recognizing blocks, do they know good methods for escaping blocks, redefining problems, combining and transforming concepts, drawing deeply appropriate but remote analogies, and so on? Is this type of creative expertise something that can be effectively learned and trained? Whether such putative expertise actually enhances creativity is an important question for future research in creative cognition.

Abstract

In the century since the Gestalt psychologists introduced insight as a component process of perception and problem solving, researchers have studied the phenomenological, behavioral, and neural components of insight. Whether and how insight is different from other types of problem solving, such as analysis, has been a topic of considerable interest and some contention. In this chapter we develop a working definition of insight and detail the history of insight research by focusing on questions about the influence of the problem solver's prior knowledge, the origins and significance of representational change, and the roles of impasse and incubation. We also review more recent investigations of the neurological correlates of insight, discuss neurobehavioral states that facilitate or inhibit insightful problem solving, and highlight new methods and techniques that are proving useful in extending our knowledge of insight.

Key Words: knowledge, fixation, impasse, restructuring, Gestalt, special process, hemispheric differences, anterior cingulate cortex, superior temporal gyrus

Insight Defined

Insight occurs when a new interpretation of a situation or the solution to a problem suddenly springs into conscious awareness, seems obviously correct, and is accompanied by a surprising and emotional experience known as the "*Aha*" phenomenon (Kaplan & Simon, 1990). Although the necessity of some of these components of insight has been disputed, most researchers and lay people agree that these are at least typical characteristics of insight. To this basic definition theorists often add the requirement that the problem solver has to restructure or change his or her thinking about some aspect of the problem or the solution in order to achieve insight. Insight is usually contrasted with "analytic" solving in which the solver consciously and deliberately manipulates problem elements to discover the solution. Before discussing the mechanisms of insight, it is important to consider whether it is a unique

process or simply a peculiar manifestation of typical problem-solving mechanisms.

Is Insight Different?

When a chapter on insight appears within a volume that includes a separate chapter on problem solving (see Bassok & Novick, Chapter 21), it is implicitly assumed that insight problem solving is fundamentally different from other types of problem solving. However, the possibility that insightful problem-solving processes share the same mechanisms as analytic processes must be considered. Theorists belonging to the "business-as-usual" camp have argued that the processes by which problems are solved via insight are the same as those used in search solutions and that it is only the affective experience that is different (Atchley, Keeney, & Burgess, 1999; Perkins, 1981; Weisberg 1986, 2006; Weisberg & Alba, 1981). In research examining

verbal protocols, Perkins reported that participants experienced insight characteristics, such as the affectively loaded *Aha* reaction, in conjunction with analytic-type search-based solutions. More recently, researchers have noted that the heuristics traditionally applied during the solution of such search problems (e.g., hill climbing and means-ends analysis, which select moves that appear to make progress toward the solution) can be used to explain the processing displayed by participants when solving with insight (Chronicle, MacGregor, & Ormerod, 2004; MacGregor, Ormerod, & Chronicle, 2001). Furthermore, research exploring the analogical transfer of information during the solution of insight problems has revealed that transfer in insight is met with the same successes and failures as transfer in other problem-solving situations (e.g., Chen & Daehler, 2000; Ormerod, Chronicle, & MacGregor, 2006). Considering the aforementioned overlap, it makes sense that an affective experience similar to that occurring with an *Aha*, and perhaps other cognitive processes typically associated with insight, could operate when achieving solutions with analysis.

Historically, researchers have identified the distinctive emotional qualities of the insight experience and the mystique or inexplicability of the process as evidence that the cognitive mechanisms involved in achieving insight solutions must be distinct from ordinary noninsight solving. Theorists adhering to this view are in the “special-process” camp, and evidence to support their perspective has steadily accumulated (Anderson et al., 2009; Aziz-Zadeh, Kaplan, & Iacoboni, 2009; Bowden & Jung-Beeman, 2003; Jung-Beeman et al., 2004; Knoblich, Ohlsson, Haider, & Rhenius, 1999; Kounios et al., 2006, 2008; Luo, Niki, & Phillips, 2004a; Mai, Luo, Wu, & Luo, 2004; Schooler & Melcher, 1995; Smith & Kounios, 1996).

Accumulating evidence demonstrating that the right cerebral hemisphere makes a unique contribution to insight not evident in analytic processing has led many researchers to accept that insight is a special process. For example, several studies investigated the time course of hemispheric differences in solution activation for compound remote associate (CRA) problems (Beeman & Bowden, 2000; Bowden & Beeman, 1998). CRAs, adapted from Mednick's (1962) remote associates task, are brief problems in which participants are presented with three words (e.g., CRAB, PINE, SAUCE) and must generate a solution word (e.g., APPLE) that

can be combined with the problem words to yield a compound word or familiar phrase (e.g., CRABAPPLE, PINEAPPLE, and APPLE SAUCE). Like many problems solved with insight, CRA solutions rely on unusual or remote associations, which are likely to capitalize on semantic processing in the right hemisphere. This hypothesized asymmetry stems from the left hemisphere's tendency to mediate fine semantic coding in which a small number of close associates are activated, whereas the right hemisphere mediates coarse semantic coding involving the weak, diffuse, activation of a larger number of distant associates, often required to solve such problems.

In several studies, participants worked on CRAs for various time limits; if they failed to solve a problem before the time limit, they were presented with a target word to name (read aloud). Target words were either solution words or unrelated (solutions to other problems), and they were presented to either the left visual field (right hemisphere) or the right visual field (left hemisphere). Participants named solution words faster than unrelated words, that is, demonstrated solution-related priming for problems they had failed to solve. Participants showed more solution-related priming when naming targets presented to the left visual field (right hemisphere) than targets presented to the right visual field (left hemisphere) for both solved and unsolved problems, and this asymmetry increased with longer solving times (Beeman & Bowden, 2000; Bowden & Beeman, 1998). The right hemisphere advantage in priming was so strong that, when participants were asked to decide whether the words presented were solutions to unsolved problems (yes or no), their responses (button press) were significantly faster for words that were presented to the left visual field (right hemisphere), without sacrificing accuracy for speed. Thus, the typical left hemisphere advantage for responding to words was reversed. Beeman and Bowden's results were in accord with the findings of previous research (Fiore & Schooler, 1998) showing that hints to insight problems are more effective when presented to the left visual field (right hemisphere) than when presented to the right visual field (left hemisphere).

Functional magnetic resonance imaging (fMRI) and electroencephalography (EEG) have also shown lateralized differences between insight and analytic solutions of CRAs. Participants solved problems while brain activity was monitored, and they reported after each solution whether they used

insight or analysis to solve the problem. Participants were told to classify solutions that arrived suddenly, seemed obviously correct, and were achieved without clear intermediate steps as insight solutions, and those that were achieved more methodically through conscious analysis as noninsight solutions. fMRI showed that insight solutions were associated with distinct lateralized activity in the right anterior superior temporal gyrus (STG), activity not evident in noninsight solutions (Jung-Beeman et al., 2004). A follow-up study (Subramaniam, Kounios, Parrish, & Jung-Beeman, 2009) confirmed this right temporal activity, as well as activity in anterior cingulate cortex and parahippocampal areas, which were just below threshold in the original study. In a separate experiment of the original study (Jung-Beeman et al., 2004), high-density EEG revealed a sudden burst of high-frequency gamma-band activity over the right anterior temporal region about 0.3 seconds prior to the button press indicating solution (thus, approximately coinciding with awareness of the solution), which was localized to a region close to that identified in the fMRI experiment. Because the STG is thought to be involved in semantic integration (e.g., St. George, Kutas, Martinez, & Sereno, 1999), and because the right hemisphere has been found to play a significant role in processing distant semantic associations and figurative language (Jung-Beeman, 2005), this activation is thought to be linked to the sudden integration of semantic information resulting in the solution.

In addition, about 1.5 seconds before participants solved problems with insight, a burst of low-alpha EEG activity occurred over the right parietal-occipital cortex (see Fig. 24.1), subsiding just as the right temporal EEG gamma burst began (Jung-Beeman et al., 2004). Low alpha activity over visual cortex is understood to reflect visual sensory gating (cf. Ray & Cole, 1985). The researchers argued that this burst of alpha-band activity signifies a brief deactivation of visual cortex, reflecting a reduction of distracting sensory inputs. Similar posterior alpha activity was measured over this region in an EEG study that explored the restructuring component of insight (Wu, Knoblich, Wei, & Luo, 2009). Wu et al. used a Chinese-character task that required chunk decomposition, a form of restructuring, to break down complex Chinese characters to form new target characters. Their results support the idea that the attenuation of visual inputs facilitates representational change.

Recently, Aziz-Zadeh and colleagues (2009) used fMRI to examine activity associated with the

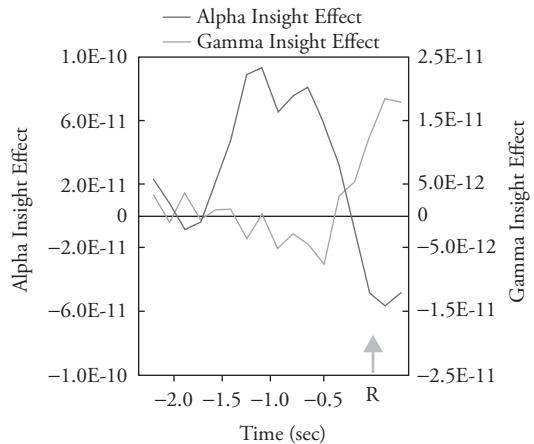

Fig. 24.1 The time course of the insight effect. Electroencephalogram (EEG) alpha power (9.8 Hz at right parietal-occipital electrode) and gamma power (39 Hz at right temporal electrode) for the insight effect (i.e., correct insight solutions minus correct noninsight solutions, in μV^2). The left y-axis shows the magnitude of the alpha insight effect (purple line); the right y-axis applies to the gamma insight effect (green line). The x-axis represents time (in seconds). The yellow arrow and R (at 0.0 s) signify the time of the button-press response indicating that a solution was achieved. Note the transient enhancement of alpha on insight trials (relative to noninsight trials) prior to the gamma burst signifying insight. (Reproduced from open source article by Jung-Beeman et al., 2004.) See color figure.

solution of anagrams by insight, and they found relatively greater right prefrontal cortex (PFC) activity associated with insight versus analytic solutions. Such results build on other recent findings demonstrating right-PFC activity associated with creativity and the production of novel ideas in normal adults (e.g., Howard-Jones, Blakemore, Samuel, Summers, & Claxton, 2005). Moreover, individuals high in schizotypy, who tend to use loose associations processed in the right hemisphere (see Mohr, Graves, Gianotti, Pizzagalli, & Brugger, 2001) solve classic insight problems at a higher rate compared to healthy, nonschizotypal adults (Karimi, Windmann, Güntürkün, & Abraham, 2007), further supporting the critical role of the right hemisphere in insight.

Although there seems to be substantial and increasing evidence that insight processes rely more on the right hemisphere than analytic processes do, such findings should not be interpreted to suggest either that the right hemisphere is exclusively used in insight and not analysis, or that left-hemisphere processing is not needed for insight. Rather, the fMRI and EEG literature indicates that, though the two strategies share many processes, additional activity in right temporal cortex and other areas

(Subramaniam et al., 2009) is present when solvers produce insight solutions. Regardless of the outcome of the debate on the hemispheres in insight, the literature supports the idea that the solution of verbal problems through insight is associated with a unique and sudden integration of weakly and distantly related problem components, and that briefly blocking sensory input facilitates the retrieval into conscious awareness of solution-related ideas initially represented at an unconscious level.

It is possible that other mechanisms, such as the application of unconstrained hypothesis generation, could explain the hemispheric asymmetry associated with insight (e.g., Vartanian & Goel, 2005). In fMRI research with anagrams, Vartanian and Goel observed significant activation in the right ventral lateral prefrontal cortex when participants solved semantically constrained (i.e., anagram letters to be rearranged to generate a word in a specific category) versus unconstrained problems (anagram letters to be rearranged to generate a word with no category specification), which they suggest indicates the role of this region in hypothesis generation in unconstrained situations. Insight problems have been labeled as unconstrained in prior research (e.g., Isen, Daubman, & Nowicki, 1987). Specifically, insight problems often either mislead people trying to solve them, because they imply one solving strategy (or one interpretation or association of problem concepts) or simply lack constraints suggesting the correct approach.

Another distinctive feature of insight is the relative inaccessibility of insight mechanisms to conscious analysis. Research on metacognition and insight has revealed that participants appear to lack conscious awareness of solution-related ideas during intermediate stages in the solving process (Metcalfe & Wiebe, 1987) and are limited in their ability to explain these thoughts aloud (Schooler, Ohlsson, & Brooks, 1993; to be discussed later). The limited accessibility of insight-related processing to conscious awareness may also be linked to the unique contributions of right-hemisphere processing to insight. Research with split-brain patients has demonstrated that conscious experience in these patients with divided hemispheres is more strongly tied to left-hemisphere processing (e.g., Gazzaniga, 1998), whereas right-hemisphere processing tends to influence their behavior without awareness.

Based on the accumulated evidence, especially the brain imaging data, a strong version of the

“business-as-usual” view of insight no longer seems tenable. Insight appears to involve “special” processes.

Insight and Conscious Awareness

When Gestalt psychologists first began to discuss insight about a century ago, they distinguished between insight and analysis based mostly on the different affective experience that accompanies insight but also because insight sometimes comes incidentally when one is not directly focusing on the problem. The Gestalt psychologists’ view was supported not only by shared experience but also by famous anecdotes of scientific insights that led to creative solutions to vexing problems. Some of the most famous of such insights were Archimedes’ eureka moment in the bathtub, Newton’s falling apple, and Poincaré’s bus ride. One thing that these discoveries have in common is that, at least according to the stories, these great thinkers were not consciously considering the problem at the time they experienced insight (see Simonton, Chapter 25). In contrast, since analytic thought is by definition deliberate, solution by incidental analysis is an oxymoron.

Insight problem solving is also different from analytic problem solving in that insight seems to involve processing that renders it inaccessible to metacognition (see McGillivray et al., Chapter 33). Metcalfe and Wiebe (1987) asked participants to periodically judge during the course of problem solving how close they were to achieving a solution. They found that prior to analytic solutions, subjects reported gradually increasing closeness to solution. In contrast, prior to insight solutions, subjects reported little or no progress toward solution right up until the point in time at which solution was imminent (cf., Smith & Kounios, 1996). Metcalfe and Wiebe, therefore, concluded that insight was fundamentally a different process, one that involves critical mechanisms that go on outside awareness.

Using a somewhat different paradigm in which participants were interrupted during solution and asked to give a verbal description of their solution efforts, Schooler and Melcher (1995) found a difference in conscious access to solution information between insight and analytic problem solving. Schooler and colleagues (1993) found that verbalization during solving interfered with the solution of insight problems but not analytic problems. Based on these findings, Schooler proposed a verbal overshadowing effect on insight due to the

inaccessibility of critical insight processes to verbal description. A recent investigation by Gilhooly, Fioratou, and Henretty (2010) suggests that verbal overshadowing might be specific to visual problems, regardless of insight or analytic solution strategy. Nevertheless, much of the research on metacognition and verbal overshadowing of insight suggests that steps in the insight process are beyond conscious analysis. Furthermore, it is possible that the inaccessibility of insight processes to linguistic analysis may be due to the involvement of the less-verbal right hemisphere.

The unconscious processing of insight antecedents may be a critical factor in the eventual *Aha!* reaction that accompanies insight solutions. The sudden conscious awareness of the solution can be particularly surprising given a comparison to analytic processes that may even be “reasoned out” either vocally or subvocally as the solver advances toward completion (Newell & Simon, 1972; Smith & Kounios, 1996; Thorndike, 1898).

Knowledge Selection and Fixation

In the first half of the 20th century, the Gestalt psychologists proposed that insight involves the application of a special type of knowledge that is different from that used in trial-and-error problem-solving strategies (e.g., Duncker, 1945; Koffka, 1935; Köhler, 1925; Wertheimer, 1945/1959). They argued that it was the incorrect application of prior knowledge that prevented the achievement of insight and that insight is facilitated only when problem solvers go beyond trial-and-error processing to acquire extraordinary knowledge structures (e.g., Duncker, Köhler). Ordinary thought is *reproductive*, involving the reuse or adaptation of older ideas or approaches, whereas insight requires *productive thought* (Wertheimer, 1945/1959; see also Mandler & Mandler, 1964) in which a deeper conceptual understanding allows problem solvers to select relevant knowledge components and combine them in novel ways, or to guide problem solvers to attend to the environmental stimuli that are most relevant. Wertheimer suggested that insight was not the result of the problem solver blindly recombining problem elements in search of a solution; rather, he argued that it requires that the problem solver gain the necessary structure on which to build a solution. Thus, a lack of success in problem solving could stem either from the retrieval of irrelevant information from long-term memory or the retrieval of relevant components that are applied or linked within an inappropriate structure.

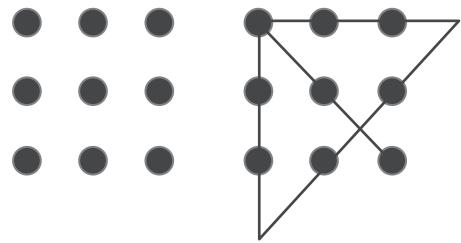

Fig. 24.2 The nine-dot problem. (*Left*) Subjects' task is to draw four straight lines that go through all nine dots without backtracking or lifting the pencil from the paper. (*Right*) One solution to the problem.

Problem solvers often do poorly in solving classic insight problems, such as the nine-dot problem (Maier, 1930; see Fig. 24.2). Researchers have suggested that participants fail to solve this problem (solution rates are consistently less than 10% without hints) because either they do not possess solution-relevant knowledge about extending lines “outside the box,” or because they lack the visuospatial capacities to mentally construct the solution configuration (e.g., Chronicle, Ormerod, & MacGregor, 2001; Kershaw & Ohlsson, 2004). However, when experimenters provide participants with training problems and strategies and give hints about the solution (e.g., Lung & Dominowski, 1985; Weisberg & Alba, 1981) or provide perceptual hints about the overall solution configuration (Chronicle et al. 2001; MacGregor et al., 2001), problem solvers achieve only modest gains in solution rates. Kershaw and Ohlsson had to provide extensive knowledge about pivoting solution lines on non-dot points and to train participants to think outside the constraints of the problem presentation space in order to substantially facilitate solution rates.

The limited transfer of problem-related information during the solution of the nine-dot problem mirrors results observed in prior research on analogical transfer using Duncker's (1945) radiation problem (see Holyoak, 2005, for a review). In the radiation problem, another classic insight problem, participants are asked to generate a solution that will enable an inoperable stomach tumor to be eradicated by allowing enough radiation to reach the tumor without destroying the surrounding healthy tissue. The problem can be solved by employing the convergence principle: Multiple rays of weaker intensity can be applied from various positions converging with sufficient strength at the tumor. In preliminary research on transfer, participants were

provided with one or more source problems that also relied on the convergence principle for solution (Gick & Holyoak, 1980, 1983). When a relevant source problem was provided prior to the radiation problem, few participants transferred the convergence principle solution unless they were explicitly told that the source information might be helpful in generating the solution. The application of the solution principle was more likely if multiple source problems with convergence solutions were presented for comparison instead of one (Gick & Holyoak, 1983; Kurtz & Loewenstein, 2007), when the source problem appeared similar in character and theme (e.g., a patient with a brain tumor) to the target problem than if the source problem was from an unrelated domain (Keane, 1987), or when abstract statements explicating the solution principle were provided (Chen & Daehler, 2000). These findings suggest that gaining problem-relevant knowledge may do little to facilitate solution success in insight unless that knowledge results in the acquisition of a deep conceptual understanding of the problem's components.

The Gestalt psychologists felt that repeated application of incorrectly selected knowledge from long-term memory (i.e., fixation) could prevent the deep conceptual understanding necessary to achieve insight (Duncker, 1945; Luchins, 1942; Maier, 1930; Scheerer, 1963). Duncker conducted much of the pioneering work on fixation, most notably with the candle problem. In the candle problem, researchers present participants with a candle, a book of matches, and a box of tacks, and ask them to devise a way to attach the candle to a door so it can burn properly. The insightful solution to this problem is to empty the tack box and use it as a ledge to support the candle. However, when problem solvers first approach the problem and see the box filled with tacks, they become functionally fixated on the standard function of the box as a container, which limits their ability to consider the tack box as having other functions that may potentially facilitate the solution to the problem. Perseveration on an object's dominant function may be so persistent that the solver reaches an impasse and becomes increasingly fixated on a solution idea, repeatedly attempting the same approach (Smith, 1995).

Modern theorists have suggested that when a problem solver's initial problem space contains irrelevant or incorrectly constructed prior knowledge, the problem solver will reach an impasse that prevents further constructive work on the problem

(Knoblich et al., 1999; Ohlsson, 1992). Knoblich and colleagues proposed that during impasse, a problem solver's prior knowledge leads him or her to incorrectly apply constraints to the problem-solving situation that limit the possibilities for solution. In their research on matchstick arithmetic problems (see Fig. 24.3), participants' prior knowledge of algebra (which is relevant in most equation solving but is irrelevant in matchstick arithmetic) blocked their consideration of relevant ideas during problem solving. For example, participants may have assumed that what happens on one side of the equation must happen on the other side, or that the operands could be subdivided to correct the equation, whereas the operators could not. Continued progress was only possible when these mental constraints were relaxed and additional ideas were considered for solution.

In imaging research exploring comprehension in insight, Lang and colleagues (2006) recorded event-related brain potentials (ERPs) in participants who gained an insightful understanding of the underlying structure in the number reduction task (NRT) and compared them to ERPs of those who did not achieve such an understanding. In the NRT, participants apply rules to sequentially presented numbers to produce a new string of numbers, the last of which is most important. For all trials, the pattern of cues was *ABCCB*, such that the last answer is the same as the second answer. Participants who came to explicitly understand that they could skip to the end of the sequence based on this pattern were viewed as achieving insight. Lang and colleagues reported that those who eventually achieved insight had greater slow-positive-waveform (SPW) amplitude across the length of each trial over parietal electrode sites and a relatively enhanced P3a

$$\text{Problem: IV} = \text{III} + \text{III}$$

$$\text{Solution: VI} = \text{III} + \text{III}$$

$$\text{Problem: III} = \text{III} + \text{III}$$

$$\text{Solution: III} = \text{III} = \text{III}$$

Fig. 24.3 Sample matchstick arithmetic problems (after Knoblich et al., 1999, p. 1536). The goal is to move a single stick in such a way that the initial false statement is transformed into a true arithmetic statement.

component over frontal-central sites, both observed from the outset of the task, compared to those who failed to achieve insight. Researchers had previously tied such effects to increased working-memory involvement (Vos et al., 2001) and the perceived novelty or distinctiveness of the stimuli (P3a; Gaeta et al., 2003). Considered together, these results suggest that thought processes applied in earlier trials determined whether participants would absorb the correct knowledge to achieve a deep conceptual understanding of the task.

Restructuring

Insightful problem solving seems to depend to a significant extent on the problem solver making one or a combination of three basic mistakes: the solver misrepresents the problem elements in such a way as to preclude solution; the solver focuses on information retrieved from memory that is not pertinent to obtaining the solution and may in fact lead him or her away from the solution (Knoblich et al., 1999; Ohlsson, 1992; Seifert, Meyer, Davidson, Patalano, & Yaniv, 1995); or the solver works with insufficient information to achieve success (Kaplan & Simon, 1990). Because they have made one of these critical errors preventing them from reaching solution, the solvers' focus on the unproductive line of reasoning must be broken via interruption or restructuring of thought allowing a shift in solution strategy (Ohlsson, 1992; Weisberg, 1995) and new paths to solution.

There are several theories as to how we change representations or restructure a problem. Gestalt psychologists stressed the importance of restructuring in insight processing and described it as an automatic process that occurs as you attempt (and fail) to solve the problem—you simply “see it in a new light” (Duncker, 1945; Koffka, 1935; Köhler, 1925). According to the cognitive view (Ohlsson, 1992), problem solvers develop a representation of the problem and apply heuristics to transform the problem space so that it looks like the solution space. Eventually, when progress stops, they apply the “restructure when stuck” heuristic (Kaplan & Simon, 1990).

As described previously, people experiencing insight are usually unable to report the processes by which they are able to restructure a problem or even that they did restructure a problem. Therefore, to explain the insight experience, restructuring theories must make room for unconscious reorganization of unsuccessful knowledge structures in favor of continued progress, though not necessarily in

a series of increments, as is common in analysis. Knoblich and colleagues (1999; see also Ohlsson, 1992) have suggested just such a process in their *representational change theory*. First, the problem solver pursues and rejects nearly all the possibilities within the presently available problem space. Once at impasse, the problem solver can reject assumptions about the problem that were made based on incorrectly selected prior knowledge, thereby clearing the path for exploring a problem space based on different assumptions. Finally, reorganization and restructuring are spontaneous and out of conscious control. For example, after reaching impasse when attempting to solve a matchstick arithmetic problem (Fig. 24.3), the participant may refocus on a non-numeric aspect of the problem that is also depicted by the matchsticks, such as the addition sign, as an element of the problem space that may be altered.

When Chronicle, Ormerod, and MacGregor proposed their *progress monitoring theory* (2001; MacGregor et al., 2001; Ormerod, MacGregor, & Chronicle, 2002), they suggested that fixation and impasse may occur prior to insight but that they are not necessary to the process. According to their theory, the problem solver actively monitors progress toward solution and is continually applying problem-solving heuristics that enable him or her to change strategy based on a lack of progress toward solution. Fleck and Weisberg (2004) generated support for the progress-monitoring theory in research using the verbal protocols of solvers attempting Duncker's candle problem. They found that participants often restructured their assumptions about the problem after they rejected solution ideas as implausible without actually having to implement them.

Other researchers have been skeptical that restructuring has to be sudden or that it even has to occur outside of awareness. In an early study on failure and insight, Weisberg and Suls (1973) proposed that failed solutions during the solving process allow participants to acquire additional knowledge regarding problem components that alters future solution attempts. For example, in the candle problem, participants may have discovered that the tacks were too short to go directly through the candle. They may then have wondered what the tacks could penetrate and subsequently made the leap to tacking through the relatively thin box. A solution that could seem like a release from functional fixedness with regard to the nature of the box may have actually been a logical extension of knowledge gained based on previous failures.

Durso and colleagues (1994) reported that participants gradually accumulated solution-related knowledge when they solved anagrams, rather than experiencing sudden, all-or-none solutions. Durso and colleagues asked participants to rate the similarity of word pairs to infer the location of words within the semantic network and to demonstrate the change in network structure that accompanies restructuring. Beginning before problem presentation, continuing during the solving process, and even after solution, participants gradually rated words that were critically involved in the restructuring process as being more similar, showing that, at some level, they may have been steadily accumulating the necessary solution-related information needed to take the critical step of restructuring.

In a series of experiments using fMRI, Luo et al. (2004a) explored the neural correlates of restructuring. It is important to note that in their experiments participants did not solve problems, but rather recognized solutions (or cues), so the cognitive and neural processes necessarily would be expected to differ from those involved in pure solving. Indeed, the patterns of brain activity observed (Luo et al. 2004a, b; Mai et al. 2004) overlap with, but differ from, those observed when people solve problems (Jung-Beeman et al., 2004; Kounios et al., 2006; Subramaniam et al., 2009). Luo et al (2004a) had 13 subjects read incomprehensible sentences followed by solution cues that would eventually trigger an alternative interpretation of a concept that was critical to understanding the sentence, e.g., "You could not tell who it was, because a professional took the photo of that old man (x-rays)." Or "His position went up because his partner's position went down (see-saw)." Participants were presented with a sentence for 7 seconds and asked whether they understood it. Then they were shown the response cue and asked if they understood it in the new context. Participants were assumed to have achieved insight if they initially failed to understand the sentence but understood it after the cue. They found a correlation of insight with activity in anterior cingulate cortex, an area known to monitor cognitive conflict (Carter et al., 2000), and left lateral prefrontal cortex, an area thought to select semantic representations from among competing alternatives (Thompson-Schill, D'Esposito, Aguirre, & Farah, 1997). In addition, the level of ACC activation present in insight trials decreased across blocks, suggesting that the ACC is more involved when the task is novel, before participants develop strategies that facilitate comprehension of sentences of this type.

In similar research, Mai, Luo, and colleagues (2004) presented participants with answers to riddles that they could not solve and examined their neural activity with fMRI. They proposed that when participants switched from their initial, prepotent response to a representation that coincides with the riddle's solution (a process possibly similar to restructuring), this should initiate cognitive conflict reflected by increased activation in the anterior cingulate cortex (ACC). Using ERPs time-locked to the solution word's presentation, Mai and colleagues reported greater negativity for insight trials than noninsight trials 250–500 ms post solution, localized via dipole modeling to the ACC.

In addition, Luo and colleagues (Luo, Niki, & Phillips, 2004b, as cited in Luo & Knoblich, 2007) observed greater ACC activation when participants attempted to solve riddles with heterogeneous solution types than when participants were presented with riddles of a single solution type. Therefore, the role of the ACC in this paradigm may be to facilitate abandonment of incorrect problem representations. However, as the novelty of the problem-solving environment decreases, there may be less experience of cognitive conflict, so the ACC may not need to mediate conflict as actively. It should be emphasized again, though, that these researchers were likely studying a representational change phenomenon that differs from insight as classically conceived—more of a recognition or understanding moment than a generative insight—although the two processes may involve some similar mechanisms.

To what degree is restructuring determined by more fundamental cognitive abilities? While working memory, vocabulary size, and visuospatial ability may help some solvers with aspects of more complex problems, there is little evidence at the moment that they correlate with the ability to restructure a problem, which is the basis of insight. Ash and Wiley (2006) examined the relationship between working-memory capacity and the size of the initial search space of a problem. Working memory is essential for maintaining the elements of a problem during solving, especially for problems with large search spaces (i.e., problems that require the exhaustion of several approaches prior to restructuring). The researchers compared problems with search spaces of different sizes so they could isolate the restructuring component of insight from other processing that may be necessary as the initial problem space becomes more complex. Ash and Wiley found a relationship between working-memory capacity and

the tendency to restructure, but only for problems with large search spaces. For problems with small search spaces, which do not involve much systematic search, working-memory capacity did not predict restructuring (see also Fleck, 2008; Gilhooly & Murphy, 2005). Thus, when restructuring is isolated from other components of problem solving, individual differences in controlled search and the conscious application of strategies are apparently unrelated to success at solving.

Impasse and Incubation

There is some controversy (Dominowski & Dallob, 1995; Smith, 1995; Weisberg, 2006) about what drives restructuring of the problem space and to what degree impasse is necessary for restructuring. Taking a break from the problem after impasse, a period known as incubation, can promote the solution of insight problems (Christensen & Schunn, 2005; Segal, 2004). Because restructuring is so critical if solvers are to overcome an initial misleading solution idea in favor of novel solution ideas (e.g., Martindale, 1995; Metcalfe & Wiebe, 1987; Ohlsson, 1992), it is vital to understand what scenarios promote restructuring. There is a significant literature on the importance of incubation in this regard.

Various theories have been proposed regarding the nature of incubation and the mechanisms of its effect (see Sio & Ormerod, 2008, for a review). First, researchers have posited that incubation may lead to insight because time away from the problem results in the deactivation of incorrect knowledge representations in the brain (i.e., selective forgetting; Smith & Blankenship, 1991). It has also been proposed that incubation may result in success because the unconscious remains at work (perhaps as spreading-of-activation) while the conscious mind is engaged on another task (e.g., Wallas, 1926; Yaniv & Meyer, 1987). In research testing these theories, Segal (2004) reported that solution rates for insight problems improved when participants took a break after impasse, regardless of the duration. Moreover, this break was more successful when the break interval was filled with a cognitively demanding task. In incubation research conducted by Kohn and Smith (2009), an incubation effect was observed when the to-be-solved problems were completely removed from sight during the incubation period, and not when they remained partially in view, implicating the value of distraction/attention switches in incubation, rather than merely selective forgetting. However, Kohn and Smith (see also Vul & Pashler,

2007) only revealed an incubation effect when participants were exposed to misleading information at a problem's outset, lending support to the selective forgetting hypothesis.

Some researchers (Fleck & Weisberg, 2004; MacGregor et al., 2001) have speculated that restructuring may occur as the result of an internal or external search for new information following impasse or failure. Spontaneous restructuring stemming from exposure to relevant external hints has also received empirical support from research demonstrating that exposure to problem-relevant information during incubation periods can facilitate the insight experience (Maier, 1930; Seifert et al., 1995).

Despite the prominent place of incubation as a means of overcoming fixation in many insight theories, research on fixation and impasse has been sparse in part because it is difficult to operationally define fixation: How long must it last? What is considered "limited" progress? Must there be repeated failure with the same incorrect solution? and so on. Although problems that typically produce insight solutions are often created by inserting misleading components designed to generate fixation on irrelevant aspects (Weisberg, 1995), it can be difficult to tell if solvers have actually been misled. Researchers have had some success verifying and evaluating fixation and impasse by collecting verbal protocols (Fleck & Weisberg, 2004; Kaplan & Simon, 1990) and using eye tracking (Grant & Spivey, 2003; Jones, 2003; Knoblich, Ohlsson, & Raney, 2001; Thomas & Lleras, 2009a). Fleck and Weisberg (2004) examined verbal protocols for the presence of impasse characteristics and were able to demonstrate that impasse-like characteristics were present in the thought processes of approximately 45% of participants attempting to solve Duncker's (1945) candle problem. Statements that led Fleck and Weisberg to classify a participant as being at impasse mostly reflected confusion about specific problem components or an inability to generate additional ideas. However, verbal-protocol analysis is not beyond criticism, because it is based on the assumption that what participants actually verbalize accurately reflects their cognitive processes and that they choose to verbalize all the mechanisms to which they can consciously attend.

The use of eye-tracking technology to measure gaze fixation has shown promise as a method for measuring what may be fixation during problem solving (e.g., Grant & Spivey, 2003; Jones, 2003).

Knoblich and colleagues (2001) operationally defined increased gaze-fixation duration to be indicative of impasse during problem solving, and they speculated that increased gaze fixation on specific problem elements could be reflective of fixation on incorrect problem components. Mean gaze-fixation duration increased across the solving period as participants attempted to solve matchstick arithmetic problems (see Fig. 24.3), indicating that solvers began to reach impasse as time spent working on the problem progressed. Furthermore, solvers fixed their gaze on irrelevant elements of the problem during the initial solving period and fixation on relevant items increased with time. Using a somewhat different approach, Jones (2003) operationally defined the point that impasse occurred in the solving process as the instant gaze fixation was at least two standard deviations above mean gaze fixation for the participant. Jones found that all solvers experienced impasse before they reached solution and speculated that impasse preceded a representational change that led to solution. Thus, eye-movement and verbal-protocol research suggests that fixation and impasse play important roles in the insight process and may be fundamental in establishing the necessary environment for representational change.

Insight: Finding the Proper State of Mind

In addition to incubation, there are other processes that facilitate insight. One of these is positive mood. Researchers have often noted a link between positive affect and creativity (e.g., Amabile, Barsade, Mueller, & Staw, 2005), and several studies have directly examined the role of affect in insight (e.g., Isen et al., 1987; Subramaniam et al., 2009). Isen and colleagues were among the first researchers to demonstrate the relationship between insight and positive affect when they observed that participants' solution rates for Duncker's (1945) candle problem increased when brief comedic films were used to induce positive affect. More recently, Subramaniam and colleagues asked participants to indicate their solution strategy (either insight or analytic) on a trial-by-trial basis for solved CRAs during fMRI scanning and to complete self-report measures of affect and anxiety. When participants were high in positive affect and low in anxiety, they solved more problems overall, especially more problems by insight.

Positive affect may promote insight and creativity because it allows people to broaden attention, both perceptually and conceptually, and consider ideas for solution that would typically fall outside the scope

of their awareness (Rowe, Hirsch, & Anderson, 2007). In research exploring the link between cognitive processes and mood, Rowe et al. observed changes in selective attention and semantic access with positive mood. A positive mood state was associated with significantly weaker selective attention (i.e., a broader scope of attention or a leakier filter) on a flanker task, as well as increased semantic access to remote associations in Mednick's (1962) RAT, than were negative or neutral moods. Mood-based performance on tasks of attention and semantic access was highly correlated ($r = .49$), a result not observed for task performance during neutral or negative moods. Rowe et al. interpreted these findings as further support for a common origin (i.e., an affective influence) for the two processes.

In similar research, researchers who compared attentional resources in creative versus less creative individuals found support for a relationship between attention and creativity. As measured by scores on Mednick's (1962) RAT, those high in creativity tended to use hints they had been instructed to disregard (Ansburg & Hill, 2003). A functional-neuroanatomical explanation for such a relationship may be seen in neuroimaging results reported by Subramaniam and colleagues (2009) in which greater positive mood assessed at the start of the experiment session was associated with an increase in insight solutions, as well as brain-related activation in the ACC, both before and during problem solving. Specifically, level of positive affect modulated dorsal ACC activation (the more positive participants were, the higher ACC activation was) during the preparatory interval prior to all problems that were eventually solved. Across all participants, this preparatory activation was stronger for problems that were subsequently solved with insight than for problems subsequently solved by analysis (see also Kounios et al., 2006). These findings led the researchers to suggest that a positive mood may create a brain state helpful for achieving insight, perhaps by modulating the cognitive control system to better detect (or switch to) weak brain activity associated with more distant associations.

The efficacy of brief training intervals in enhancing insight problem solving (e.g., Ansburg & Dominowski, 2000; Cunningham & MacGregor, 2008; Dow & Mayer, 2004; Lung & Dominowski, 1985; Maier, 1933; Schwert, 2007) has also been tested. Training typically involved advice on avoiding common obstacles to achieving insight: initial ideas during problem solving are often misleading;

problem solving may be difficult because you are applying unnecessary constraints to the problem (see Ansburg & Dominowski, 2000; Cunningham & MacGregor, 2008). After learning the heuristics, participants usually worked on example problems that demonstrated the solution and its associated logic. Results of such training regimes have so far been generally limited to domain-specific or even problem-specific training effects, similar to those present with training to solve other types of problems (Ansburg & Dominowski, 2000; Dow & Mayer, 2004; Gick & Holyoak, 1980). Furthermore, training was most beneficial in enhancing solving ability for traditional insight problems, such as riddles and puzzles, and less influential when the insight problems involved real-life contextual information (Cunningham & MacGregor, 2008).

Investigators have also enhanced insight rates by altering the solving process through provision of implicit hints (e.g., Grant & Spivey, 2003; Sio & Ormerod, 2009; Thomas & Lleras, 2007). Furthermore, Christensen and Schunn (2005) observed an increase in insightful problem solving when external hints related to the solutions were incidentally provided during incubation periods that occurred at regular intervals throughout the problem-solving task.

Hints diverting attention from one problem component to another can facilitate the occurrence of insight (e.g., Grant & Spivey, 2003; Kaplan & Simon, 1990; Thomas & Lleras, 2009a). Grant and Spivey were able to enhance solution rates for Duncker's (1945) radiation problem, described earlier, by presenting the problem with the outside surface of the body flashing, drawing attention to a component that could trigger insight. Thomas and Lleras (2007) also directed participants' attention to the problem's solution by having participants track a series of letters and digits that appeared on the computer screen in a sequence such that the eye-movement pattern mirrored the layout of the problem's solution (i.e., across the surface of the skin and moving in toward the tumor). Similar effects occurred when participants directed their attention to letter and number locations resembling the solution pattern without physically moving their eyes to track the stimuli (Thomas & Lleras, 2009a). Furthermore, having participants engage in physical movements that coincided with the solution to Maier's (1931) two-string problem (i.e., swinging their arms back and forth in a pendulum-like motion) facilitated problem solving (Thomas & Lleras, 2009b). This

research collectively supports the benefit of shifting attention from misleading to relevant problem components in facilitating insight.

In addition to facilitatory effects from external hints, the likelihood of experiencing insight has been associated with specific preparatory brain states. For example, Kounios et al. (2006) discovered that neural activity immediately prior to the presentation of a problem predicts whether solutions will arise with insight or analytically. They asked participants to solve a series of CRA problems using the insight judgment procedure. Of interest was the time window preceding the presentation of a CRA problem. EEG and fMRI measures of neural activity during this preparatory time window predicted whether the subsequently displayed problem would be solved with insight or analytically. The analysis of low-alpha EEG activity (8–10 Hz) revealed greater preparatory activity for trials subsequently solved with insight measured over midfrontal, bilateral temporal, and bilateral somatosensory regions. In contrast, the interval preceding trials solved analytically was associated with greater activity over posterior brain regions. A parallel experiment with fMRI generally replicated the results of the EEG experiment and further clarified the neural components underlying the strategy differences, identifying increased signal strength for insight trials in the ACC, posterior cingulate cortex, and bilateral middle and superior temporal gyri. These results suggest that a form of preparation before problem presentation helps determine whether a subject will tackle the subsequent problem with an insight or analytic strategy. Preparation for insight apparently involves inward focus of attention and priming of brain regions supporting semantic processing. In contrast, preparation for analysis involves outward focus of attention on the screen on which the expected problem will appear.

A more recent study by the same researchers revealed that even resting-state brain activity, that is, brain activity when an individual is not engaged in task-directed cognition, predicts that individual's likelihood of later solving problems insightfully or analytically. Kounios and colleagues (2008) grouped participants into high-insight and high-analytic groups based on the proportions of anagrams they solved with insight. High-insight subjects showed greater right-hemisphere EEG activity and more diffuse activity of visual cortex suggestive of broader attention in accord with previous research highlighting an association among insight, right-hemisphere activity, and broad attention (Fiore & Schooler,

1998; Jung-Beeman, 2005; Martindale, 1995). These results demonstrate that the tendency to solve problems with one or the other strategy is a function of states and processes that begin well before the presentation of a problem. Indeed, these states may be relatively stable and constitute a dispositional cognitive style. Such studies of insight-related preparatory and resting-state activity imply that getting the problem solver into the appropriate brain state may be one of the most effective means to enhance insight.

Conclusions: Current Perspectives in Insight

In the current chapter we reviewed the themes and advances in insight research over the last century. Regarding the debate between “business-as-usual” and “special-process” views of insight, research revealing right-hemisphere contributions to insight not present in analysis, as well as the contribution of unconscious processing in insight, has strengthened the perspective that insight is fundamentally different from analysis. Insight researchers have expanded our understanding of the components of insight to include the occurrence of impasse/fixation and the eventual restructuring of thought. Much of the research surrounding these components has focused on mechanisms that facilitate restructuring, and therefore, insight, including the benefits of incubation, external hints, and preparatory mind states. Next we review three of the most significant developments in insight research since the resurgence of research in this area.

Three recent developments in insight research have substantially changed how we study insight and what we know about its cognitive, neural, and affective underpinnings. First, methodological developments in the construction of problem stimuli have circumvented criticisms of the traditional approach of studying insight based on classic insight problems. These methodological developments have laid the groundwork for the second development, namely, the application of neuroimaging techniques to study aspects of insight that could not easily be studied using traditional methods (see Morrison & Knowlton, Chapter 6). Third, there is a new emphasis on examining factors that enhance insight. These three points are briefly discussed next.

Although much was learned in the decades spent studying the solution of more complex “classic” insight problems such as the candle, nine-dot, and two-string problems, more recent innovations

in stimulus construction and methodology have begun to transform the study of insight. The traditional approach of comparing performance on such insight problems with performance on analytic problems has two basic flaws. First, while *processing* can be insightful or analytic, *problems* are neither. Generally, classic insight problems are often solved with a flash of insight. But there is nothing about such problems that *requires* that they be solved with insight. Undoubtedly, subjects sometimes solve them analytically. So the assumption that so-called insight problems are always solved insightfully is problematic. Second, the analytic and classic insight problems used in past studies are complex. Evidence that different types of processes are used to solve them is ambiguous because these two classes of problems differ from each other in many ways—working memory load, modality specificity, and so on—and not just in terms of the insight/analytic distinction.

One approach to overcoming this problem is the development of larger sets of smaller, relatively homogeneous, problems amenable to standardization and norming. An important example of this approach is the development and application of CRA problems (described earlier). These problems can be solved within a few seconds, allowing researchers to acquire more data per subject within a session, which is a prerequisite for neuroimaging studies (see Jung-Beeman et al., 2004, for more on the advantages of such stimuli). Though it is possible that aspects of the insight process are lost when simpler stimuli are utilized, distinctions between the insight processes involved in the solution of classic insight problems and such modern stimuli, should they exist, will be revealed as research in the field progresses.

A related development, based on the notion that a defining feature of insight is the sudden awareness of the solution, is the systematic use of subjects’ judgments about their own solving strategies. As described earlier, the studies of Beeman, Bowden, Kounios, and others require subjects to report, for each solution, whether it was the product of insight or analysis, a distinction with which virtually all subjects indicate that they are familiar. In this way, insightful and analytic processing can be directly compared while controlling for ancillary differences between the stimuli that result in these two types of processes by using many examples of a single type of problem (e.g., CRAs and anagrams).

These methodological developments have fueled an ongoing series of neuroimaging studies of insight

focusing on aspects of problem solving that are, at best, difficult to study using traditional behavioral techniques. As noted earlier, researchers using fMRI and EEG have corroborated the unique role of right-hemisphere processing in insight (Aziz-Zadeh et al., 2009; Jung-Beeman et al., 2004), observed initially in behavioral research. Furthermore, this research has clarified the role of sensory gating and semantic integration in the solution of verbal problems with insight (see Jung-Beeman et al., 2004). Researchers have also linked activity in the ACC, a region associated with conflict monitoring, to the restructuring component of insight (Luo et al., 2004a; Mai et al., 2004); this activation may signify processing involved in the abandonment of incorrect problem representations in favor of continued progress. Finally, neuroimaging has contributed to our understanding of the resting (Kounios et al., 2008) and preparatory (Kounios et al., 2006) brain states associated with the subsequent occurrence of insight.

Because insight can be instrumental to real-world innovation, researchers have also been expanding their efforts to isolate components of insight and factors that influence or facilitate these components. Studies have shown that some components of insight processing rely on the same core abilities as analytic processing, such as working memory, fluid intelligence, general problem-solving ability, and vocabulary (Ash & Wiley, 2006; Davidson, 1995; Fleck, 2008; Gilhooly & Murphy, 2005; Schooler & Melcher, 1995; Sternberg & Davidson, 1982), so methods that improve more fundamental problem-solving abilities (see Koedinger & Roll, Chapter 40) would naturally be expected to improve insight as well. Researchers have also begun to explore correlates of insight that could be exploited in the future as mechanisms for enhancing insight. For example, one correlate that investigators have identified is divergent thinking (Ansburg, 2000; Davidson, 1995; DeYoung, Flanders, & Peterson, 2008). Divergent thinking is the ability to rapidly generate multiple solutions for a single problem, such as listing as many uses as possible for a brick. Divergent thinking has been explored extensively in creativity research (Guilford, 1950) and efforts have been made to enhance it (Clapham, 2001; Runco & Okuda, 1991).

The aforementioned developments in problem stimuli and neuroimaging methods, as well as additional knowledge regarding insight components and factors relevant in facilitating insight, have set the stage for further advances in insight research. We conclude with a discussion of some of the questions

and concerns to be considered by researchers in this advancing field.

Future Directions

The evolution of theories and methodologies in the study of insight has fashioned an ideal climate to enable researchers to continue the exploration of fruitful veins of research, as well as consider topics that have received little attention to date. Neuroimaging offers continued promise in isolating and identifying components of insight, such as restructuring and impasse. We believe that employing a broad range of advances in neuroscientific techniques and theories constitutes an important approach to further elucidating mechanisms of insight and adjudicating among contrasting theories. However, to reach their full potential, neuroscientific approaches must be fully integrated, both in terms of methodology and theory, with behavioral techniques and cognitive theory. For example, metacognitive research supports the notion of sudden conscious awareness of an insight near the point of solution (Metcalfe & Wiebe, 1987; Smith & Kounios, 1996), whereas other behavioral research indicates the accumulation of partial information prior to solution (Durso et al., 1994). If both veins of research are valid and the possibly gradual reorganization of thought occurs outside of awareness and enters consciousness in a sudden leap, then we should be able to determine the point at which enough solution-relevant information has been acquired or activated on the unconscious level to enter into conscious awareness. This should be possible by integrating existing behavioral methods with neuroimaging techniques, thus permitting researchers to correlate the conscious experiences of the individual with associated neural activity.

Though neuroimaging studies have begun to isolate insight-related brain regions thought to reflect relevant information-processing components, equally important is the identification of component sequencing and mutual influence exemplified, for example, by how aspects of impasse may affect restructuring (Fleck & Weisberg, 2004). If insight is best conceptualized in terms of constraint satisfaction implemented by parallel processing, then the use of neuroimaging techniques should be expanded beyond identifying critical brain regions to explore how these regions work together to yield insights (e.g., Payne & Kounios, 2009).

While we learn more about insight itself, we must continue to explore how insight is related to other

forms of creativity and innovation (see Smith & Ward, Chapter 23). Although hypothesized connections among insight and other forms of creativity are helping to stimulate interest in insight, research examining the hypothesized overlap between insight and other types of creative cognition is lacking. Such research will contribute toward delineating the field of creativity research, which suffers from vague and outmoded definitions.

Clarifying the relationships among insight and other forms of creativity is particularly important for the development of techniques to enhance insight (e.g., Cunningham & MacGregor, 2008). Research in the field of creativity enhancement has achieved recent successes, which may very well be generalizable to insight. For example, Markman, Lindberg, Kray, and Galinsky (2007) have evaluated the use of *counterfactual mindsets* as a means of enhancing either creative or analytic thought. In their research, priming people with additive counterfactuals (achieved through statements modifying reality by adding elements to a situation) induced a mindset that enhanced creativity, whereas priming with subtractive counterfactuals (achieved through statements modifying reality by removing elements from a situation) enhanced analytic thought. In a similar manner, Friedman and Förster (2005) have successfully enhanced either creative or analytic problem-solving success by inducing approach or avoidance motivational states. If the relationship between insight and other forms of creativity can be clarified, then these and other creativity-enhancement factors and techniques can be examined for their potential efficacy in facilitating insight.

Interest in facilitating insight, combined with recent advances in delineating the cognitive components and functional neuroanatomy of insight, has raised the possibility of using brain-stimulation techniques such as transcranial direct current stimulation or transcranial alternating current stimulation to enhance insight during problem solving (van Steenburgh, 2011). This approach will undoubtedly contribute to our understanding of the neural basis of insight, though whether brain stimulation ever becomes a practical technique for enhancing insight is currently unknown.

Recent advances in insight research have fostered additional questions for future research to answer. For example, to what degree are the existing research findings generalizable? By defining insight in terms of the subjective sudden awareness of a solution or interpretation, are we lumping together phenomena

that should really be considered separate? Is recognition that a presented solution is correct ("Uh-duh;" Luo et al., 2004a; Mai et al., 2004; Qiu et al., 2008) the same as generating an insight solution oneself ("Aha;" Jung-Beeman et al., 2004; Knoblich et al., 1999)? To what degree can we make conclusions about perceptual insight based on findings using primarily verbal stimuli (Gilhooly et al., 2010)? When an individual solves a CRA problem, an anagram, or, for that matter, a classic insight problem, is this similar to what happens when a person makes a scientific breakthrough (see Dunbar & Klahr, Chapter 35) or comes to a new realization about a real-world situation? With new methodological tools and theoretical perspectives, researchers must take advantage of the current momentum in insight research to broaden their efforts in ways that address such concerns and bridge the gap between the laboratory and life.

Abstract

Scientific research on genius began in the early 19th century and increased in popularity throughout the end of the century and the beginning of the 20th century. Although the first investigations used mainly historiometric methods, later psychologists introduced psychometric and experimental techniques. Definitions of genius fall into two categories: superlative intellect and phenomenal achievement, where the latter can be subdivided into extraordinary creativity, exceptional leadership, and prodigious performance. However defined, genius has been studied from four main psychological perspectives: general intelligence, domain expertise, heuristic search, and blind variation. Each of these perspectives has distinct advantages and disadvantages as explanatory accounts. As a consequence, a comprehensive understanding of how geniuses think and reason will require an integration of all four perspectives. The chapter closes with a discussion of future directions for research.

Key Words: genius, intelligence, IQ, creativity, leadership, prodigies

Introduction

As a psychological phenomenon, genius has been around for centuries. The first genius to leave a name in the historical records was perhaps Imhotep, an Egyptian polymath who lived in the 27th century BCE. The pharaoh's vizier, Imhotep attained fame as the first physician, engineer, and architect—most famous for building the step pyramid of Djoser. Of course, over the centuries the inventory of celebrated geniuses has become very large. Every world civilization produces its own list of prime candidates (Kroeber, 1944; Murray, 2003). In European civilization, names like Isaac Newton, René Descartes, William Shakespeare, Michelangelo Buonarroti, and Ludwig van Beethoven come immediately to mind. Indeed, one could argue that any given civilization is largely defined by the works that its geniuses have created. How much would our perceptions of European civilization change without the *Principia Mathematica* (the Three Laws of Motion),

the *Discourse on Method* ("I think, therefore I am"), *Hamlet* ("To be or not to be"), the Sistine Chapel frescoes (The Creation of Adam), or the Fifth Symphony (the duh-duh-duh-dah "fate knocks at the door" theme)? Such contributions have become iconic.

Although the scientific study of genius is much more recent, the first empirical investigation dates back to the early 19th century, making it one of the oldest research topics in the psychological sciences. Research began when the Belgian mathematician Adolphe Quetelet (1835/1968) published a quantitative study of the careers of eminent English and French playwrights. However, because this investigation was tucked away in a much larger work on "social statistics," Quetelet's contribution to the subject is most often overlooked. The first book-length study entirely and explicitly devoted to genius is Francis Galton's (1869) classic *Hereditary Genius*, an expansion of a journal article he had published

4 years earlier (Galton, 1865).¹ By the end of the 19th century and the beginning of the 20th century the topic of genius had attracted the attention of several notable scientists, some of whom have their own claim to genius (e.g., Cattell, 1903; Ellis, 1904; Freud, 1910/1964; Lombroso, 1891).

Many of these early investigations used historiometric methods. That is, the investigators subjected biographical and historical data to objective and quantitative analyses (Simonton, 1999c). In the 1920s, with the introduction of psychometric assessment, scientific research on genius could pursue a different direction. In 1916, Lewis Terman had devised the Stanford-Binet intelligence scale, and 5 years later he used the measure to identify more than 1,500 high-IQ boys and girls, who where then followed into adulthood. The psychometric results were reported in four volumes of *Genetic Studies of Genius* (Terman, 1925–1959; a fifth volume was a historiometric study published by Cox, 1926). Terman's classic longitudinal investigation had a profound impact on how genius was conceived both within psychological science and among the public at large. To offer one noteworthy instance, Terman's purely methodological decision to use IQ 140 as the threshold criterion for “genius” ended up in the dictionary, a point that we will return to shortly.

Finally, I should mention a third major approach to studying genius. Rather than use historiometric or psychometric methods, a few investigators have employed laboratory experiments. For example, Chase and Simon (1973) conducted an experimental investigation on short-term memory for chess positions using Hans Berliner, a former World Correspondence Chess Champion, as one of the research participants. Similarly, Jensen (1990) published an experimental study of reaction times using Shakuntala Devi, an incredible calculating prodigy who could do the arithmetic faster than she could deliver the answers. However, because contemporary geniuses are seldom willing to expose themselves to such inconvenient scrutiny, laboratory experiments are much less common than either historiometric investigations (where the raw data are archival) or psychometric studies (where the measurements can often be conducted via mail or the Internet). In fact, whether these laboratory participants can be considered “geniuses” depends on how genius is defined. It is to that issue that we turn first. After genius is defined, we will then examine the four principal perspectives on how geniuses think and reason.

Definitions

The word *genius* has a long history of etymological development (Murray, 1989). The word harks back to Roman mythology, where a genius was a person's “guardian spirit” and hence had something to do with that individual's fate and uniqueness.² Over the years, its meaning changed in multiple ways so that most dictionaries give it a half-dozen different definitions. Nonetheless, two definitions have received the most attention in psychological research, namely, phenomenal achievement and superlative intellect. Although distinct, these two usages share a common attribute: Both definitions are highly exclusive, even elitist. Although anybody in Roman times could have a genius, only a very tiny percentage of the population today can be considered to exhibit genuine genius.

Phenomenal Achievement

When Galton (1869) published the first scientific monograph on genius, his focus was clearly on those individuals who made a name for themselves for their phenomenal achievements. In particular, Galton defined *genius* in terms of achieved eminence or reputation, which he conceived as “the opinion of contemporaries, revised by posterity” that prove that given person is “a leader of opinion, . . . an originator, . . . a man [or woman] to whom the world deliberately acknowledges itself largely indebted” (p. 37). It comes as no surprise, then, that Galton listed not only outstanding creators but also exceptional leaders. The creators included eminent scientists, poets, painters, and composers, whereas the leaders included distinguished politicians, commanders, jurists, and religious figures. What is more surprising was a third group: illustrious wrestlers and oarsmen—persons who made a mark in sports! These athletes would presumably have been persons who, had they lived a century later, might have become medalists in the Olympics. Just as interesting, the chapter that appears just before those on wrestlers and oarsmen names winners of “Senior Classics” at Cambridge University, an honor comparable to “Senior Wrangler” in mathematics at the same institution. Both honors were highly competitive—essentially an intellectual Olympics (viz. the “Tripos”). If Galton were conducting the study today, he might have also included the victors of chess championships, prestigious piano competitions, and perhaps even spelling bees!

Galton's (1869) broad conception of genius compels us to consider three manifestations of

phenomenal achievement: outstanding creativity, exceptional leadership, and prodigious performance (cf. Simonton, 2009b). As will become apparent in this chapter, the three manifestations do not all have the same status as candidates for genius, nor do the three necessarily involve the same thinking and reasoning processes.

OUTSTANDING CREATIVITY

A creative idea or behavior is usually defined as having the joint properties of (a) novelty or originality and (b) utility or usefulness (Simonton, 2000b). The first attribute distinguishes creativity from the routine or mundane, the second from the eccentric or insane. Both properties are quantitative rather than qualitative attributes. For example, an idea might be novel or useful with respect to a single person, the person's family, his or her nation, or the world in general. Undoubtedly, for creativity to attain the level of genius, both novelty and utility must be truly outstanding. Not only did no one else come up with the same idea but also the utility of the idea is universal, or nearly so. Einstein's general theory of relativity is a prime example. Apropos of this instance, Immanuel Kant (1790/1952) defined the work of genius as something both original and *exemplary*. Einstein's theory is not only original but also exemplary—a paradigm that provides guidance for subsequent theoretical physicists. Obviously, Kant's definition is closely related to that of Galton.

Nevertheless, Kant (1790/1952) differed from Galton (1869) in arguing that creative genius is found in the arts but not in the sciences. Kant's exception stems from his belief that scientific creativity was governed by a method that could be learned and applied, whereas artistic creativity lacked such guidance. Artistic creators had to devise their own rules for creating exemplary art. Regardless of whether we accept Kant's distinction, it should be evident that there is no such thing as an all-inclusive psychological description of outstanding creativity (Simonton, 2009c). The thought processes by which Mendeleev devised the Periodic Table of the Elements were certainly not isomorphic with those by which his compatriot and contemporary Tchaikovsky wrote his fantasy-overture *Romeo and Juliet*. Even so, the difference may be a matter of degree rather than kind.

Although creative genius is often applied as a qualitative attribute—as if some people are geniuses and others are not—it should be emphasized that outstanding creativity can be treated as a quantitative

variable that admits degrees. For instance, magnitude of genius can be gauged by creative productivity, such as the number of high-impact works (Albert, 1975). The low end of the scale would then be anchored by those “one-hit wonders” who only manage to make a single notable contribution to their field (see, e.g., Kozbelt, 2008b). On the other hand, the highest-order geniuses would be highly prolific. The quantitative rather than qualitative status of genius also holds for the remaining two manifestations of phenomenal achievement.

EXCEPTIONAL LEADERSHIP

The concept of genius was first applied to outstanding creators, and only much later was it extended to exceptional leaders (Murray, 1989). For example, the Thomas Carlyle's (1841) inventory of “heroes” (a.k.a. “geniuses”) includes not only the creators Dante Alighieri, William Shakespeare, Jean-Jacques Rousseau, and Robert Burns but also the leaders Napoleon Bonaparte, Frederick the Great of Prussia, Oliver Cromwell, Martin Luther, and Mohammed, the Prophet of Islam. In some respects, this extension of the concept was unfortunate. For instance, exceptional leadership is far more contingent on nonpsychological situational factors—political, cultural, ideological, and so on—than holds for outstanding creativity (Simonton, 1995). As a result, variables such as general intelligence have a more ambiguous role in the case of exceptional leaders. Although there is no evidence that a creator can be too intelligent to be creative, there is reason for believing that leaders can be too intelligent to lead (Simonton, 1985, 2006). This contrast leads to another: the difference between contemporary and posthumous recognition. According to Galton (1869), genius is judged by “the opinion of contemporaries, revised by posterity” (p. 37). For leaders, both of these assessments are required, whereas only posterity's evaluation is needed for creators. Creators like poet Emily Dickinson and biologist Gregor Mendel can now bask in posthumous recognition and thereby become belatedly identified as geniuses. In contrast, those generals who had no opportunity to lead their armies in decisive battles or those heads of state who never had the chance to make history-making decisions will be forever left out of consideration. Hence, leader genius is more separated from psychological variables than is creator genius. This divergence is one reason why this form of genius will receive less attention than the others.

PRODIGIOUS PERFORMANCE

I have already suggested that Galton (1869) could have included other varieties of prodigious performers besides just celebrated athletes and prize-winning scholars. Anyone who wins competition in a highly valued domain, and by this means has his or her name set down in the corresponding “record book,” might qualify as a genius according to this more inclusive definition. This third definition might be extended to encompass those individuals who never attained such adulthood accomplishments but still established some reputation as child prodigies (Radford, 1990). A notorious illustration is William James Sidis, a mathematics wiz who never realized his potential as an adult (Montour, 1977). A counterfactual example would have been Wolfgang Amadeus Mozart had he died in his early teens, before creating his first masterworks (Hayes, 1989).

Also problematic are savants who exhibit a prodigious level of performance in some very narrow domain despite having almost no capacity to lead anything close to a normal life (Miller, 1999). This group is particularly tricky because savants, unlike most exceptional leaders and unlike all extraordinary creators, are seldom capable of producing ideas or behaviors that feature both novelty and utility. In this way, savants can also be contrasted with prodigious performers, such as a basketball point guard who devises a new tactic to circumvent a novel defense or a virtuoso violinist who conceives an ingenious phrasing for a particularly difficult cadenza. That said, the difference between a child prodigy and a savant may very well be quantitative rather than qualitative. Furthermore, some of the same cognitive processes underlying one might also underlie the other, such as extreme domain-specific memory. Where some music savants can play a composition perfectly after only a single hearing, Mozart famously wrote down the extremely complex score to Allegri’s *Miserere* with only minor corrections after hearing it only once.

Although prodigious performance probably has many more divergent manifestations than either extraordinary creativity or exceptional leadership, it is more similar to creativity in having a largely psychological foundation.

Superlative Intellect

If prodigious performance is going to be taken as a guise of genius, then what about someone whose achievement places him or her in the *Guinness Book of Records*? To be sure, some of the categories

appear far removed from anything truly worthy of the record books, such as the most paperclips strung together in a 24-hour period (Simonton, 2009b). Yet what about a more impressive accomplishment, such as having the highest recorded score on an IQ test? The latter feat would seem legitimate certification for genius status. After all, one respected dictionary followed Terman (1925–1959) by explicitly defining genius as “A person who has an exceptionally high intelligence quotient, typically above 140” (*American Heritage Electronic Dictionary*, 1992). That Marilyn Vos Savant received a Guinness-record entry for having an IQ of 228 would automatically qualify her not only as a genius but also as the world’s greatest genius (McFarlan, 1989). Because IQ tests are among the most reliable instruments in the psychometric arsenal (Stanovich, Chapter 22), defining genius as superlative intellect would seem the optimal strategy from the standpoint of psychological science. This definition has the additional asset that researchers have a much better idea about what is being assessed relative to any of the three criteria of phenomenal performance. Intelligence tests contain specific subscales that make it patent exactly what is being measured—verbal comprehension, vocabulary, general information, analogical reasoning, working memory, perceptual organization, spatial reasoning, processing speed, and so forth (depending on the specific composition of the IQ test). In addition, because all intelligence measures are designed, validated, and standardized prior to administration, it would seem reasonable to assume that these instruments provide a direct evaluation of the thinking and reasoning capacities responsible for phenomenal performance. This assumption was the actual basis for Terman’s (1925–1959) longitudinal study. After assessing his young research participants on the Stanford-Binet, he hoped to show that more than three decades later they would grow up to become adult geniuses as defined by phenomenal achievement.

We will get back to this definition shortly. But before we do, let us at least acknowledge that intelligence tests do not exhaust all the possible psychometric instruments that might be germane to the assessment of genius. Given the manifest connection between genius and outstanding creativity (Smith & Ward, Chapter 23), it is sensible to ask: What about using CQ rather than IQ? That is, why not use a creativity test to gauge genius rather than use an intelligence test? It turns out that the answer is too simple. No consensus yet exists on the optimal

psychometric scale for assessing creativity. This is not to say that no such measures have been created. On the contrary, the number of such instruments has proliferated with abandon (Simonton, 2003a). Although these assessments can exhibit modestly positive intercorrelations (e.g., Carson, Peterson, & Higgins, 2005; Gough, 1979), the relations do not approach the magnitude of alternative IQ tests (cf. McNemar, 1964). Thus, if the goal is to define genius in terms of superlative intellect, an IQ assessment at present surpasses a CQ assessment. Alternative IQ measures are far more likely to triangulate on the same candidate, whereas alternative CQ measures will point to multiple competing candidates.

Be that as it may, I must note a peculiar manner in which the superlative intellect definition is diametrically opposed to the original concept of genius. As noted earlier, genius first indicated something unique about the individual, a meaning preserved in the outstanding creativity definition, and to a lesser extent in the exceptional leadership definition. Geniuses generate something unique that sets them well apart from the crowd, whether it is Whitman's *Leaves of Grass* or Lincoln's "Gettysburg Address." Even the prodigious performance criterion leaves open the option that someone might accomplish something exceptional in a unique and even exemplary manner—such as Dick Fosbury introducing the "Fosbury flop" that completely revolutionized the high jump. Yet the use of an IQ test does not allow for such individualism. Although there are many ways of obtaining a mediocre score on such a test (depending on which specific responses were right or wrong), there is only one way of obtaining a perfect score like Vos Savant did to earn her record IQ. More generally, the higher a person's score on a standardized test, the more that person is reasoning and thinking according to some socially established norm of optimal cognitive performance. This norm is shaped by the group on which the test was standardized and by the psychometrician who created the test in the first place. In this sense, achieving a top score on an IQ test is analogous to ringing the bell at the carnival's fair strength test. The winning ring can only be achieved one way: a perfect strike with maximum force.

Perspectives

Given the definitions discussed earlier, the next task is to identify the cognitive processes or mechanisms that provide the foundation for genius. These can be roughly collated into the following four

categories: general intelligence, domain expertise, heuristic search, and blind variation. Next I review each perspective, laying out the explanatory advantages and disadvantages of each.³ To avoid misunderstanding at the outset, these categories are not mutually exclusive. Quite the opposite, genius will often entail some mix of two or more (see, e.g., Kozbelt, 2008a). The specific nature of the mixture will depend heavily on the particular type of genius. Perhaps only in the case of creative genius are all four perspectives highly relevant.

General Intelligence

Samuel Johnson (1781), the author of the first English dictionary, claimed, "the true Genius is a mind of large general powers, accidentally determined to some particular direction" (p. 5). Expressed in modern terms, geniuses are those who would score high on a test of general intelligence. They then apply this generic cognitive capacity to an arbitrarily selected domain, and phenomenal achievements result. Actually, this concept is not far removed from that held by Galton (1869), who assumed that geniuses were those who enjoyed unusually high "natural ability," so high that they were in the upper tail of the population distribution. Galton argued that it was almost inevitable that an individual with that level of ability would go on to achieve great things. Such intellects just needed to discover the proper subject on which to apply their brilliance. That choice very likely would depend on childhood and adolescent interests and hobbies (e.g., Roe, 1953; Schaefer & Anastasi, 1968) as well as early exposure to role models and mentors (e.g., Bloom, 1985; Simonton, 1984a; Walberg, Rasher, & Parkerson, 1980).

ADVANTAGES

First, the most obvious asset of this explanation is its simplicity—a one-size-fits-all account. Indeed, it provides the most elegant solution by effectively equating the superlative intellect and phenomenal achievement definitions. Second, the explanation also has some empirical support: Psychometric and historiometric studies show that geniuses in most domains are extremely intelligent, most having IQs high enough to fit the dictionary definition of genius (e.g., Roe, 1953; Simonton & Song, 2009). Some studies even find that the degree of achieved eminence is positively associated with the magnitude of estimated intelligence (Simonton, 2006, 2008a; Simonton & Song, 2009; Walberg, Rasher, & Hase,

1978). Third, the explanation also fits nicely with the position that intelligence represents a single latent variable most often referred to as “Spearman’s *g*” (cf. Spearman, 1927), a factor that provides a broad predictor of success by a wide range of criteria (Gottfredson, 1997; Ones, Viswesvaran, & Dilchert, 2005). It would seem natural, therefore, to have the same factor apply to achieved eminence. Fourth, because we supposedly know what goes into a test of general intelligence, it should be relatively easy to infer the cognitive processes that provide the basis for phenomenal achievement (e.g., Jensen, 1992). Presumably, those test subscales that load highest on *g* would assess the most relevant cognitive capacities (e.g., the abilities that underlie performance on Ravens Advanced Progressive Matrices; see Carpenter, Just, & Shell, 1990). Fifth and last, to the extent that genius depends on general intelligence, we obtain a precise answer to the classic question of whether genius is born or made—the issue that Galton (1869) first attempted to answer. The answer is directly expressed by *g*’s heritability coefficient, as estimated in behavior genetics (e.g., Bouchard & McGue, 1981). By this criterion, genius is very much (even if not entirely) born.

DISADVANTAGES

In the first place, not every psychologist subscribes to a single-factor theory of intelligence; rather, many view intelligence as having multiple factors (e.g., Guilford, 1967; Sternberg, 1996). In the specific context of genius studies, the most visible dissenter is Howard Gardner (1983, 1993), whose theory of multiple intelligences allots a distinctive intellect to Albert Einstein (logico-mathematical), T. S. Eliot (linguistic), Pablo Picasso (visual), Igor Stravinsky (musical), Martha Graham (bodily-kinesthetic), Sigmund Freud (intrapersonal), and Mahatma Gandhi (interpersonal). Gardner’s theory thus provides a separate intelligence for exceptional leadership (interpersonal) and even implies an intelligence appropriate for great athletes (bodily-kinesthetic). Gardner (1998) has also speculated about the existence of additional intelligences beyond these seven, namely, naturalist, spiritual, and existential intelligences. If Gardner is correct, then different geniuses do not think and reason in the same manner. Their thoughts have distinct modalities and patterns.

Secondly, it is manifest that genius as phenomenal achievement cannot be taken as equivalent to genius as superlative intellect, at least not as defined by an IQ test. Exceptions exist at both ends of the

intelligence distribution. At one extreme is Marilyn Vos Savant who, though boasting the word’s highest IQ, has yet to produce anything that would ensure an enduring reputation in the absence of her record-breaking IQ score. At the other extreme is someone like William Shockley who did not obtain an IQ score high enough to enter Terman’s (1925–1959) sample and yet still managed to earn a Nobel Prize for Physics as co-inventor of the transistor (Eysenck, 1995). Nobody who was admitted into Terman’s sample attained so exalted an honor. Just to show that Shockley’s case is not unique, a sizable proportion of phenomenal achievers do not have IQs in the genius range (e.g., Cox, 1926; Roe, 1953; Simonton, 2006). A nontrivial minority would not even be smart enough to join Mensa, the high IQ society that stipulates a threshold of around IQ 130 (depending on the test). In sum, the IQ definition yields both false positives and false negatives.

One reason why general cognitive ability corresponds so imperfectly with actual high-grade accomplishments is that the concept of intelligence probably must be broadened to encompass dispositional variables. Galton (1869) himself defined natural ability to include not just intellect but also energy and determination. Cox’s (1926) historiometric study of 301 geniuses concluded that drive, persistence, and determination—or what has more recently been termed GRIT (Duckworth, Peterson, Matthews, & Kelly, 2007)—can readily compensate for a person lacking a stellar IQ. Others have widened the concept of intelligence to include the “intelligent personality” (Chamorro-Premuzic & Furnham, 2006). A critical portion of this intelligent personality must entail openness to experience, a factor that may be more predictive of phenomenal achievement than is intelligence alone (Cassandra & Simonton, 2010; Rubenzer, Faschingbauer, & Ones, 2000; Simonton, 2006; see also McCrae, 1987). Closely related to openness is conceptual or integrative complexity, a cognitive style variable shown to have some predictive value for both extraordinary creators and exceptional leaders (Feist, 1994; Simonton, 2006; Suedfeld, 1985; Suedfeld, Corteen, & McCormick, 1986). Someone high on complexity can view the world from multiple perspectives and then integrate them into a comprehensive perspective—something like the elusive goal of the current chapter!

Aside from all of these considerations, we have to recognize that phenomenal achievement is almost invariably dependent on first attaining sufficient

domain-specific expertise. In all likelihood, this is biggest single reason why Vos Savant, for all her superlative intellect, has been unable to produce a phenomenal achievement. She is a Jane of all trades, master of none.

Domain Expertise

A very large empirical and theoretical literature has developed on expert performance and the acquisition of domain-specific expertise (Ericsson, 1996; Ericsson, Charness, Feltovich, & Hoffman, 2006). With respect to this chapter, the bulk of the work appears most applicable to instances of prodigious performance, such as becoming a virtuoso pianist or a chess grandmaster (e.g., Chase & Simon, 1973; de Groot, 1978; Ericsson, Krampe, & Tesch-Römer, 1993). Even so, the core ideas can easily be extrapolated to the two other forms of phenomenal achievement, especially outstanding creativity. The basic argument is that (a) phenomenal achievement first requires the acquisition of domain-specific knowledge and skills and (b) this domain-specific expertise necessitates approximately a full decade of deliberate practice and study—the “10-year” rule. Only after persons get beyond this period of extensive apprenticeship can they be expected to have the expertise needed to make world-class contributions to their chosen domains. To illustrate, Hayes (1989) studied 76 famous classical composers and determined the age when they began the intensive study of music and the age when they contributed their first unquestioned masterpiece to the repertoire. Typically, these two developmental landmarks were separated by 10 years (see also Simonton, 1991b). This rule even applied to a precocious composer like Mozart.⁴

ADVANTAGES

First and foremost, by viewing genius as dependent on domain-specific expertise, this perspective overthrows a commonplace myth about genius, namely that it is utterly born rather than made—a position dating back to Galton (1869). Instead, genius in any domain certainly requires hard work in the form of study and practice. This requirement is especially crucial for outstanding creativity (where assiduous study is more critical) and prodigious performance (where dedicated practice may be more imperative), but it is probably important in many domains of extraordinary leadership as well. It is certainly no accident that the general most likely to emerge victorious on the battlefield is the leader with the most experience leading his or her forces

in combat (Simonton, 1980). This is not to say that luck or serendipity never plays a role. Some persons are fortunate to be at the right place at the right time (Simonton, 1994). But such individuals seldom attain the highest levels in the annals of genius. As an example, Karl Jansky, an engineer with Bell Telephone Laboratories, made a chance observation that directly contributed to the development of radio astronomy. Yet he is not considered a major figure in astronomy (Murray, 2003). He had no expertise in the domain.

A second significant advantage of this approach is that it provides a strong basis for empirical research. Investigators can examine the specific components of a given domain expertise as well as the optimal procedures for acquiring that expertise (Ericsson, Charness, Feltovich, & Hoffman, 2006). For example, Chase and Simon (1973) conducted a now classic study of chess expertise that showed that while an expert player was better able to reconstruct chess positions when they represented actual games, an expert did no better than novices when the pieces were placed randomly on the board (see also de Groot, 1978). Experts can quickly “chunk” familiar but not unfamiliar arrangements. This acquired chunking ability also provided the basis for Shakuntala Devi’s prodigious calculating abilities (Jensen, 1990). She evidently cannot even view a multiple-digit number without instantaneously breaking it down into factors! Yet it took her a great many years to acquire this capacity. She was not born with the talent.

So impressive are such findings that they have led some researchers to believe that genius can be totally explicated in terms of acquired domain-specific expertise (e.g., Howe, 1999). In a sense, “innate talent” does not exist (e.g., Howe, Davidson, & Sloboda, 1998). If Einstein is considered one of the greatest physicists of all time, it is because he studied harder and longer than his contemporaries. The world’s best student must necessarily become the world’s most praised genius. Valedictorians always come out victorious.

DISADVANTAGES

The first problem with the domain expertise perspective is implied by the close of the preceding paragraph: Its advocates too often take their position to the extreme, arguing for the sole impact of “nurture” with as much misguided enthusiasm as Galton (1869) had argued for “nature.” Although empirical research has shown that eminence is often

enhanced by promoting extreme positions, including on the nature-nurture issue (Simonton, 1976b, 2000c), that is probably not the optimal route to acquiring a full understanding of such a complex phenomenon. Rather than view them as mutually exclusive, it is probably more productive to integrate the two into a single coherent perspective. For instance, it is possible to define talent in terms of expertise acquisition (Simonton, 2008b). Someone can be considered talented if he or she inherited a set of cognitive abilities and dispositional traits that allow him or her to (a) accelerate the acquisition of domain-specific expertise or (b) attain higher performance levels with a given amount of domain-specific expertise. As this definition has it, talent cannot even be defined without assuming the acquisition of domain expertise. It otherwise has no meaning.⁵

In line with the preceding problem, there are certain empirical characteristics of genius that cannot be accommodated entirely within the domain expertise perspective (Simonton, 2000a). This explanatory deficiency is especially conspicuous in the case of extraordinary creativity. One should infer that the optimal strategy would be extreme specialization, concentrating expertise on a specialty area so as to become the world's leading expert in that domain. Yet the opposite is the case: Creative geniuses tend to be much more versatile than the norm, having both extremely wide interests and the exceptional capacity to contribute to multiple domains or subdomains (e.g., Cassandro, 1998; Root-Bernstein, Bernstein, & Garnier, 1993, 1995; Root-Bernstein et al., 2008; Simonton, 1976a, 1976b, 2000a; Sulloway, 1996; White, 1931). The same versatility connection seems to hold for exceptional leadership as well (Simonton, 1976a, 2006; White, 1931). If the 10-year rule applied in these cases, then they would need two or more lifetimes to accomplish what they achieved in a single career. This inconsistency with straightforward domain expertise implies that breadth of knowledge and openness to experience contribute to creative thinking in a manner that has no parallel in those domains that rely exclusively on deliberate practice. This inference is reinforced by what was said earlier about the intelligent personality. For certain kinds of genius, something more is required than simply "practice makes perfect."

Heuristic Search

To get around the limitations of the foregoing two perspectives, we can call up the notion that

some forms of genius are engaged in problem solving of a very high order (e.g., Weisberg, 1992, 2006). This enables us to draw upon the theoretical and empirical work on problem solving pioneered by Newell, Simon, and their colleagues and students (e.g., Klahr & Simon, 1999; Newell, Shaw, & Simon, 1958; Newell & Simon, 1972). Put in a nutshell, researchers in the Newell-Simon tradition make an instructive distinction between "strong" and "weak" methods in problem solving (Bassok & Novick, Chapter 21).

At one extreme, strong methods tend to be highly domain specific but also highly algorithmic, so that the methods pretty much guarantee a solution if competently applied. To offer a simple illustration, anyone with a sufficient amount of algebra can provide the solution ("roots" or "zeros") for the equation $y = 3x^2 - 2x + 10$. The numbers 3, -2, and 10 only have to be plugged into the appropriate spots in the quadratic formula.

At the other extreme, unusually difficult problems—problems that are far more novel and complex—do not easily lend themselves to such tried and true techniques. On the contrary, problem solvers will then have to rely on weak or "heuristic" methods. Unlike algorithmic methods, heuristic methods are often more generic in the sense that they are often applicable to a wide range of problems. Yet partly because of that very domain generality, none of them can guarantee a solution, and it may not always be self-evident which heuristic method is applicable to a given problem. Heuristic methods of the broadest scope include generate and test (or trial and error), hill climbing (or steepest ascent), means-end analysis, and analogy (Klahr & Simon, 1999). Analogy, for instance, has been shown to play a major role in the thinking of scientific geniuses (Gentner & Jeziorski, 1989; Dunbar & Klahr, Chapter 35). A light "wave" is an analogy (Holyoak, Chapter 13).

Needless to say, if creativity is defined by novelty and utility, then heuristic methods are far more likely to produce creative solutions than are algorithmic methods. Algorithms can guarantee a solution, but they cannot assure that the solution will be original. Indeed, although the generate-and-test strategy is probably the weakest of all methods, it frequently assumes primary importance. As Newell, Shaw, and Simon (1962) said, "In spite of the primitive character of trial-and-error processes, they bulk very large in highly creative problem-solving; in fact, at the upper end of the range of problem difficulty

there is likely to be a positive correlation between creativity and the use of trial-and-error generators” (pp. 72–73). A portion of this process will entail trying out alternative heuristic methods and thereby elevate generate and test to what has been called a “trial-and-error meta-heuristic” (Simonton, 2004).

ADVANTAGES

Perhaps the most prominent asset of this perspective is that it demystifies the concept of creative genius (Hayes, 1989). Because creativity is nothing more than ordinary problem solving “writ large,” researchers do not have to call upon any mysterious processes like some “stroke of genius” or “flash of inspiration.” The contrast between everyday creativity and genius-level creativity is quantitative rather than qualitative. Marie Curie did not inherently think any differently than the average person on the street but rather merely applied a set of strong and weak methods to a particular area of expertise. As this statement implies, the heuristic search perspective also connects nicely with the domain expertise perspective, as would be expected given that Herbert Simon directly contributed to both viewpoints. The two perspectives together can explain all three forms of phenomenal achievement, exceptional leadership and prodigious performance as well as extraordinary creativity. These three guises of genius would simply involve a different mix of domain-specific strong methods along with a differential dependence on weak methods. For example, the chess champion probably depends more on game-specific strong methods, whereas the artistic genius probably leans more on the application of more generic weak methods, including trial and error (Simonton, 2007). This contrast may be partially responsible for a striking contrast: Although computers have yet to write poetry deserving of a Nobel Prize or even Pulitzer Prize, computers have beaten the best human chess player in the world (Hsu, 2002). Among other reasons, chess genius is much more algorithmic than poetic genius is.

Another major advantage of the heuristic search perspective is its capacity for inspiring research. Much of this research entails laboratory experiments on problem solving (e.g., Qin & Simon, 1990), but a considerable literature has also been devoted to developing and testing computational models (e.g., Langley, Simon, Bradshaw, & Zythew, 1987; Shrager & Langley, 1990). Of special interest are the discovery programs that purport to replicate the actual creative achievements of geniuses, many

of the programs being explicitly named after those geniuses, such as OCCAM, BACON, GALILEO, GLAUBER, STAHL, FAHRENHEIT, BLACK, and DALTON. A case in point is BACON, a program that has made numerous data-driven or inductive discoveries (Bradshaw, Langley, & Simon, 1983). Of these achievements, the program’s rediscovery of Kepler’s Third Law of Planetary Motion has probably received the most attention. This law relates the planet’s period of rotation around the sun, P , to its distance from the sun, D , according to $P^2 = kD^3$, where k is a proportionality constant. When given the raw data for the planets, BACON was able to arrive at the same law. Furthermore, rather than use a brute-force approach that would examine all possible mathematical functions, the program conducted a heuristic search that restricted the problem space (Simon, 1983). Given that Kepler scores as one of the greatest geniuses in the history of astronomy (Murray, 2003), and given that his three laws are considered among his most significant contributions, BACON can be said to have provided a computer simulation of scientific genius.

It should be noted that the computer program BACON has no domain-specific expertise, so this simulation would seem to contradict the domain expertise perspective. Because BACON also does not display any general intelligence whatsoever, the simulation challenges that perspective as well. Thus, one final advantage of the heuristic search perspective is its seeming egalitarianism: Almost anybody can become a genius. Neither a stratospheric IQ nor 10 years of domain expertise is required. Ironically, although Herbert Simon can certainly be considered to have been one of the great geniuses in the history of cognitive science—as polymath and Nobel laureate—he put much emphasis on this point. For instance, Simon (1973) held that “Mendeleev’s Periodic Table does not involve a notion of pattern more complex than that required to handle patterned letter sequences” (p. 479). Similarly, Simon (1986) conducted an informal experiment indicating that nothing out of the ordinary was needed to discover something that would win the discovery’s originator a Nobel Prize:

On eight occasions I have sat down at lunch with colleagues who are good applied mathematicians and said to them: “I have a problem that you can perhaps help me with. I have some very nice data that can be fitted very accurately for large values of the independent variable by an exponential function, but

for small values they fit a linear function accurately. Can you suggest a smooth function that will give me a good fit through the whole range?" (p. 7)

Of the eight lunch companions, five got a solution in only a few minutes. Not one wondered what Simon was surreptitiously about, nor did any recognize the historic status of the problem they were given. Even so, those five colleagues had independently derived Max Planck's equation for black body radiation. In a separate clandestine experiment, a graduate student in chemical engineering derived the Balmer formula for the hydrogen spectrum (Qin & Simon, 1990). Genius does not amount to much if historic achievements can be replicated so effortlessly by anonymous faculty and graduate students. Although Simon does not provide enough information to discern whether any of his participants had genius-level IQs, he does provide sufficient reason to conclude that none of them had any domain-specific expertise.

DISADVANTAGES

As should be apparent by now, one problem with the heuristic search perspective is that in the process of demystifying genius it ends up trivializing genius. It is not simple to score at stratospheric levels on an IQ test nor is it easy to put in the 10 years of hard labor necessary to attain first-class expertise in an achievement domain, and yet BACON was able to derive in a few seconds what it took Kepler many years to discover. However, this derivation ignores the far richer biographical and historical context in which this discovery was actually made. The Third Law emerged out of a complex matrix of ideas (including the first two laws and his unique physical interpretation of the heliocentric system), and the law was tested on observational data inferior to those fed into BACON. What appears obvious in retrospect was far from obvious in Kepler's day. Indeed, Kepler's astronomy was not fully appreciated by his older contemporary Galileo (who insisted on circular rather than elliptical orbits). It is not even clear that BACON's heuristics would have been available to Kepler in the early 17th century. Kepler may have had to discover from scratch what BACON had programmed a priori into its operation. If this trivialization of genius were justified, then genius would be far more common (rather than less common) than implied by the superior intellect definition. As a rough estimate, rather than represent 1% or less of the population, geniuses should constitute 10% or more.

A second problem concerns this perspective's limited focus. Unlike the domain expertise perspective, research on heuristic search has concentrated mostly on creative problem solving, and often more specifically on scientific discovery (Klahr & Simon, 1999). The two other forms of phenomenal achievement—outstanding leadership and prodigious performance—receive much less attention, if any. Yet it is fair to say that this limitation is not that critical. Insofar as genius-grade leadership requires superior problem-solving skills, there is no reason why the heuristic search perspective cannot provide valuable insights. And, with regard to prodigious performance, it is probably likely that problem solving per se is much less prominent, and when problems do present themselves they might be best solved through strong methods.

A final difficulty with the heuristic search perspective is the insufficient attention it gives to individual-difference variables. Although contrasts in general intelligence might be acknowledged as well as variation in acquired expertise, personality factors are largely ignored, if not outright denied (e.g., Klahr & Simon, 1999; for further discussion, see Simonton, 2003b). Yet as pointed out earlier, phenomenal achievement is associated with a large number of dispositional variables. Although some of these variables may not be particularly germane to understanding how geniuses think and reason (e.g., motivation; but see Amabile, 1996), others are certainly relevant (e.g., cognitive style). We will return to this matter shortly after we present the fourth and final perspective.

Blind Variation

Donald Campbell (1960) proposed that creative thought could be explicated in terms of the two-step process of blind variation and selective retention, or BVSR (cf. BV+SR in Nickles, 2003). In essence, the creator generates two or more "thought trials" or "ideational variants" without secure knowledge of their probable outcomes, and then selects those that appear most useful. The connection between BVSR and the definition of creativity should be obvious: The BV step generates the idea's novelty and the SR step determines the idea's utility. It is essential to acknowledge the following two characteristics of Campbell's original BVSR theory. First, blind variation does not require that the ideational process be random. Although all random processes are necessarily blind, even systematic searches can be blind as well (e.g., radar scans and search grids). Second,

the theory is not predicated on an analogy with biological evolution. On the contrary, Campbell claims that the original prototype of BVSR creativity may be found in Bain (1855/1977), who published his theory 4 years before Darwin's *Origin of Species*. Hence, it is incorrect to call BVSR "Darwinian" (cf. Kronfeldner, 2010; Simonton, 1999b). Indeed, it might be more correct to call it "Popperian" given its close connection with Karl Popper's philosophy (Dennett, 1995; e.g., Popper, 1972).

Unfortunately, Campbell (1960) never fully developed BVSR as a theory of creativity, but instead turned to questions of sociocultural evolution and evolutionary epistemology (e.g., Campbell, 1965, 1974). However, over the past couple of decades Simonton has published a series of target articles (1999a, 2007, 2010), book chapters (e.g., 1993, 2009a), and books (1988, 1999b) that gradually converted BVSR into a comprehensive theory of creative genius in both the arts and sciences. So it is Simonton's version of Campbell's theory that we here refer to as the blind variation perspective on genius. One asset of the updated version is that Simonton (2010, 2011a) provided a formal (mathematical) definition of "blindness" that removed a regrettable imprecision in Campbell's informal (verbal) definition. That definitional vagueness had inspired too many unnecessary objections to the BVSR position (e.g., Kronfeldner, 2010; Sternberg, 1998; Thagard, 1988).

Like the previous three perspectives, the blind variation perspective has both advantages and disadvantages.

ADVANTAGES

To begin with, the blind variation perspective is integrative: Rather than restrict creativity to a single process, the theory recruits a wide range of processes to generate the ideational variations, the only stipulation being that they have some degree of blindness (Simonton, 1999b, 2011b). According to this perspective, the thinking and reasoning processes underlying genius-level creativity can be placed along a continuous dimension from total sightedness to complete blindness (Simonton, 2011a). In the parlance of the heuristic search perspective, problem-solving methods can range from algorithmic strong methods to an exceedingly weak method like generate and test, with the heuristic procedures used by BACON to discover Kepler's Third Law falling in the middle (Simonton, 2011b). Other processes or procedures far more likely to reside near the blind end of this dimension include (a) remote

associations (Mednick, 1962), (b) rare associations (Gough, 1976), (c) divergent thinking of various kinds (e.g., "unusual uses;" Guilford, 1967), (d) primordial or primary process cognition (Martindale, 1990; Suler, 1980), (e) Janusian associations and homospatial imagery (Rothenberg, 1979), (f) allusive or overinclusive thought (Eysenck, 1995), (g) clang associations (Hadamard, 1945), and (h) behavioral tinkering (Kantorovich, 1993). An illustration of the last blind-variation procedure is how James Watson came up with the DNA code via the trial-and-error manipulation of cardboard models for the four bases (Simonton, 2011b). In line with what Newell, Shaw, and Simon (1962) suggested earlier, the more extraordinary the creativity, the higher is the likelihood that the participating processes operated closer to the blind end of the spectrum. Accordingly, the blind variation perspective purports to be especially useful in comprehending creative genius of the highest order.

Besides being integrative, the blind variation perspective claims considerable explanatory power (Simonton, 1999b, 2010). That is, many aspects about creativity and creative genius become more interpretable within a BVSR framework. For instance, the perspective is most consistent with several individual-difference variables associated with creative achievement, such as why creativity is positively associated with reduced latent inhibition (e.g., Carson, Peterson, & Higgins, 2003). Highly creative people often come up with ideas in states of defocused attention in which they notice things they are supposed to ignore (e.g., how a certain mold ruins bacteria cultures). Because reduced latent inhibition is also associated with psychoticism and schizotypy (Eysenck, 1995), this connection provides a basis for comprehending why exceptional creativity is often linked to some degree of psychopathological symptoms, especially among artistic geniuses and revolutionary scientists (Ko & Kim, 2008; Ludwig, 1992; Post, 1994). Perhaps for this reason highly creative individuals are more prone to come from family lineages with higher than average rates of psychopathology (e.g., Carlson, 1970; Richards, Kinney, Lunde, Benet, & Merzel, 1988). Creativity and psychopathology have been shown to share a genetic basis (Kéri, 2009; see also Eysenck, 1995).

In addition, the blind variation perspective accounts for certain key developmental factors (Simonton, 1999b, 2010). As an illustration, Campbell (1960) speculated that "persons who have been uprooted from traditional cultures, or who have

been thoroughly exposed to two or more cultures, seem to have the advantage in the range of hypotheses they are apt to consider, and through this means, in the frequency of creative innovation" (p. 391). This speculation enjoys empirical support (e.g., Leung, Maddux, Galinsky, & Chiu, 2008). Similarly, data are in line with Kuhn's (1970) conjecture that revolutionary scientists are often "very new to the field whose paradigm they change" (p. 90; see Jeppesen & Lakhani, 2010; Simonton, 1984b). Excessive expertise can hinder exceptional creativity if it prematurely truncates the range of ideational variants (Simonton, 2000a, 2011b). It may be for this cause that experiments find that creative performance is often enhanced when individuals are exposed to unpredictable, novel, or incongruous stimuli (Finke, Ward, & Smith, 1992; Proctor, 1993; Rothenberg, 1986; Sobel & Rothenberg, 1980; Wan & Chiu, 2002).

Finally, the blind variation perspective has had some predictive value (Simonton, 1999b, 2007, 2010). Of special importance are combinatorial models that can account for a wide range of phenomena related to extraordinary creativity, such as creative output across and within careers or the dramatic event where two or more scientists independently arrive at the same discovery (Simonton, 2004, 2010). It is also worth mentioning in this context the existence of computer programs that operate according to BVSR principles (Goldberg, 1989; Holland, 1975, 1992; Koza, 1992). These programs have successfully planned fiber-optic telecommunication networks, made forecasts in currency trading, designed steam and gas turbines, enhanced oil exploration and mining operations, and improved the efficiency of jet engines (Holland, 1992), and solved difficult problems in algebraic equations, the determination of animal foraging behavior, the design of electrical circuits, and the identification of optimal game-playing strategies (Koza, 1994; Koza, Bennett III, Andre, & Keane, 1999). One of these programs even rediscovered Kepler's Third Law (Koza, 1992). Thus, these blind variation programs more than hold their own relative to the discovery programs that implement heuristic searches. Given that all computer programs that simulate creativity have so far relied on some kind of random generator (Boden, 2004), it would seem that blind variation has a critical place in extraordinary creativity (Simonton, 2010, 2011b).

DISADVANTAGES

The primary drawback of the blind variation perspective is that it has only been extensively developed

for just one form of genius, namely extraordinary creativity. Although it might be at least partially applicable to exceptional leadership as well, such an application remains to be worked out. The perspective is not likely to have any value for understanding most forms of prodigious performance. Whereas the improvisations of a virtuoso jazz musician probably depend somewhat on blind variation, it is hard to imagine the value of such processes for a chess champion or Olympic athlete. Finally, it would be absurd to hold that superlative intellect was contingent on BVSR. In general, the more a domain of genius is contingent on acquired expertise (including intelligence test performance as a very special form of expertise), then the less relevant BVSR becomes as an explanatory perspective. The blind variation perspective is confined to situations when the genius must "think outside the box," "go beyond the information given," or engage in "lateral thinking." Hence, blind variation largely begins where expertise ends. Nevertheless, insofar as extraordinary creativity counts as the most prototypical form of the phenomenon of genius, this limitation may not be all that irksome.

Paradoxically, a second shortcoming of the blind variation perspective ensues from one of its strong points: its very integrative nature. BVSR theory is inclusive rather than exclusive, accommodating so many diverse forms of thinking and reasoning—explicit and implicit, voluntary and involuntary, logical and irrational, systematic and stochastic, and so on. Hence, a critic of the perspective must seriously wonder whether it has any conceptual integrity. This skepticism might only be reinforced rather than reduced by the intimate connection between the BVSR theory of creativity and "universal selection theory" (Cziko, 1995, 1998, 2001). A theory that applies with equal success to biological evolution, the immune system, neurological development, operant conditioning, and other phenomena cannot possibly provide more than a superficial account of genius, creative or otherwise. Consilience can certainly be a virtue (Wilson, 1998). Yet such knowledge unification can also be a vice. By explaining everything, a theory might just end up explaining nothing.

The last failing could be connected with a third flaw: In comparison to the previous three perspectives, the blind variation perspective has not stimulated nearly as much empirical research. Moreover, the bulk of the research regarding the model has been historiometric rather than psychometric or experimental (e.g., Simonton, 1991a, 2007). Yet it is conceivable that this deficiency might be remedied in the

future as increasingly more investigators come to view creative genius from this perspective. Alternatively, a critic could very well argue that the blind variation perspective is so inclusive that it cannot support empirically decisive tests. One critic of the blind variation perspective even said that it represents a religion rather than a science (Sternberg, 1999).

Conclusions

Genius can be defined in two principal ways: as superlative intellect and as phenomenal achievement. Furthermore, the second definition can encompass extraordinary creativity, exceptional leadership, or prodigious performance. Given this conceptual heterogeneity, it is understandable that the phenomenon has been examined from at least four major perspectives: general intelligence, domain expertise, heuristic search, and blind variation. Each perspective has variable utility depending on the definition of genius. This linkage between definition and perspective is most obvious in the case of general intelligence and superlative intellect because the latter tends to be most frequently defined by the former. The domain expertise perspective probably has the greatest explanatory value for understanding prodigious performance, whereas the heuristic search and blind variation perspectives prove most useful in discussing extraordinary creativity.

It is apparent that exceptional leadership has received somewhat less attention as a guise of genius. Because leadership is an intrinsically social rather than individual phenomenon, it is reasonable to assume that much more is involved relative to the other kinds of genius. This increased complexity could entail individual characteristics as well as the situational factors touched upon earlier. For instance, charisma no doubt has a role to play in exceptional leadership (Deluga, 1997, 1998; Emrich, Brower, Feldman, & Garland, 2001; House, Spangler, & Woycke, 1991). Yet charisma probably has a minimal place in extraordinary creativity or prodigious performance—and certainly not in superlative intellect. Nobody needs charisma to score at the highest levels on an IQ test.

Future Directions

A great deal has been learned about genius since the days of Quetelet, Galton, and Terman. Yet much more needs to be learned as well. Certainly more scientific work is needed on how geniuses think and reason. This additional research should most fruitfully pursue the following three lines of inquiry:

1. With genius coming in four varieties—superlative intellect and three types of phenomenal performance (extraordinary creativity, extraordinary leadership, and prodigious performance)—perhaps the most vital question is their empirical interconnections. To what extent are the three kinds of phenomenal performance contingent on not just superlative intellect but also various subsidiary forms of cognitive ability, such as spatial reasoning (see Hegarty & Stull, Chapter 31)? To what degree does extraordinary leadership depend on extraordinary creativity? Can charismatic leadership be conceived as prodigious performance?

2. In a like manner, with four major perspectives on genius, of whatever variety, an equally central issue is how these perspectives interrelate not only with each other but also with the four varieties of genius. For example, how does general intelligence relate with the three other perspectives? Is there a minimum IQ necessary to acquire domain-specific expertise, and does that intelligence threshold depend on the form of expertise? Do different heuristic methods have differential applicability to diverse forms of phenomenal achievement? How does blind variation intermesh with the application of heuristics? Does it enter passively or tacitly by default? Can the capacity for blind variation be acquired as a part of a person's expertise?

3. The resolution of the previous two enigmas must then be connected with several related issues. As an example, how exactly do various individual-difference variables—whether cognitive style or personality traits—impinge on the thinking and reasoning processes behind phenomenal achievement? We know that openness to experience is a consistent correlate of both creativity and leadership, but how specifically does openness affect domain expertise, heuristic search, or blind variation? Can the same individual-difference variable have a positive impact on one but a negative impact on their other? A closely related issue is the relative influence of nature and nurture. For example, to what extent is conceptual or integrative complexity, which is associated with both creativity and leadership, a function of genetic and environmental influences?

A caveat is now in order. Scientific psychology has long been split into two independent subdisciplines (Cronbach, 1957; see also Tracy, Robins, & Sherman,

2009). On the one side of the division is experimental psychology, with its interest in the general human mind—a tradition that harks back to Wilhelm Wundt, the reputed founder of experimental methods. On the other side of the division is correlational psychology, with its fascination with how human beings vary and the way those individual differences covary—a tradition dating back to Francis Galton, the founder of correlational methods. These two psychologies not only have distinct methods (e.g., analysis of variance versus regression analysis) but distinctive perspectives on psychological phenomena. These differences in outlook show up in the research on genius. For example, where the general intelligence perspective belongs to correlational psychology, the domain expertise and heuristic search perspectives belongs to experimental psychology. The blind variation perspective is the only one of the four to try to bridge the gap. Regardless of whether that specific integration was successful, it should be clear that a comprehensive understanding of genius must require researchers to aspire to such an integration of the two scientific psychologies.

Notes

1. One could argue that Liu Shao's *Jen wu chih* (*The Study of Human Abilities*), written around the mid-3rd century CE, might have historical priority, but having read both Liu and Galton, I must side with the latter. Although Liu is admirably systematic and objective, he fails to specify any core hypotheses, systematically collect any data, or subject any such data to quantification. The same contrasts apply to other candidates for writing the first scientific work solely devoted to genius as a psychological phenomenon. Galton was the first.

2. To be precise, men had a genius and women a juno, but the latter term did not contribute to the later development of the concept. There are female geniuses, but no female junii.

3. It will become apparent that the evaluation of the four perspectives will depend on neither qualitative single-case studies of geniuses nor introspective reports of those geniuses about their thought processes. Although such impressionistic information can sometimes provide useful illustrations, they cannot be considered reliable scientific data. Such data can be used for or against any perspective (e.g., Dasgupta, 2004; Simonton, 2004; Weisberg, 2006).

4. Hayes (1989) committed one conspicuous error, however, saying that "Albeniz's first masterwork was written in the 72nd year of his career!" (p. 296). That composer died before his 49th birthday.

5. The participants in the Study of Mathematically Precocious Youth (SMPY) may eventually illustrate how incredibly accelerated expertise acquisition translates into adulthood genius (Lubinski & Benbow, 1994; Lubinski, Webb, Morelock, & Benbow, 2001; Wai, Lubinski, & Benbow, 2005). Although this longitudinal inquiry still has some time to go before it reaches the scope of the Terman (1925–1959) investigation, it has already

produced one recipient of the Fields Medal, the so-called "Nobel Prize of Mathematics" (Muratori et al., 2006).

Development of Thinking in Children

Susan A. Gelman and Brandy N. Frazier

Abstract

Children's thinking is of broad relevance to the study of thinking and reasoning, because it provides insight into fundamental issues concerning the building blocks of cognition, the role of experience, and how conceptual change comes about. The present chapter reviews four main aspects of children's thinking: (1) developmental changes, and how best to characterize such changes; (2) early cognitive capacities in infancy and early childhood, and the methodological tools that reveal these capacities; (3) causal reasoning and naive theories in childhood; and (4) the ways in which children are prepared to learn from the actions and testimony of others. The chapter ends with open questions and directions for future research.

Key Words: children, thinking, causal reasoning, naive theories, testimony, development, Piaget

Introduction

Why Study Thinking in Children?

Many people study thinking in children because they are interested in children: They may work with children in some capacity (as a teacher, or a speech therapist, for example), or they are parents and have had opportunity to observe their own child's growth (as with Charles Darwin, who wrote detailed observations of the development of his oldest son, William), or they may simply find children to be charming and inherently interesting (recall the popularity of the television show *Kids Say the Darndest Things* in the 1990s). There are also several theoretical reasons that the study of children's thought is relevant, indeed central, to anyone interested in thinking and reasoning.

(1) *The study of children tells us how knowledge comes about and how it evolves.* The kinds of learning that take place in childhood are profound. Consider that in the first 4 years of life, children construct

mental structures to deal with number, space, time, human relationships, physical principles, and organization of the objects and events surrounding them. These achievements entail inherently developmental issues—conceptual change, critical periods, nature-nurture—that can best be studied by a focus on children.

(2) *A focus on children reveals what is intelligent in even the humblest of behaviors.* The simple act of grasping a rattle, or sucking on a hand, or retrieving a dropped toy, can reveal layers of capacity and skill (Oztop, Bradley, & Arbib, 2004; von Hofsten, 2007). This, in turn, helps sharpen the questions, What is thinking? and What are its separable components?

(3) *A focus on children tells us about human preparedness.* What is special about our species that permits us to learn certain skills rapidly and with minimal training? Language is a key example. Children are actually better language learners than adults (Johnson & Newport, 1989).

This suggests a biological preparedness to learn language. At the same time, this prepared learning takes place within certain constrained conditions (e.g., learning from live interlocutors, not televised images; Kuhl, Tsoa, & Liu, 2003).

(4) *Childhood lays bare human reasoning biases.* Human thought is limited, biased, and prone to heuristics and shortcuts (Gigerenzer, 2000; Kahneman, Slovic, & Tversky, 1982). If one focuses on adults, these limitations can sometimes be difficult to see. In children, however, they are overt. One example is that of egocentrism. Originally proposed by Piaget and Inhelder (1956) to be characteristic of an early developmental stage, it turns out to be a tendency throughout the lifetime (Keysar, 2007).

(5) *Development is a methodological tool.* The study of development answers questions that cannot otherwise be addressed when reasoning structures are well in place. Stephen Jay Gould (1983) exemplifies this point in his discussion of whether a zebra is a white animal with black stripes or a black animal with white stripes. An examination of a mature zebra provides no insight, since white and black stripes are intertwined. To answer this question, biologists have had to examine the developing zebra embryo (thereby reaching the conclusion that a zebra is a black animal with white stripes!). When focusing on human thought, developmental methods likewise permit special insights: Longitudinal methods reveal the stability of traits or beliefs over time, and microgenetic methods reveal the process of change as it unfolds (Siegler & Crowley, 1991).

Plan of This Chapter

This chapter takes a selective approach to the vast subject of the development of thinking, focusing on four main topics. First, we review the broad developmental changes in thought that take place in childhood, and we briefly discuss theoretical debates concerning how best to characterize these changes. Second, we review a sampling of the rich and varied evidence for early cognitive capacities, in infancy and early childhood. A consistent theme throughout the past 40 years has been the surprising complexity and sophistication of early thought. In this section, we also briefly touch on the importance of appropriate methodological tools for uncovering these abilities. Third, we consider the realm of causal reasoning and naive theories, as an example of the cognitive structures that children are building

as well as processes that contribute to those structures. Finally, we note the importance of social input to children's developing thought, and the ways in which children are prepared to learn from the actions and testimony of others.

Developmental Change

When interacting with children, one is immediately struck by the differences in behavior as a function of age. Just by knowing a child's age, it is possible to predict quite accurately which skills the child will and will not yet have acquired. A newborn infant can't grasp a toy or recognize herself in a mirror, let alone talk or add a series of numbers. A 5-year-old child is highly skilled at language and mirror recognition and can recall past events but typically can't yet read or multiply numbers. A 10-year-old child can read, write, multiply, and divide but doesn't seem to have much grasp of the political issues of the day, has no methodological approach to scientific problems, and reasons about moral issues in a manner that seems rather rule-bound and rigid. A 17-year-old seems on a different plane of thought, able to reason skillfully about all of the issues that elude the younger children.

The theory that is best known and most influential to describe and explain these developments is that of Jean Piaget, the prominent Swiss scholar who is widely considered the "father" of cognitive developmental psychology. Piaget is rightly credited for a number of remarkable achievements. He came up with an ambitious, overarching theory that explains all of cognitive development (as opposed to working on just one aspect or sliver of cognition), and he is still recognized as capturing fundamental differences between children of different ages. Aspects of his theory are surprisingly forward looking and validated by more recent research. Piaget envisioned children as active, constructive thinkers, not simply passively taking in information supplied by others. He emphasized the importance of intrinsic motivation (vs. reward). And, over the course of a remarkably productive career, he made an amazing variety of interesting observations about children's thinking across many topics ranging from children's understanding of physical causality to their understanding of dreams, to their understanding of morality.

It is beyond the scope of this chapter to provide a full description or evaluation of Piaget's theory (see Flavell, 1963; Ginsburg & Opper, 1969; Piaget, 2000). However, we will briefly review his theory of stages and turn to four broader questions that

underlie this framework: whether there can be said to be qualitative change over childhood in the nature of thought; whether children's thinking is domain general or domain specific; the nature of individual and cultural variation; and the effects of training and environmental experiences on cognitive development.

Piagetian Stages: A Brief Overview

Piaget proposed that children progress through four stages of thought, corresponding to distinct age periods: sensorimotor (0–2 years), preoperational (2–7 years), concrete operational (7–11 years), and formal operational (11 years +). Each of these stages is said to be characterized by certain limitations as well as certain achievements. For example, at the beginning of the sensorimotor period, infants don't realize that objects still exist when they disappear from view (i.e., they lack object permanence); at the beginning of the preoperational period, children don't realize that quantities are unchanging if their shape is transformed (i.e., they lack conservation of number, conservation of volume, etc.).

According to Piaget, stages have the following characteristics: Each stage is a qualitative advance from the previous stage; at a given stage, thinking is uniform, making use of the same structures to address a broad range of problems across a broad range of topics; the sequence of stages is unchanging and universal; and children can't be trained to move to a new stage before they're ready. Each of these assumptions has been called into question on the basis of more recent research evidence, which we review here.

Qualitative Versus Incremental Change

One tenet of stage theories is that children undergo qualitative changes in thought over time. For example, Piaget and Inhelder (1956) proposed that preoperational children are egocentric, literally having difficulty taking into account a perspective other than their own. On this view, it is not until the concrete operational stage that nonegocentric thought becomes possible. For example, when given a three-dimensional display depicting three mountains and asked to report the perspective of a person sitting across the table from themselves, preschool children typically report that the person sitting across from them will see the same spatial perspective as their own. In contrast, by 7 years of age, children will consistently report the other person's perspective correctly.

One of the central challenges to a stage theory is that Piaget underestimated children's abilities—sometimes strikingly so. Although there is controversy regarding just how capable infants and young children are (see Woodward & Needham, 2009, for discussion), there is broad agreement than children are much more capable than Piaget's initial observations would suggest (see the later section entitled "Early Competence"). This critique has been directed toward both methodological and theoretical issues. At a methodological level, the concerns are multiple. Piaget's methods were highly demanding and complex from an information-processing perspective. Children were often asked to explain their answers (thus requiring verbal and metacognitive abilities, in addition to whatever conceptual capacity was being measured). In addition, Piaget's tasks were often embedded in an unfamiliar experimental context that did not permit children to make use of more familiar strategies or contexts. (We also note, however, that novel contexts may be required to reveal reasoning as opposed to retrieval of learned routines.)

Considering once again the example of egocentrism, researchers have found that a variety of modifications can lead to significantly earlier success on a perspective-taking task, including the following: simplifying the display (e.g., presenting a single object with distinctive vantage points, such as a mouse holding a candle in one hand, rather than a scene with multiple objects; Fishbein, Lewis, & Keiffer, 1972), simplifying the task (e.g., asking the child to rotate the mouse so that the candle is facing the researcher, rather than reporting a given perspective; Fishbein et al., 1972), or embedding the task in a more natural set of actions (e.g., communicating the presence of a hidden toy to a parent who has either witnessed the hiding event or not; O'Neill, 1996).

Furthermore, careful task analysis reveals that constructs that Piaget analyzed as unitary may have different levels, so that early capacities are present much younger than Piaget would have granted (again, undermining the notion of a qualitative leap in capacity). For example, perspective-taking turns out to have at least two distinct levels that emerge at different points developmentally (Flavell, Everett, Croft, & Flavell, 1981). Level-1 perspective taking entails knowing *that* someone has a different perspective from one's own; Level-2 perspective taking entails knowing *what* that perspective is. Children may fail to figure out what perspective another person has, while still having a basically nonegocentric grasp of perspectives. Furthermore, children

18 months of age understand that different people can have competing desires (Repacholi & Gopnik, 1997), even though an understanding of competing beliefs takes longer to develop (Bartsch & Wellman, 1995; Rakoczy, Warneken, & Tomasello, 2007).

From a theoretical standpoint, researchers have criticized Piaget's assumption of developmental "dichotomies" (e.g., from concrete to abstract; Keil, Smith, Simons, & Levin, 1998). They note that the reverse developmental pattern can take place as well: An abstract conceptual "framework" may then later be filled in with specifics. For example, long before children have learned the particulars of what differentiates the insides of animals versus machines, they expect animals and machines to differ in their internal parts (Simons & Keil, 1995).

A final point of criticism is that adult thinking isn't as logical and mature as Piaget had suggested. Egocentrism provides a compelling example. Rather than being restricted to a particular developmental stage, egocentrism is found even among adults, using more subtle methods. For example, when placed in a referential communication task and given an ambiguous instruction that could be interpreted from either the speaker's perspective or from an egocentric perspective, adults first gaze toward the referent that is the egocentric interpretation (Keysar, Barr, Balin, & Brauner, 2000). Similarly, when asked to judge whether a hypothetical hiker would be in greater need of food or drink, participants implicitly take an egocentric perspective, being more likely to select "drink" when they themselves are thirsty than when they are not (Van Boven & Loewenstein, 2003).

What do these critiques of Piaget imply about the broader issue of qualitative versus incremental change? Some have concluded that there is no qualitative change in cognitive development, and that instead what is most striking is the continuity from childhood through adulthood (Keil, 1981; Spelke, 2004). Others argue for qualitative change, without the additional commitment to stages, though the nature of that change is quite varied. For example, some have proposed that children's thought changes from associative to theory based (Rakison & Lupyán, 2008; Sloutsky, 2003), whereas others argue that children's thought is more akin to theory change in science (Carey, 2009; Gopnik & Schulz, 2004). Maturational changes (e.g., in working memory; in prefrontal cortex and inhibitory control) have also been proposed to yield stage-like shifts (Case, 1992, 1995; Halford, Cowan, & Andrews, 2007; Morrison

& Knowlton, Chapter 6). These issues are among the most central puzzles of cognitive development.

Domain Generality Versus Domain Specificity

Piaget proposed that thinking at a given stage was "all of a piece"—a child who is preoperational when reasoning about quantity is also preoperational when reasoning about morality, gender, classification, or perspective taking. In other words, he assumed that *domain-general* principles characterize thought. Although domain-general principles are important, more recent evidence shows that domain-specific principles are also important. For example, children do better than adults at learning a second language, whereas adults do better than children at learning higher mathematics, thus suggesting that different processes are at work in these different domains (Gelman & Noles, 2011).

At least three sources have been offered to account for domain differences in cognitive development: modularity, experience and expertise, and causal theories. Modularity is the position that certain cognitive processes are biologically constrained as the result of our evolutionary heritage. Development in these areas is thought to be highly predictable, making use of innate structures and domain-specific processes. Often (though not necessarily) these domains are associated with particular brain regions. A classic example is that of face perception, which emerges early and predictably in infancy and is associated with the fusiform face area (FFA) in the brain (Kanwisher & Yovel, 2009). Other cognitive processes that have been hypothesized to reflect modularity are language acquisition (Pinker, 1994) or numerical reasoning (Feigenson, Dehaene, & Spelke, 2004).

Expertise can also exert powerful domain-specific effects in children's cognitive performance. A striking example is that a child chess expert outperforms an adult chess novice, when it comes to memory for chess pieces on a chessboard (Chi, 1978). These differences disappear when examining memory outside the domain of expertise (e.g., digit span). One area where expertise effects have significant long-term implications is that of becoming a skilled reader, and there is great interest in understanding the changes that take place with increasing literacy experiences (Treiman & Kessler, 2007).

A final perspective on domain specificity is that children construct causal knowledge structures, often referred to as naïve theories, that reflect the particular

ontology and causal processes of a particular domain (e.g., a theory of mind concerns thoughts and beliefs; a theory of physics concerns objects and forces). On this view, children are seen as analogous to scientists who devise theories to explain phenomena around them and revise those theories in light of contradictory evidence. However, young children differ from scientists in several important respects: They do not systematically test the hypotheses they entertain, and they do not engage in precise measurement or disconfirmation of alternative hypotheses (Kuhn et al., 1988). Nonetheless, children are like scientists in positing basic ontological distinctions and making causal predictions (Wellman & Gelman, 1998). Furthermore, children take in new evidence and revise their hypotheses on the basis of such evidence, as can be seen in the layers of increasing detail and specificity in infants' understanding of physical support (Baillargeon, Li, Ng, & Yuan, 2009).

Individual and Cultural Variation

One area that has not received much research attention concerns the nature of individual differences in cognitive development, as well as cultural variation in the processes of developmental change. Of particular interest is whether these simply involve changes in *rate* of development (e.g., some individuals achieving a certain milestone earlier than others), or whether there are qualitative changes in the *process or outcome* of development.

Recent evidence suggests that there are remarkably stable individual differences in various areas, including theory-of-mind reasoning (Wellman, Lopez-Duran, LaBounty, & Hamilton, 2008), mathematics reasoning (Halberda, Mazzocco, & Feigenson, 2008; see Opfer & Siegler, Chapter 30), and processing speed (Rose, Feldman, & Wallace, 1988). For example, individual differences at age 14 in children's ability to discriminate large, uncountable sets of dots in a visual attention task correlate highly with scores on standardized mathematics achievement tests going back to kindergarten (Halberda et al., 2008). These data suggest that differences found in infancy or early childhood relate to more complex tasks presented later in life, and they argue for continuity across strikingly different tasks.

The importance of cultural context is also a critical issue that has not been sufficiently acknowledged in the past but is beginning to receive more attention. Research with adults demonstrates that cognitive principles once thought to be universal may reflect particular cultural values (Markus & Kitayama,

1991; Nisbett, 2003). For excellent developmental work on this topic, see Greenfield, Keller, Fuligni, and Maynard (2003), Rogoff (2003), Astuti, Solomon, and Carey (2004), and Waxman, Medin, and Ross (2007).

Effects of Training and Experience

Piaget (1964) famously proposed that training cannot affect the progression of stages; the child must be developmentally ready before he or she is capable of benefitting from experience. To some extent this is certainly true: A lesson in calculus will have no effect on a 4-year-old child. Yet it is also clear that children are much more susceptible to training effects than Piaget had originally conceived. Recent intriguing studies demonstrate that certain motor experiences have broad cognitive consequences. For example, the onset of self-propelled locomotion (either crawling or use of a walker) is associated with a host of changes, including reluctance to cross a visual cliff (Campos et al., 2000). Furthermore, providing 3-month-olds with the means to pick up objects, by giving them "sticky mittens" (i.e., Velcro-backed mittens and Velcro-backed toys), leads them not only to explore the objects more intensely (Needham, Barrett, & Peterman, 2002) but also to interpret perceived events in a more sophisticated way (i.e., seeing a reach toward an object as directed toward a particular goal, rather than just a movement of a certain trajectory; Sommerville, Woodward, & Needham, 2005).

Experience can also lead to dramatic changes in perceptual and categorical processing. For example, specific experiences can lead to a process known as perceptual narrowing. At 6 months, infants can universally discriminate all the phonemes of the world's languages (e.g., p vs. b; l vs. r). However, with experience with just their native tongue(s), by 12 months infants lose the capacity to distinguish phonemes to which they are not exposed (e.g., infants exposed to just Japanese lose the capacity to distinguish l vs. r; infants exposed to just English lose the capacity to distinguish two different t sounds in Hindi; Werker & Desjardins, 1995). Perceptual narrowing is not simply an effect of speech perception, but rather seems to be found in a broad range of perceptual abilities (Scott, Pascalis, & Nelson, 2007). One intriguing example concerns face perception, where infants at 3 months show the capacity to discriminate faces of all races equally well, but by 9 months do much better discriminating faces to which they have been exposed; for example, White

babies distinguish other White faces better than Asian faces (Kelly et al., 2007).

Early Capacities

In the prior section, we reviewed some of the evidence indicating that children are much more capable than traditional Piagetian theory would suggest. In this section we consider what children's early capacities are like. We start by discussing methodological issues. Then, because this topic is too large to review in entirety, we have selected a few key themes: infants can represent objects and events; children are not limited to concrete representations; and learning concepts entails more than forming associations. Collectively, these phenomena illustrate the surprising subtlety and sophistication of early thought.

Methodology Matters

One firmly established lesson from the past 40 years of research on children's cognitive development is that methodology matters: How one operationalizes and assesses children's thinking has a powerful influence on children's performance and on the conclusions we draw about their capacities. Time and again we see that task modifications can lead to much more sophisticated performance. Children—especially young children—face difficulty when presented with tasks that require sophisticated verbal, metacognitive, planning, or information-processing skills. For example, Piaget's object permanence task requires that infants pull a cover off a hidden object to demonstrate knowledge that an object remains in existence even if it is out of sight. This requires an ability to hold and grasp the cover, as well as sufficient memory and planning skills to keep in mind the goal of retrieving the object while focusing on the task of removing the cover. The method of tracking infants' looking-time presents a much less demanding task (all babies need do is look), and it shows that infants do indeed track the existence of hidden objects, expecting them to occupy space of a certain size (and therefore evidencing surprise when a barrier moves through the space that the object should occupy; Baillargeon, 1987). More generally, numerous experimental techniques have been devised for infants that make use of the behaviors they have at their disposal (e.g., habituation, head turning, or high-amplitude sucking techniques; Cohen & Cashon, 2006).

Moreover, in some cases infants have limitations that interfere with a conceptual understanding they in fact possess. A good example of this is again

with object permanence tasks. One clever task that Piaget devised is the "A-not-B" task, where babies see a desired object hidden repeatedly at one location (A), and then see the object hidden at a new location (B). By 10 months of age, infants successfully find the object in location A, but erroneously continue to search at location A even when they saw the desired object being hidden at B. This is known as the A-not-B error. Piaget attributed this error to an incomplete representation of the object. However, it turns out that a difficulty inhibiting well-practiced responses contributes to this error (Diamond, 1991).

Even when studying older children, it is easy to underestimate their capacity. One problem is that children have difficulty verbalizing concepts that they possess. For example, children have trouble talking about traits (Livesley & Bromley, 1973), yet they show an understanding of cross-situation consistency when tested with more directed questioning (Heyman & Gelman, 1998; Liu, Gelman, & Wellman, 2007). Another issue involves information-processing demands. For example, one study found that children's pattern of picture recall seemed to differ systematically from that of adults, with children focusing exclusively on individual items and adults focusing exclusively on the category to which the items belonged (Sloutsky & Fisher, 2004a, b). However, when the length of time each item was presented to participants is controlled, by equating the length of exposure for children and adults, the developmental difference disappeared (Wilburn & Feeney, 2008).

Although simpler methods reveal earlier capacities in children, this point does not imply that there are no developmental changes in children's cognitive abilities. At times, simplified tasks reduce the need for sophisticated performance. Similarly, earlier knowledge can be more fragile or limited than later understandings. Thus, for example, although even preschool children can perform analogical reasoning when the perceptual or causal bases for comparisons are made salient (Goswami, 1992), there are nonetheless developmental changes in the depth, complexity, and sophistication of the conceptual relations children can consider (Uttal, Gentner, Liu, & Lewis, 2008).

Infants Can Represent Objects and Events

As seen by the earlier brief review of object permanence, we now know that preverbal infants can represent objects and events, even when they are

out of sight. Not only do infants represent that an object exists, they also represent details of that object, such as its height, density, solidity (e.g., object vs. substance), and capacity to contain things (Baillargeon et al., 2009). They can link visual cues with cross-modal cues (e.g., understanding that a visually bumpy surface matches a tactiley bumpy surface; Gottfried, Rose, & Bridger, 1977). They expect objects to display unity across time and space (Spelke, 2004). They represent the distinction between animate and inanimate objects and expect only animate objects to move on their own (Opfer & Gelman, 2010). They can interpret point-light displays and distinguish animate from inanimate motion on this basis (Arterberry & Bornstein, 2002). They detect patterns in complex motion, parsing action into distinct events (Baldwin, Baird, Saylor, & Clark, 2001). And they represent the number of objects in an array and can perform simple operations of addition and subtraction (Wynn, 1992).

Preverbal infants are also capable of representing information over time; that is, they form enduring memories. Thus, upon viewing a novel event, such as a person making a special lightbox light up by pushing down on it with his forehead, 9-month-olds remember the event over a delay, reproducing the event when presented with the box 1 week later (Meltzoff, 1988). Infants can remember novel events (e.g., the steps required to form a toy rattle) over periods lasting a year or more, although the quality of the memory and the amount retained over time improve with age (Bauer, 2006).

Infants still have a tremendous amount to learn about the world around them, but they have a wealth of early-emerging capacities that make sense of experience.

Young Children Are Not Limited to Concrete Representations

A long-standing and persistent view in the developmental literature is that development entails a process of moving from concrete to abstract. On this view, young children are capable of holding only *concrete* representations and are unable to form more abstract ideas (see Simons & Keil, 1995, for review). This position, however, is belied by a variety of evidence showing that even preschool children readily reason about nonobvious, nonvisible, or abstract entities. One realm in which this is powerfully demonstrated is that of reasoning about mental states (thoughts, beliefs, desires). Although there is clear improvement over time in children's theory of

mind (Wellman, in press; Wellman & Liu, 2004), even before 2 years of age, infants implicitly recognize that a person may hold a false belief (Onishi & Baillargeon, 2005), and that a failed action nonetheless has an intended goal (Brandone & Wellman, 2009; Meltzoff, 1995).

Another demonstration of children's ability to represent abstraction is in the realm of what is called "generic knowledge" (Prasada, 2000). Although children have experience strictly with individuals (this apple, that chair), they rapidly and readily generalize from experience with individuals to abstractions regarding the category as a whole (apples, chairs; Waxman & Markow, 1995). For example, by 30 months of age, children make use of subtle linguistic cues ("Blicks drink milk" vs. "These blicks drink milk") to extend a novel property to a broad class of instances (Graham, Nayer, & Gelman, 2011). Generic concepts may even be a default representation for young children, as they seem to learn generics before more formal modes of expressing generalization such as quantified noun phrases (e.g., "all blicks;" Hollander, Gelman, & Star, 2002; Leslie, 2008).

By 3 years of age, children can use verbal information to update their representations of absent objects (Ganea, Shutts, Spelke, & DeLoache, 2007) and use abstract symbols such as maps or model representations to skillfully to navigate through space (DeLoache, 1987; Uttal, Gregg, Tan, Chamberlin, & Sines, 2001). They can reason about abstract relations, such as ownership, despite the fact that an owned object is concretely no different from a nonowned object (Blake & Harris, 2009; Gelman, Manczak, & Noles, in press; Kim & Kalish, 2009; Neary, Friedman, & Burnstein, 2009; Williamson, Jaswal, & Meltzoff, 2010). For example, they place special value on their own special toys or objects and would much rather own the original attachment object than an exact duplicate (Hood & Bloom, 2008). They believe that food or drink can contain invisible particles (Au, Sidle, & Rollins, 1993; Legare, Wellman, & Gelman, 2009), and that germs can lead to illness (Kalish, 1996; Raman, 2009). They believe that unseen internal parts or power can have causal effects (Gelman, 2003; Gottfried & Gelman, 2005; Sobel, Yoachim, Gopnik, Meltzoff, & Blumenthal, 2007). They seem to posit an invisible "essence" shared by members of a category (Gelman, 2003).

The evidence indicates that children are not limited to concrete representations. Indeed, in some cases the developmental process is from abstract to concrete rather than the reverse: The child at times

starts with a more abstract representation that then gets filled in with concrete details over time (Gelman & Williams, 1998; Simons & Keil, 1995; Wellman & Gelman, 1998).

Learning Concepts Entails More Than Forming Associations

Another important theme regarding cognitive development is that when children learn concepts (and words to express those concepts), they are not simply forming associations but instead are creating meaningful interpretations of experience (Waxman & Gelman, 2009). For example, Preissler and Carey (2004) taught 18-month-old and 24-month-old toddlers a new word (“whisk”) while showing them a photograph of the referent (namely, a photo of a whisk). After repeated experience with this name-picture association, children were presented with a test in which they were asked to pick the “whisk,” given a choice between (1) another photo that was highly similar to the one used during teaching and (2) an actual, three-dimensional whisk object. If the word-learning process is merely one of association (see e.g., Sloutsky, 2003), then children should select the choice that is more perceptually similar to the taught-upon item, namely, the picture. However, if the word-learning process entails conceptual interpretation, then children should understand the relationship to involve *reference* (not merely association) and select the object (which the picture symbolizes). When this same experiment is conducted with autistic children, they respond differently, linking the word with the picture—thus arguably treating the word as associatively linked to the object rather than representing the object (Preissler & Carey, 2005).

A further important demonstration that children do not treat word-object links as purely associative is that children attend to pragmatic, communicative cues from the speaker. If such cues are unavailable, children will not link a word to a referent. Thus, if a novel word is presented in an incidental, nonintentional manner (e.g., projected over a loudspeaker in the room in which the child is sitting), children fail to link the word to the object. The word must be spoken in an intentional, face-to-face interaction (Baldwin, 1993). Furthermore, if the speaker and the child are initially focused on different objects, children check the speaker to gauge her direction of gaze and link the word to the speaker’s focus of attention, not to their own initial focus of attention (Baldwin, 1993). Put a slightly different way,

the association between word and object is blocked when the appropriate communicative cues are not in place. Again, however, autistic children perform differently, linking the word to their own focus of attention rather than that of the speaker (Baron-Cohen, Baldwin, & Crowson, 1997). Finally, if the speaker expresses some uncertainty as to the correctness of the label, children also fail to link the word to the referent (Sabbagh & Baldwin, 2001). Again, this suggests that the word-object relationship is one of reference rather than association.

Causal Reasoning and Naïve Theories

A number of researchers have advanced the view that children’s thought can be construed as sharing important similarities with scientific theories, with a focus on domain-specific ontologies, causal processes, and coherent knowledge structures that undergo qualitative reorganizations over time (Carey, 1985; Gopnik & Wellman, 1994). Although the analogy is imperfect (e.g., young children are poor at conducting systematic scientific investigations to test their theories; Kuhn et al., 1988), the “theory theory” has been a productive framework for characterizing cognitive development. In this section, we focus on the role of ontologies and causation in children’s early reasoning, as well as the implications of the theory theory for conceptual change.

Ontologies

Ontological commitments are those that distinguish different kinds of entities that participate in distinct causal laws. For example, everyday intuition tells us that mental states are distinct from physical objects, even though the mind influences the body (and vice versa), and even though mental states ultimately have a physical basis in the brain. Despite these demonstrable links between mental and physical, we act as if mental entities and physical entities are wholly different sorts of things. Indeed, children and adults alike seem to have difficulty even considering a relation between these two domains, maintaining a strict dualism (Bloom, 2004; Notaro, Gelman, & Zimmerman, 2001; Schulz, Bonawitz, & Griffiths, 2007).

From early childhood, children show evidence for ontological commitments in at least three distinct domains: physics, psychology, and biology (Wellman & Gelman, 1998). That is, they have expectations regarding three-dimensional, bounded physical objects, expectations regarding mental states and mental activities, and expectations regarding self-moving, spontaneously growing entities. Thus, even

infants expect that objects, but not shadows, occupy space (Van de Walle, Rubenstein, & Spelke, 1998), that mental states are distinct from physical objects (Wellman, *in press*), and that people and inanimate objects engage in different patterns of object motion (Opfer & Gelman, 2010).

Causality

Infants are also highly sensitive to causal relations linking objects or events. For example, 3-month-old infants readily learn the contingency between their own action and a causal effect (e.g., kicking to make a mobile move; Rovee-Collier & Barr, 2001), and within the first year of life, infants respond with more positive affect to events that they cause versus those that are uncorrelated with their actions (Gunnar-Vongnechten, 1978; Lewis, Alessandri, & Sullivan, 1990; Watson, 1972). Seven-month-old infants also distinguish a causal physical event (e.g., a ball colliding with another ball, causing it to move) from the backward version of that same event (Leslie, 1984; but see Oakes & Cohen, 1990).

An attention to causal relations can be seen in older children's commonsense theories as well. Children place special priority on causal features, treating them as more important than other sorts of features (an effect known as the "causal status hypothesis"; Ahn & Kim, 2001). For example, if children learn that a novel animal has three features, one of which (promicin in its bones) causes the other two (thick bones, big eyes), they are more likely to classify a new instance as a member of that category if it possesses the causal feature but is missing one of the other two features, than if it possesses the other two features but is missing the causal one (Ahn, Gelman, Amsterlaw, Hohenstein, & Kalish, 2000).

Within specific theories, children display a combination of openness to new causal relations (informed by statistical patterns in the input) and expectations or biases that are informed by prior knowledge and/or ontologies. So, for example, children are highly attentive to statistical cues in the input and use them to learn about how a machine works (Gopnik & Sobel, 2000), what a new word means (Xu & Tenenbaum, 2007), or how to generalize a new property from one animal to another (Rhodes, Gelman, & Brickman, 2010). At the same time, children have a "self-agency bias," whereby they are biased interpreters of statistical evidence: They are more likely to interpret their own action as having a causal effect than the actions of another person (Kushnir, Wellman, & Gelman, 2009).

As another example, children below about 10 years of age expect that mental states cannot have physical effects, thereby resisting the notion of psychogenic illness (e.g., worrying causing a stomach ache; Schulz et al., 2007). However, if children receive repeated empirical evidence in favor of such a causal account, then even 3–1/2-year-olds can overturn this assumption (Bonawitz, Fischer, & Schulz, *in press*). Children, like scientists, make use of a combination of preexisting theoretical assumptions and empirical evidence to derive new conclusions (see Cheng & Buehner, Chapter 12).

Theory Change

One of the more far-reaching implications of treating children's concepts as organized into naive theories is what this approach suggests about conceptual change. Carey (2009, p. 18) argued that theory change in childhood is analogous to theory change in science: "human beings, alone among animals, have the capacity to create representational systems that transcend sensory representations and core cognition... [they] create new representational resources that are qualitatively different from the representations they are built from." For example, although infants have an innate capacity to represent quantities (a parallel individuation system that represents individuals and so permits solving simple addition and subtraction problems; Wynn, 1992), they do not accurately represent positive integers until 3 or 4 years of age (Carey, 2009). Other domains in which conceptual change has been argued for and studied include object kinds, social kinds, theory of mind, matter/substance, and heat/temperature.

Learning From Others

To this point, we have largely focused on the impressive capacities and knowledge of infants and children. However, cognitive development happens not just in the head of the developing individual but also through a process of social interactions with others from whom children can learn (without having to discover everything themselves; see Gelman, 2009; Rogoff, 2003; Vygotsky, 1934/1962).

Learning from others is a powerful tool for gaining knowledge about a range of topics, and especially those that are difficult to observe firsthand (Harris & Koenig, 2006). For example, during the preschool and elementary school years, children learn about how our brains are related to thinking, remembering, and personal identity (Johnson

& Wellman, 1982); they learn that the earth that we live on is a sphere despite the flat appearance of the surrounding ground (Vosniadou & Brewer, 1992); and they learn that when a living thing dies, it is often related to the breakdown or cessation of hidden internal body parts (such as a heart that stops beating; Slaughter & Lyons, 2003). Coming to these conclusions would be difficult without the provision of information (or “testimony”) from more expert adults (Harris & Koenig, 2006).

Pedagogical Stance

From infancy onward, children seem to expect that the people around them have the goal of teaching them new information (i.e., a “pedagogical” stance; Csibra & Gergely, 2009). Infants and young children interpret and learn differently from situations that they construe as pedagogical (e.g., where the adult deliberately seeks and maintains eye contact with the child) than from situations that they construe as nonpedagogical (e.g., where the adult makes no attempt to engage the child’s attention). They seem biased to interpret intentional communication as conveying information that will generalize to new contexts. For example, to use Csibra and Gergely’s example, if I demonstrate how to open a certain type of container (e.g., a milk carton), the child will assume that I am teaching him how to open containers of that kind in general. He does not need repeated demonstrations in order to reach this conclusion. Furthermore, some of children’s seeming “errors” can be reinterpreted in light of this bias. For example, consider infants’ classic A-not-B error (searching for an object in a location where it has most typically been hidden, rather than in the location where it was last hidden; Piaget, 1954). Csibra and Gergely suggest that this error reflects infants’ assumption that the adult is teaching them where the toy is supposed to be stored (i.e., they assume that the adult is teaching them something general about this toy). And indeed, consistent with this interpretation, if the experimenter does not provide communicative cues (e.g., by not first making eye contact with the infant), then the A-not-B error is greatly reduced (Topál, Gergely, Miklósi, Erdőhegyi, & Csibra, 2008).

Imitation

One important means of obtaining information from others is imitation, or copying the actions of others. It is well established that children can engage in imitation of others from earliest infancy

(Meltzoff & Moore, 1977; Meltzoff & Williamson, 2010). Furthermore, children’s imitation appears to have certain qualities that are distinct from that of other species. First, children imitate rather than merely emulate (Tomasello, 1999). That is, children attempt to copy the model’s (intentional) actions, and they do not simply learn something about the environment as a result of observing the results of the model’s actions. For example, if shown how to obtain a toy by holding a tool in a particular fashion, young children will carefully rotate the tool to imitate the precise action of the model, whereas apes will not attend to the manner in which the tool is used (Penn & Povinelli, Chapter 27; but see Whiten, McGuigan, Marshall-Pescini, & Hopper, 2009, for some evidence of imitation in chimpanzees).

Second, children overimitate rather than just focus on the relevant task dimensions (Lyons, Young, & Keil, 2007). For example, if shown how to operate a novel machine using a sequence of actions that includes both causally efficacious (e.g., removing a bolt) and causally irrelevant steps (e.g., tapping on an empty compartment), preschool children will imitate both the efficacious and irrelevant steps. Lyons et al. suggest that children do so because they presume that all the steps provided by the model are causally relevant, even in the face of seemingly contradictory evidence.

And third, children imitate intentional actions and intended actions, rather than just surface behaviors (Meltzoff, 1995). Thus, if 18-month-old children view an adult engaging in an unsuccessful attempt to extract a toy from a location, but where the intended goal is clear, they will imitate in such a way as to carry out the intended action, and not simply to carry out the observed (uncompleted) motor movements. Thus, children’s imitation does not simply involve mimicking surface features of an action, but it entails consideration of the model’s intentions. If an action is highlighted as clearly accidental rather than intentional, toddlers will selectively imitate the intentional aspect (Carpenter, Akhtar, & Tomasello, 1998). Similarly, if an unusual action (e.g., turning on a lightbox with one’s head rather than one’s hands) has no obvious causal basis, children imitate precisely what the model has done (turning it on with their head), but if the unusual action has an obvious causal basis (e.g., the model’s hands are otherwise occupied), then children imitate the more efficient means of carrying out the result (e.g., turning it on with their hands) (Gergely, Bekkering, & Király, 2002).

Evaluating Testimony

Although children learn in contexts that are intended to be instructional, they also extract a great deal of knowledge from the everyday activities taking place around them (Callanan, 2006). For example, everyday conversations provide a rich source of information about gender (Gelman, Taylor, & Nguyen, 2004) and natural kind categories (Gelman, Coley, Rosengren, Hartman, & Pappas, 1998)—even when adults do not intend to teach children specifically about these topics. In addition, children play an active role in obtaining information through conversation. By 2.5–3 years of age, children begin to actively seek knowledge from others by persistently asking causal questions of adults (Callanan & Oakes, 1992; Chouinard, 2007; Hood & Bloom, 1979). Even from this young age, children appear to be asking these “why” and “how” questions with the goal of obtaining explanations—they react with satisfaction when they get an explanation and are likely to repeat their question when they do not (Frazier, Gelman, & Wellman, 2009; see Lombrozo, Chapter 14).

However, the information provided by those around us is not always accurate, as informants may intentionally or unintentionally provide incorrect information. Again, children are not passive in this process. Children actively discriminate between different sources of information and choose from whom they should learn (or, alternatively, ignore).

Early work on children’s attention to adult “testimony” was focused on word-learning tasks. For example, Koenig, Clément, and Harris (2004) asked children to observe two individuals: one who gave correct labels for familiar objects, and one who gave incorrect labels (e.g., stating, “That’s a shoe” in reference to a ball). The children then saw the same two individuals naming a novel object with two different novel names (“That’s a mido/toma”). When asked what the object is called (“Is this a mido or a toma?”), both 3- and 4-year-olds in this study picked the label from the accurate informant over the one provided by the previously inaccurate informant.

This methodology (choosing between two informants with conflicting claims) has been extended from word learning to a variety of tasks, including (but not limited to) causal inferences (Kushnir, Wellman, & Gelman, 2009), object functions (Birch, Vauthier, & Bloom, 2008), and emulation of actions (Birch, Akmal, & Frampton, 2010). This research has also explored many factors that affect

which person’s testimony children will choose to use to guide their learning. Children robustly attend to testimony from accurate informants across a variety of situations and types of knowledge. Preschoolers track the relative accuracy of informants (Pasquini, Corriveau, Koenig, & Harris, 2007), favoring those who provide the highest proportion of accurate answers. Three- and 4-year-olds are sensitive to not only what an informant knows but also whether that informant has been allowed to use that knowledge (e.g., when the knowledgeable informant has been blindfolded; Kushnir et al., 2009). Five-year-olds expect that an individual who provides the correct labels for familiar objects will also know more about words, will know more general facts, and, interestingly, will also behave more prosocially (Brosseau-Liard & Birch, 2010). Children are even willing to override their own observations when they conflict with the testimony being offered by a previously accurate informant (Jaswal, 2010; Ma & Ganea, 2010).

Children’s ability to evaluate informants also demonstrates appropriate flexibility; information regarding the social characteristics of the informant interacts with information regarding their accuracy in the decisions children make about whom to believe. For example, children evaluate an expert as more knowledgeable than a nonexpert (Lutz & Keil, 2002). And when given the choice between a child and an adult informant, if both are accurate, 3- and 4-year-old children prefer the adult (Jaswal & Neely, 2006). However, if the adult provides inaccurate labels, preschool-aged children trust the testimony of a child over that of the inaccurate adult (Jaswal & Neely, 2006). In addition, providing trait labels (referring to an informant as “very good” or “not very good” at answering a question as opposed to “right” or “wrong”) can lead 4-year-olds to prefer an accurate informant after only one trial (Fitneva & Dunfield, 2010). Even 2-year-old children use non-verbal cues from a single instance to select confident informants over informants who appear uncertain (Birch et al., 2010). However, an open question in this research concerns developmental changes in children’s ability to critically evaluate the statements of deceptive individuals with self-serving motives (Heyman, 2008).

A larger open question for this body of research concerns how children’s trust in testimony relates to their important social relationships. We know that preschoolers ask questions and that they are capable of focusing on the accuracy of testimony (even in the

presence of other conflicting, tempting factors), but we do not yet know much about whose testimony children seek out and pay attention to within their everyday lives. A study by Corriveau et al. (2009) begins to explore this question in an interesting way. These researchers looked at the relationship between the attachment status of preschoolers and their willingness to accept their mother's versus a stranger's claims. The researchers found that children with secure attachment status preferred their mother's claims over that of the stranger (unless there were conflicting perceptual cues favoring the stranger's claim). However, regardless of the perceptual cues, children classified as having an avoidant attachment status were more likely to favor the stranger's claim over their mother's, and the children classified as reactive attachment status showed the opposite pattern (relying more on their mother's claims even with conflicting perceptual information that favored the stranger's claim).

Conclusions and Future Directions

Children's thinking is of broad interest to cognitive scientists, because it provides insight into fundamental issues concerning the building blocks of cognition, the role of experience, and how conceptual change comes about. As reviewed in this chapter, prior research provides a wealth of evidence regarding these issues. Nonetheless, many open questions remain. One set of questions concerns the early capacities in infancy that have been uncovered over the past 30 years. Increasingly sophisticated methods have revealed increasingly sophisticated understandings in preverbal infants, yet we still do not fully understand the basis of these capacities. What is innate, and what is learned rapidly during the first few months of life? Is early infancy a kind of critical period? In a related vein, what kinds of input should children receive at a young age? For example, to what extent do the first few months or years of life represent a special period during which rich exposure to different languages, faces, and so on is crucial, and to what extent can these capabilities be acquired later in development? Another puzzle raised by the findings of early capacities in infancy is why infants sometimes succeed on tasks that older children fail (e.g., theory of mind understanding; grasp of physical laws; e.g., Hood, Carey, & Prasada, 2000; Onishi & Baillargeon, 2005).

Another set of open issues stems from the finding that much of children's knowledge comes about from social interactions with others (Gelman, 2009).

Clearly, social understanding plays a major role in cognitive understanding. This then raises the question of how children determine which sources of knowledge to attend to and learn from. Children must somehow sort out the different sources of knowledge, to figure out whom to believe and trust, and whom not to believe or trust. To what extent do (and should) children learn from media sources (e.g., TV, books, videos)? Other useful endeavors would be to integrate the research on testimony with research examining the questions children ask in informal learning contexts, and to investigate how children and adults work together to build an understanding of a phenomenon (e.g., Crowley et al., 2001; Siegel, Esterly, Callanan, Wright, & Navarro, 2007; see Callanan & Valle, 2008 for a related integration).

Finally, future research would benefit from examining cognitive development from new perspectives—both new from a comparative approach and new from a methodological approach. Examining children's thought in a variety of social and cultural contexts promises to reveal new insights. New advances are being made in examining what (if anything) is unique to humans versus other species. And of course it will be crucial to understand the neurological bases of cognitive performance and cognitive change.

Acknowledgments

Support for this chapter was supported by NICHD grant HD-36043 to Susan A. Gelman. We thank Keith Holyoak and Bob Siegler for very helpful comments on a prior draft.

The Human Enigma

Derek C. Penn and Daniel J. Povinelli

Abstract

Why is there such an enormous gap between human and nonhuman minds? Humans have been asking themselves this question for millennia. But if anything, the question has only become more enigmatic since Darwin and the genetic revolution. In the present chapter, we review the various answers that have been proposed to this question in recent years—from a “language instinct” and a “Theory of Mind” to the “massively modular” hypothesis—and argue that none of them provides a satisfactory solution to the enigma of the human mind.

Key Words: human mind, evolution, higher order relational reasoning, language, Theory of Mind, big brain, social intelligence hypothesis, language instinct

In most respects, we’re a rather unimpressive animal. We’re slow, weak, flat-footed, fragile, and flabby. We have big brains. But our social groups are mired in pointless conflict. Our eyesight and hearing pale in comparison to many bird-brained species. We can barely smell ourselves, let alone predators or prey. But it’s been a few billion years since life first evolved on this planet. And in all that time, we’re the only ones that have ever figured out how to light fires, sew, paint, call meetings, throw dinner parties, and send our children to school. Regardless of whether we want to admit it, there’s something remarkable about the human mind.

Of course, our species’ cognitive ability is hardly the only feature that distinguishes us from other animals. Compared to the rest of the great apes, we are also notable for our hairless sweaty skin, the unusual dexterity of our hands, the unique morphology of our eyes, our ability to swim, the prolonged helplessness of our children, and the peculiar biology of our sialic-acid-recognizing proteins, to mention only a few examples among many. But all these other

differences between human and nonhuman apes pale in comparison to the discontinuity between human and nonhuman cognition.

So here’s the enigma, perhaps the most profound enigma in cognitive science today: *Why is the gap between human and nonhuman minds so enormous?*

Humans have been asking themselves this question for a very long time—at least since the ancient Greeks and probably a lot longer than that. But if anything, the question has become even more enigmatic over the last century. Ever since Darwin, we have known that there is a profound biological continuity between humans and every other species. Indeed, we now know that the human species split off from other ape lineages just 5–6 million years ago—the blink of an eye on an evolutionary timescale. And we know that the vast majority of our DNA is identical to that of other living apes (Chimpanzee Sequencing and Analysis Consortium, 2005; Varki & Altheide, 2005). The more we learn about the biology of the human species, the more enigmatic our peculiar mental abilities become.

The striking gap between human and nonhuman cognition has only become more intriguing given what we have learned about nonhuman minds over the last 40-odd years (for a general overview, see Shettleworth, 2010). We now know, for example, that tool making is not a feat unique to chimpanzees—or even primates (cf. McGrew, 1992; Tomasello & Call, 1997). Corvids have turned out to be some of the most proficient tool makers in the animal kingdom (Bluff, Weir, Rutz, Wimpenny, & Kacelnik, 2007; Clayton & Emery, 2005). Species as unassuming as little African cichlid fish and great tits have turned out to behave in ways that seem, at least at first blush, to require “logical” reasoning (Groseclose, Clement, & Fernald, 2007; Peake, Terry, McGregor, & Dabelsteen, 2002). The idea that humans are the only animal with minds has been soundly discredited. Yet we are the only ones with nose rings, iPhones, and baskets. Why?

Over the last decade, scientists and philosophers have proposed any number of explanations for what makes the human mind unique, ranging from symbols (Deacon, 1997) to singing (Mithen, 2006). In this chapter, we examine the most prominent of these hypotheses and argue that none of them provides a satisfactory solution to the enigma of the human mind.

It's Not Just the Size of Our Brains

The human brain has grown enormously since our lineage separated from that of other apes (for a general overview, see Striedter, 2005). And one of the most popular hypotheses in neuroscience and anthropology over the course of the 20th century was that the difference between human and nonhuman cognition could be attributed largely to a difference in the size of our brains. This hypothesis fit well with Darwin's claim that the difference between human and non-human minds is “one of degree and not of kind” (Darwin, 1871). Indeed, Darwin was a proponent of the basest form of this hypothesis: the notion that putative differences in intelligence between human races could also be attributed to relative brain size:

The belief that there exists in man some close relation between the size of the brain and the development of the intellectual faculties is supported by the comparison of the skulls of savage and civilized races, of ancient and modern people, and by analogy of the whole vertebrate series. (Darwin, 1871 chapter II, p. 42)

The absolute size of an animal's brain, however, has turned out to be a very poor indication of an

animal's or human's intelligence (Roth & Dicke, 2005). Monkeys have brains that are much smaller, in absolute terms, than those of ungulates, although few researchers would claim that ungulates are the more intelligent species. Bird-brained species such as crows are some of the smartest animals on the planet (Seed, Emery, & Clayton, 2009). And the 1.35 kg brain of *Homo sapiens* is dwarfed by the brains of elephants and many cetaceans. Even within our own species, very little of the differences in intelligence among individuals can be attributed to differences in brain size (Rushton & Ankney, 2009; Schoenemann, Budinger, Sarich, & Wang, 2000).

Some researchers argue that it is the size of an animal's brain relative to its body, that is, its “encephalization,” that is the critical metric (see Dunbar & Shultz, 2007 for a recent review). The human brain, it is true, is four to five times larger than would be expected for an average mammal of the same size. Primates tend to have larger brains relative to body size than other mammals. And within the hominid (ape) line, the size of the human brain is an outlier: An average human brain weighs about 1,300 grams, and an average chimp brain weighs about 400 grams.

One prominent hypothesis argues that the driving force behind the evolution of larger relative brains is the demands of living within complex, often antagonistic, social relationships (Dunbar, 1993, 1998). Byrne and Whiten originally coined the term “Machiavellian intelligence” to refer to the cognitive demands of surviving among antagonistic social relationships, and they argued that the increase in relative brain size across primate lineages correlates well with a number of metrics of social complexity, including overall group size, number of females, frequency of coalitions, and frequency of incidents of social learning and tactical deception (Byrne, 1993, 1994, 1996; Byrne & Whiten, 1988). Recently, proponents of the “social brain” hypothesis, as it is now known, have argued that complex dyadic relationships, especially pair-bonds among parents, may be an even more powerful factor (Dunbar & Shultz, 2007).

But there are many reasons why encephalization has not fared much better than absolute brain size as an explanation for human cognitive uniqueness (Gazzaniga, 2008; Roth & Dicke, 2005; Schoenemann, 2006). First off, even in our own lineage, the relationship between brain size and cognitive ability is a complex story. Our ancestors had big brains for millions of years without any great leap forward in their cognitive abilities. Neanderthals probably had a

higher encephalization quotient than *Homo sapiens*, but there is little doubt that *Homo sapiens* were their intellectual superiors. Indeed, the size of *Homo sapiens'* brain has actually decreased by about 150 cc over the course of our species' history (Rightmire, 2004).

Even among other animal species, the relationship between encephalization and social complexity is spotty at best. Capuchin monkeys, for example, have higher encephalization quotients than chimpanzees and gorillas. It turns out that there is no association between sociality and encephalization across extant Carnivora (i.e., cats, dogs, bears, weasels, and their relatives). And thus there is little support for the hypothesis that sociality was the causal agent for increased encephalization in mammals in general (Finarelli & Flynn, 2007, 2009).

Many proponents of the social brain hypothesis focused on the relative size of the neocortex, arguing that this was the area that was disproportionately expanded in primates. And it is true that we have a bizarrely enlarged neocortex relative to other apes (but see Preuss, 2004; cf. Semendeferi, Armstrong, Schleicher, Zilles, & Van Hoesen, 2001). But this fact alone does not tell us much about why a big neocortex makes us so smart in our species-specific ways. Explaining human cognitive uniqueness requires a much more detailed understanding of the structural and functional differences between human and nonhuman brains.

Numerous features of the human neocortex have attracted researchers' attention in recent years, including the disproportionate amount of white matter in the human prefrontal cortex (Schoenemann, Sheehan, & Glotzer, 2005), the lateral specialization between our cerebral hemispheres (Gazzaniga, 2000), the reorganization of the human temporal lobe (Rilling & Seligman, 2002), the dynamics of neural synchrony (Uhlhaas & Singer, 2006; Varela, Lachaux, Rodriguez, & Martinerie, 2001), and the role played by our prefrontal cortices, particularly our anterior prefrontal cortices, in uniquely human forms of relational reasoning (Amati & Shallice, 2007; Cho et al., 2010; Ramnani & Owen, 2004; Semendeferi et al., 2001). But at the moment, we are still a long way from understanding how these neural-level traits conspire to produce the computations that make human cognition unique or even, for that matter, what those uniquely human computations are. And as Marr (1982) taught, there's not much point understanding the neural-level details of a cognitive system if you don't know what computations that cognitive system is doing.

It's Not Only Our Words

The most popular explanation today for human cognitive uniqueness is also the oldest one on the books: language. Ever since the ancient Greeks, philosophers have argued that the difference between human and nonhuman minds must be due to our unique capacity for language. And a large number of philosophers and scientists still claim that language is at the heart of "what makes us so smart" (Bermudez, 2003; Bickerton, 2009; Carruthers, 2002; Deacon, 1997; Dennett, 1995; Diamond, 1992; Dupre, 2003; Gentner, 2003; Mithen, 1996; Premack, 2004). Dennett (1996, p.17) has staked out the extreme version of this hypothesis: "Perhaps the kind of mind you get when you add language to it is so different from the kind of mind you can have without language that calling them both minds is a mistake."

Language clearly plays a crucial role in "extending" human cognition (Clark, 2001, 2006). The most obvious way in which human language enables human cognition is by giving us the ability to employ symbolic tokens to represent features, entities, and ideas, not just for the purposes of communicating with others but also for thinking novel thoughts by ourselves (see Carruthers, 2002). Gentner and colleagues, for example, have shown that relational "labels" play an instrumental role in facilitating children's ability to grasp relational similarities and potential analogies (Gentner & Christie, 2008; Gentner & Kurtz, 2005; Loewenstein & Gentner, 2005; and see Holyoak, Chapter 13). The ability to use symbolic tokens to count and perform mathematical calculations is another obvious example of the unique role that symbolic tokens play in human cognition (Bloom & Wynn, 1997; Dehaene, 1997; see Gleitman & Papafragou, Chapter 28). And many researchers have shown that the development of normal human social cognition is heavily influenced by a child's linguistic environment. Deaf children raised by hearing parents, for example, tend to be "late signers" and show persistent deficits in tasks that require them to reason about others' psychological states relative to deaf children raised by deaf parents (Peterson & Siegal, 1995, 2000; Siegal, Varley, & Want, 2001). Normal human cognition clearly relies on normal language development (Baldo et al., 2005).

But although language enables and catalyzes normal human cognition, there is compelling evidence that the human mind is nevertheless distinctively human even in the absence of natural language sentences (Bloom, 2000b; Garfield, Peterson, & Perry,

2001; Siegal et al., 2001; Varley, Siegal, & Want, 2001). Varley and Siegal (2000), for example, studied the cognitive abilities of an agrammatic aphasic man who was incapable of producing or comprehending sentences and whose vocabulary was essentially limited to perceptual nouns. In particular, he had lost all his vocabulary for mentalistic entities such as “beliefs” and “wants.” Yet this patient continued to take care of the family finances and passed a battery of causal reasoning and Theory of Mind (ToM) tests (see also Siegal et al., 2001; Varley, Klessinger, Romanowski, & Siegal, 2005; Varley et al., 2001). Another example: although late-signing deaf children’s cognitive abilities may not be “normal,” they nevertheless manifest grammatical, logical, and causal reasoning abilities far beyond those of any nonhuman subject (Peterson & Siegal, 2000). And the many remarkable cases of congenitally deaf children spontaneously “inventing” gestural languages with hierarchical and compositional structure provide further confirmation that there is something unique about the human mind even in the absence of normal linguistic enculturation (Goldin-Meadow, 2003; Sandler, Meir, Padden, & Aronoff, 2005; Senghas, Kita, & Ozyurek, 2004).

The cognitive accomplishments of humans deprived of normal linguistic enculturation are all the more striking in contrast to the failures of even the most well-trained animal to master anything even remotely resembling a human language. Over the last 35 years, comparative researchers have tried mightily to teach nonhuman animals of a variety of taxa to use and/or comprehend language-like symbol systems (Herman, 1986; Herman, Richards, & Wolz, 1984; Kaminski, Call, & Fischer, 2004; Pepperberg, 2002; Savage-Rumbaugh, Shanker, & Taylor, 1998; Schusterman & Gisiner, 1989; Schusterman & Krieger, 1986). Many of these animals have experienced protracted periods of enculturation that rival those of modern (coddled) human children. And the stars of these animal language projects have indeed been able to approximate certain superficial aspects of human language, including the ability to associate arbitrary sounds, tokens, and gestures with external objects, properties, and actions and a rudimentary sensitivity to the order in which these “symbols” appear.

But the most striking thing about the achievements of all these animals is how rudimentary they are relative to those of human children. Even after decades of exhaustive training, no nonhuman animal has demonstrated a mastery of abstract grammatical

categories, closed-class items, hierarchical syntactic structures, or any of the other defining features of a human language (cf. Kako, 1999). There is no evidence that even the most exceptional animal understands “words” with anything like the flexibility or systematicity of the average human child (Bloom, 2000a, 2004). If any human child learned words the way animals do, the child’s parents would run screaming to their local pediatrician.

If the history of animal language research demonstrates nothing else, it demonstrates that you cannot create a human mind simply by taking a nonhuman one and teaching it to use language-like symbols. There must be substantive differences between human and nonhuman minds that allow the former, but not any of the latter, to master grammatically structured languages to begin with. Darwin (1871, p. 57) put it perfectly: “the mental powers of some early progenitor of man must have been more highly developed than in any existing ape, before even the most imperfect form of speech could have come into use.”

It’s Not Our “Language Instinct”

Ever since Noam Chomsky’s seminal work in the 1950s, the standard explanation for why only humans have language is that only human minds possess an innate “language faculty” in which the universal rules of human grammar have been encoded (e.g., Jackendoff, 2002; Pinker, 1994). The notion of a specialized language faculty tuned to a universal grammar fits nicely with the presumption that, outside of language, the rest of the human mind is more or less like that of any other ape. At the extreme, Hauser et al. (2002), for example, suggest that the sole qualitative difference between human and nonhuman cognition might be the computational mechanism of recursion putatively at the core of all human languages.

But there are about 5,000 to 8,000 distinct languages spoken by humans today. And as comparative linguists are increasingly pointing out, the remarkable diversity of all these languages makes the notion of a universal grammar difficult to sustain (Evans & Levinson, 2010). There are some languages with no derivational morphology or constituent structure; there are some that do not employ fixed orders of elements. Some languages have no words for numerals. Some have no sounds (e.g., sign languages). There are languages without adverbs or adjectives. And even recursion turns out to be a feature that has a thousand variations and is apparently absent

in the Amazonian language Pirahá (Everett, 2005). Nevertheless, despite this spectacular diversity, any normal human child can learn to comprehend and employ any human language. How is this possible?

Perhaps the answer lies in the fact that human languages have been shaped by the idiosyncrasies of the human mind, rather than the other way around (see Christiansen & Chater, 2008). In other words, the statistical properties of human languages evolved, by natural and cultural selection, to be just those that our brains were capable of learning. And the evidence suggests that many of aspects of language acquisition, such as word learning and grammar comprehension, rely on general-purpose systems—such as our ability to attribute beliefs to others and to make analogical inferences—that originally evolved for other purposes and still perform these nonlinguistic functions to this day (e.g., Bloom, 2000a; Christiansen & Kirby, 2003; Tomasello, 2000).

It is likely that evolution of human language profoundly “rewired” the human brain, as Bermudez (2005) and Bickerton (2009) have suggested. But there must have been a complex, coevolutionary relationship between the human cognitive architecture and human language in order for language to take root (see again Christiansen & Chater, 2008). And the comparative evidence suggests that the human brain must have been uniquely human before even the simplest proto-language could even get started (cf. Bickerton, 2009). So language alone cannot be the first, or even the most fundamental, difference between humans and nonhuman minds.

It's Not by Culture Alone

In their book, *Not by Genes Alone*, Richerson and Boyd (2004) demonstrate that the cultural transmission of beliefs, practices, and specialized knowledge has played a unique role in shaping the human mind. The dynamics of cultural evolution, they show, are analogous to those of biological evolution but nevertheless limited to the human species. Many animals may have “cultures” of their own, and young animals routinely learn from their elders (Hunt & Gray, 2004; Rendell & Whitehead, 2001; van Schaik et al., 2003; Whiten, 2000; Whiten et al., 1999). But nonhuman species never accumulate complex behaviors or knowledge over successive generations as human cultures do (Richerson & Boyd, 2004; Richerson, Boyd, & Henrich, 2002; Tennie, Call, & Tomasello, 2009). Is human culture, then, the source of human cognitive uniqueness?

Humans, it is true, are inordinately dependent on each other and exceptionally social. We are not just a “prosocial” animal; we are, as Gazzaniga (2009) put it, “the party animal.” Hrdy (2000, 2009) highlights the crucial role that cooperative maternal care has played in the evolution of our species’ peculiar cognitive abilities. The complexity and importance of cooperative interactions among humans is unrivaled in any other species (Burkart, Hrdy, & Van Schaik, 2009; Silk, 2003; Silk et al., 2005). And it is obvious that all of our species’ most salient achievements—from fire building to Twitter—would be unthinkable without the transmission of enormous bodies of knowledge between generations, the ability to assimilate symbolic cultural norms, and an inherently prosocial orientation. At the extreme, some researchers have argued that a human child kept alive on a deserted island and magically raised to adulthood without any human contact would “not differ very much—perhaps a little, but not very much” from other great apes (Tomasello & Rakoczy, 2003, p. 121).

But a close examination of the comparative data does not support the hypothesis that cultural learning and prosocial motivations alone make us unique. Many chimpanzees have been raised by devoted researchers under conditions that rival those of coddled human children. Yet after decades of enculturation, even the most gifted chimp’s ability to reason about the world does not rival that of the average human toddler (David Premack, & Premack, 2003; Penn, Holyoak, & Povinelli, 2008). Even more fundamentally, while the parents of many species often facilitate social learning among their offspring (Bender, Herzing, & Bjorklund, 2009; de Waal, 2001; Hoppitt et al., 2008), only human teachers take into account what their students do and do not know.

For example, one of the most widely publicized examples of “teaching” among animals comes from the stars of Animal Planet’s *Meerkat Manor* (Thornton, 2008; Thornton & McAuliffe, 2006). For meerkats, scorpions are a delicacy. But a scorpion’s stinger would be a serious threat to a young meerkat. So meerkat parents kill or disable the scorpions before giving them to their pups. At first, parents give new pups dead scorpions. Then, when the pups are a little older, the parents give them live scorpions with the stinger removed. Eventually, the young meerkats graduate to the whole package, stinger and all.

At first glance, this seems like a compelling example of human-like teaching—and the popular media has certainly portrayed meerkats in this way. But the same researchers who first documented the

meerkats' lesson plan were also the first to discover that meerkats do not actually cater their lessons to the skill level of the pup but to the quality of their begging calls (see also Madden, Kunc, English, & Clutton-Brock, 2009). Play a recording of a young pup and the mother will give her older pups a dead scorpion. Play a recording of an older pup and a meerkat mother will give her infant a live scorpion, stinger and all, even though this may kill her child.

Without the scaffolding provided by human culture, our species' cognitive achievements might be paltry indeed. But what remains to be explained is why only human children can learn the lessons that human parents have to teach and why only human teachers take into account what their students do and do not know.

It's Not Only Our "Theory of Mind"

Premack and Woodruff (1978) originally coined the term "Theory of Mind" (ToM) to refer to our ability to impute mental states to others—such as goals, intentions, beliefs, and doubts—and to use these hypothetical and unobservable entities to predict and explain others' behavior. This cognitive system properly counts as a "theory," Premack and Woodruff argued, because "such [mental] states are not directly observable, and the system can be used to make predictions about the behavior of others" (p. 515).

Whether any nonhuman animal has a ToM is a question that has been "fraught with controversy" from the get-go (Shettleworth, 2010). Over 10 years ago, Heyes (1998) reviewed the experimental work to date and concluded that there had been no "substantial progress" in answering this question. It is far from clear that any more progress has been made since then. Over the last decade, there has been a flurry of new experiments claiming to provide evidence that nonhuman animals understand at least some psychological states in others (see Call & Tomasello, 2008 for a review). But these claims remain controversial. Penn and Povinelli (2007b), for example, argue that there is still no evidence that nonhuman animals have anything even remotely resembling a ToM. As Emery and Clayton (2009) recently put it, whether one believes that animals reason about others' mental states or not may be largely a matter of "faith."

It is clear that social vertebrates of many taxa are adept at interpreting the observable *behavior* of others, including how conspecifics are likely to behave given those specific individuals' past behavior and the behavior of other conspecifics under similar circumstances

(Emery & Clayton, 2009; Povinelli & Vonk, 2004). And it is clear that many animals—including apes, dogs, monkeys, and corvids—are quite good at acting *as if* they were taking others' perspective into account in certain species-specific contexts (Call, Brauer, Kaminski, & Tomasello, 2003; Emery & Clayton, 2008; Flombaum & Santos, 2005; Kaminski, Brauer, Call, & Tomasello, 2009; Santos, Nissen, & Ferrugia, 2006). But nonhuman animals consistently fail any task that requires them to reason about another individual's beliefs when that individual's beliefs are different from their own (Call & Tomasello, 2008; Kaminski, Call, & Tomasello, 2008).

So does something about our social intelligence and our "prosocial" personalities explain what makes human cognition unique? Many researchers believe so (see chapters in Kappeler & Silk, 2010). Tomasello and his colleagues, for example, argue that humans have evolved a suite of unique skills for understanding other individuals as cooperative agents with whom one can share emotions, experience, and collaborative actions (Tomasello, 1999, 2008; Tomasello, Carpenter, Call, Behne, & Moll, 2005a, 2005b; Tomasello & Rakoczy, 2003). And Tomasello argues that this species-specific ability to participate with others in collaborative activities with shared goals and intentions (i.e., what he calls "shared intentionality") lies at the heart of human cognitive uniqueness.

Although nonhuman animals clearly do not have the ability to collaborate or communicate with each other in human-like ways, the hypothesis that our capacity for "shared intentionality" alone lies at the heart of the gap between human and nonhuman minds seems difficult to sustain. It is very hard to see how a discontinuity in social-cognitive abilities alone could explain the profound differences between human and nonhuman animals' abilities in other nonsocial domains, such as our ability to create complex tools, diagnose causal relationships and construct theories about the world (Penn & Povinelli, 2007a; Povinelli, 2000, *in press*). For example, chimpanzees and corvids are quite adept at using sticks to retrieve out-of-reach objects, but there are consistent and glaring gaps in their understanding of the causal relationships involved (Holzhaider, Hunt, Campbell, & Gray, 2008; Povinelli, 2000; Seed, Tebbich, Emery, & Clayton, 2006; Taylor, Hunt, Medina, & Gray, 2009; Visalberghi, 2000; Visalberghi & Tomasello, 1998).

Tomasello and his colleagues recently carried out a massive experiment to test their "cultural

intelligence” hypothesis by comparing the social and physical reasoning skills of 106 chimpanzees and 32 orangutans against those of 105 2–3-year-old human children (Herrmann, Call, Hernandez-Lloreda, Hare, & Tomasello, 2007). All subjects were exposed to a common battery of 16 tasks. One set of tasks tested subjects’ ability to keep track of the number and location of objects as they were moved around, out of sight, beneath opaque cups. Another set of tasks tested subjects’ ability to reason about causal-logical relationships. For example, the experimenters hid a reward inside one of two cups and then shuffled the cups so the subjects couldn’t tell which cup contained the reward. On some trials, the experimenters shook the empty cup, which made no noise. On other trials, the experimenters shook the baited cup, which made a loud rattling sound. The subjects had to infer which cup contained the reward without looking inside. A third set of tasks tested subjects’ social intelligence. For example, the experimenters demonstrated the correct solution to a problem or looked at where a reward was hidden and the subjects were graded on how well they responded to the experimenters’ cues.

Herrmann et al. (2007) reported that there was no significant difference between children’s and chimpanzees’ performance on the tests of perceptual, quantitative, and causal-logical reasoning. However, human children performed significantly better than chimpanzees and orangutans on the social tasks. “Human children are not overall more intelligent than other primates,” the authors concluded, “but instead have specialized skills for social cognition. They learn in a way that chimpanzees don’t learn.” (p. 1360)

But a close inspection of Herrmann et al.’s (2007) data tells a very different story. To claim that there was no significant difference between human and nonhuman subjects on tests in the physical domain, the authors lumped all the scores on the spatial, quantitative, and causal-logical tasks into one composite average. When the scores on the individual tasks are considered separately, it turns out that the only test of causal-logical reasoning on which chimpanzees outperformed children was a task in which subjects had to retrieve an out-of-reach reward with a wooden stick: that is, the very tool-use task that is the chimpanzee’s special forte. And on this critical task, the children were given 1 minute to retrieve the reward and the apes were given 2 minutes. On every other test of causal-logical reasoning, the children performed significantly better than both the chimpanzees and the orangutans. Given these

results, Herrmann et al. (2007, p. 1365) themselves admit that “it is possible that what is distinctively human is not social-cultural cognition as a specialized domain…Rather, what may be distinctive is the ability to understand unobserved causal forces in general, including (as a special case) the mental states of others as causes of behavior.”

The hypothesis that our prosocial tendencies alone lie at the heart of the gap between human and nonhuman minds also does little to explain why only humans are capable of learning to manipulate symbols in a rule-governed fashion. Symbol-trained animals have no trouble learning to use symbols to get what they want. But as we discussed in the section, “It’s Not Our ‘Language Instinct,’” symbol-trained animals never master even the most rudimentary grammatical rules. Learning a human language appears to require a suite of inferential abilities that are both domain general and uniquely human (Christiansen & Chater, 2008; Christiansen & Kirby, 2003). Indeed, in a different context, Tomasello himself has argued that human language learners rely on cognitive capacities—such as analogical reasoning and abstract rule learning—that are independent from ToM and absent in nonhuman animals (Tomasello, 2000). So while our ability and desire to participate in collaborative activities and take each others’ beliefs into account is surely a distinctive feature of the human mind, it cannot be the only or even the most basic one.

The Human Mind Is Not a Beak

The latest explanation for the gap between human and nonhuman minds is inspired by the neo-Darwinian hypothesis that minds are collections of specialized “modules,” each one evolved to fulfill a particular adaptive function in our ancestral niche (e.g., Barkow, Cosmides, & Tobby, 1992; Carruthers, 2006; Pinker, 1997). According to this hypothesis, human minds have a “language” instinct and scrub jays have a “nut-caching” instinct; and the differences between human and nonhuman minds are like the differences between the beaks of Darwin’s finches: multifarious, incremental, and highly specialized.

There is considerable merit to this hypothesis. Many aspects of animals’ minds clearly evolved for particular tasks: The spatial memory of food-caching birds is a particularly well-studied and compelling example of “adaptive specialization” (e.g., de Kort, Tebbich, Dally, Emery, & Clayton, 2006; Shettleworth, 2003). But the comparative evidence suggests that an animal’s intelligence is not exclusively modular or domain

specific. For example, animals who regularly use tools in the wild—such as capuchin monkeys and New Caledonian crows—are not necessarily more adept at solving novel tool-use problems than other closely related species who do not normally use tools—such as vervet monkeys and rooks (Bird & Emery, 2009; Santos, Pearson, Spaepen, Tsao, & Hauser, 2006; Tebbich, Seed, Emery, & Clayton, 2007). Furthermore, the same species that are the most adept at solving new tool-use problems in captivity also tend to be the most adept at solving novel problems in every other domain, from social interactions to symbol manipulation (Clayton & Emery, 2005; Emery & Clayton, 2004; Seed et al., 2009).

The same is true for humans. Human language is the product of innumerable adaptive specializations, ranging from the mechanics of vocal production to the reorganization of our temporal lobes (Pinker & Jackendoff, 2005). And we know that there are specific regions and systems in the human brain tuned to thinking about mental states (Saxe, 2006; Saxe & Powell, 2006) and manipulating complex tools (Johnson-Frey, 2004), to mention only a few examples of the many evolved specializations peculiar to our species. The human mind is clearly not the product of one lucky mutation (Dennett, 1995). But the massively modular hypothesis favored by neo-Darwinian psychologists does not explain why there is an analogous discontinuity between human and nonhuman minds across every domain of cognition, from spatial navigation and tool use to language and cooperation. If there were some animals that used fire, some that built baskets, and some that had language and culture, the “massively modular” hypothesis might be more credible. But we’re the only ones who do any of these things. So it seems highly implausible that the discontinuities in all of these domains are the result of independent, domain-specific “modules” or that the human mind is simply the serendipitous result of a large number of unrelated adaptations. It seems much more likely (not to mention parsimonious) that some common set of adaptations coevolved with these domain-specific adaptations to enable a qualitative leap in human intelligence across the board.

The crux of the matter then is to identify the core set of changes that enabled this qualitative leap forward in the human species and no other.

The Relational Reinterpretation Hypothesis

Here’s one possible hypothesis: One of the essential features of any animal’s mind is its ability to

learn about novel relations in an adaptive fashion. Honeybees navigate by remembering and recalculating the relation between landmarks and their hive (Menzel & Giurfa, 2006). Baboons make inductive generalizations about how to behave based on the changing relationships between conspecifics, and they respond differently to different *kinds* of tertiary relations (Bergman, Beehner, Cheney, & Seyfarth, 2003; Seyfarth & Cheney, 2003). Teach a rat that it gets a reward when it presses a lever and it will quickly grasp the goal-directed relation between its action and the outcome (Dickinson & Balleine, 2000); and rats don’t respond to a *causal* relationship in the same way as they do to a mere association (Blaisdell, Sawa, Leising, & Waldmann, 2006). Relations, in short, are the currency of cognition. But Penn et al. (2008) argue that humans take relations one huge step further than the rest.

Many animals can learn the instrumental relation between a symbol and an object in the world. But only human children learn to grasp the higher order relation between symbols in terms of abstract grammatical rules. Animals of many taxa can learn to use tools to solve specific tasks. But only human children develop theories to explain how the world works. Figuring out how others are likely to act based on their observable behavior is a cognitive feat that nearly every social species has mastered. Figuring out how others are likely to act based on what they *believe* is something only human children learn.

All these disparate examples of uniquely human cognition—from ToM and theory building to language and tool use—have something critical in common: They all involve relations that aren’t manifest in the perceptual features of the objects themselves: You can’t see a grammatical rule, smell a theory, or touch somebody else’s thoughts. These unobservable entities are all invented by the human mind (Vonk & Povinelli, 2006). And a large and growing body of research shows that the ability to represent and reason about the unobservable relation between perceptual relations and the abstract roles that entities play in those relations—that is, what researchers call *role-based relational reasoning* (see Holyoak, Chapter 13)—subserves all these various aspects of human cognition from childhood on (Gentner, 2003; Gentner, Holyoak, & Kokinov, 2001; Goodwin & Johnson-Laird, 2005; Halford, 1993; Halford, Wilson, & Phillips, 1998, 2010; Holyoak & Thagard, 1995; Johnson-Laird, 1983; and see Doumas & Hummel, Chapter 5). Arguably, role-based relational reasoning lies at the core of

what makes human cognition unique (Gentner, 2003; Halford et al., 2010; Holyoak & Thagard, 1995; Penn et al., 2008).

Role-based relational reasoning requires the capacity to represent structured relations in terms of the bindings between concrete, observable entities and functional, unobservable roles (see Holyoak, Chapter 13). According to the relational reinterpretation hypothesis (Penn et al., 2008), because nonhuman animals are incapable of forming role-based representations, they are limited to reasoning about the relationship between things they can see, touch, hear, or smell. Only human minds reinterpret perceptual relations in terms of higher order relations that can't be perceived, such as rules, analogies, stories, and theories. The available evidence suggests that all these different kinds of higher order relations are processed by a general-purpose, multi-component system that has been grafted onto the systems for reasoning about perceptual relationships we inherited from our nonhuman ancestors. Adding this extra level of relations to a mind is not like moving from a one-story to a two-story house. It's like moving from a two-dimensional to a three-dimensional world.

Although we are far from possessing a complete understanding of the neural bases of higher order role-based relational reasoning (see Holyoak, Chapter 13 for a review), the available evidence provides promising support for the relational reinterpretation hypothesis. It is now clear that the human brain contains a specialized system for learning and reasoning about higher order relationships that crucially involves the anterior-most region of the prefrontal cortex traditionally identified as Brodmann Area 10 (Buckner, Andrews-Hanna, & Schacter, 2008; Bunge & Zelazo, 2006; Christoff et al., 2001; Gilbert et al., 2006; Kroger et al., 2002; e.g., Miller, 2000; Ramnani & Owen, 2004; Wendelken, Nakhabenko, Donohue, Carter, & Bunge, 2008; and see Morrison & Knowlton, Chapter 6). The anterior prefrontal cortex has been implicated in every form of relational reasoning that is uniquely human: from planning for the future and making logical deductions to constructing causal explanations and empathizing with others' emotional states. Within the anterior prefrontal cortex, the more medial regions seem to play an instrumental role in empathizing with other people's feelings, pondering our own thoughts, planning for the future, and imagining hypothetical scenarios; and the more lateral regions seem implicated in reasoning about analogies, logical

relations, and abstract rules (Burgess, Dumontheil, & Gilbert, 2007; Gilbert et al., 2006; Halford et al., 2010; Wendelken et al., 2008). Not coincidentally, the anterior prefrontal cortex is one of the newest parts of the human brain and a part of our brain that differs dramatically from that of other apes (Preuss, 2000; Semendeferi et al., 2001). Many features of the human brain have changed since our lineage split from that of other apes, but arguably the changes in our anterior prefrontal cortex are the ones that lie behind our unique ability to reason about role-based relations and thus to master grammatically structured languages, reason about others' thoughts, manufacture wheels, and ponder the peculiar nature of our own minds.

Conclusions and Future Directions

Although the relational reinterpretation hypothesis may provide a promising framework for understanding what makes human cognition unique, it is far from complete and there are still many questions left unanswered. For example, although there is some evidence suggesting that the development of a ToM is causally dependent on higher order relational reasoning (Andrews, Halford, Bunch, Bowden, & Jones, 2003; Apperly & Butterfill, 2009; Zelazo, Jacques, Burack, & Frye, 2002), there has been no conclusive evidence showing that deficits in role-based relational reasoning must necessarily produce deficits in ToM functioning as the relational reinterpretation hypothesis claims. The same criticism applies to the relationship between language learning and higher order relations: Although there is good evidence that language comprehension and production involve higher order relational computations similar to those involved in analogical reasoning and ToM (see Christiansen & Kirby, 2003; Christoff et al., 2001; Halford et al., 2010; Waltz et al., 2004), we do not yet know to what extent role-based relational reasoning is necessary to support normal language use and development.

Worse, while neuroscientists have been relatively successful at identifying *where* in the brain higher order relationships are processed, we still know very little about *how* the human brain performs its remarkable computations or what those computations actually consist of. A few researchers have attempted to address this question in a neurally plausible fashion (Doumas & Hummel, 2005, and Chapter 5; e.g., Hummel & Holyoak, 2003, 2005). While we applaud these efforts and believe they have already shed new light on what makes human

cognition unique, our species' best models to date are still a very long way from accounting for the unique and still enigmatic features of the human mind.

New Perspectives on Language and Thought

Lila Gleitman and Anna Papafragou

Abstract

In this chapter we discuss the question of whether, how, where, and to what extent language plays a causally fundamental role in creating categories of thought, and in organizing and channeling thought that is already mentally present. In general, both logic and currently available evidence suggest a disclaimatory view of strongest proposals (Benjamin Whorf, 1956) according to which particulars of certain human languages are important progenitors of thought, such that elements of perception or conception would be permanently altered by learning one or another language. However, several credible lines of experimental and developmental evidence suggest significant influence of linguistic representation during online processing in many cognitive and perceptual domains: Insofar as languages differ in the short-term processing demands that they pose to listeners, interpretational outcomes and styles, including characteristic ambiguity resolution, may look quite different cross-linguistically as a function of concomitant population differences (e.g., age-group) and task demands.

Key Words: categorical perception, Whorf, linguistic relativity, linguistic determinism

The presence of language is one of the central features that distinguish humans from other species. Even in very early infancy, during the (misnamed) prelinguistic stage of life, infants respond positively to strangers who are speaking in the special melodies of the exposure language, but they shrink away from those speaking a different language or dialect (Kinzler, Shutts, DeJesus, & Spelke, 2009). Cultures materially define themselves by the way that they and “others” speak, down to the smallest details. Blood has in many times and places been spilled in consequence. A famous case, and the origin of the word itself, is the biblical tale of *shibboleth*.¹

In light of this intimate bond between language and cultural identification, it is easy to understand the intense interest for laypersons and specialists alike on the topic of this chapter: *the relations between language and thought*. Many people actually identify these two notions; they share the intuition that they

think “in” language, hence that the absence of language would, *ipso facto*, be the absence of thought itself. One compelling version of this self-reflection is Helen Keller’s (1955) report that her recognition of the signed symbol for “water” triggered thought and emotional processes that had theretofore—and consequently—been utterly absent. Statements to the same or related effect come from the most diverse intellectual sources: “The limits of my language are the limits of my world” (Wittgenstein, 1922/1961); and “The fact of the matter is that the ‘real world’ is to a large extent unconsciously built upon the language habits of the group” (Sapir, 1941, as cited in Whorf, 1956, p. 75). On this kind of supposition, we may have no way to think many thoughts, conceptualize many of our ideas, without language, or outside of and independent of language. Moreover, different communities of humans, speaking different languages, would think differently to just the extent

that their languages differ from one another. But is this so? Could it be so? That depends on how we unpack the notions so far alluded to so informally.

Do We Think “in” Language?

In the obvious sense, language has powerful and specific effects on thought. After all, that’s what it is for, or at least that is one of the things it is for: to transfer ideas from one mind to another mind. Imagine Eve telling Adam *Apples taste great*. This fragment of linguistic information, as we know, caused Adam to entertain a new thought with profound effects on his world knowledge, inferencing, and subsequent behavior. Much of human communication is an intentional attempt to modify the thoughts and attitudes of others in just this way. This information transmission function is crucial for the structure and survival of cultures and societies in all their known forms (also see Rai, Chapter 29).

Traditionally, language has been considered mainly in this conduit role, as the vehicle for the expression of thought rather than as its progenitor. From Noam Chomsky’s universalist perspective, for example, the forms and contents of all particular languages derive, in large part, from an antecedently specified cognitive substance and architecture, and therefore they provide a rich diagnostic of human conceptual commonalities:

Language is a mirror of mind in a deep and significant sense. It is a product of human intelligence... By studying the properties of natural languages, their structure, organization, and use, we may hope to learn something about human nature; something significant, if it is true that human cognitive capacity is the truly distinctive and most remarkable characteristic of the species. (Chomsky, 1975, p. 4)

This view is not proprietary to the rationalist position for which Chomsky is speaking here. Classical empiricist thought maintained that our concepts (sensory discriminations aside) derive from experience with properties, things, and events in the world and not, originally, from language:

To give a child an idea of scarlet or orange, of sweet or bitter, I present the objects, or in other words, convey to him these impressions; but proceed not so absurdly, as to endeavor to produce the impressions by exciting the ideas. (Hume, 1739/2000; Book I)

And as a consequence of such experience with *things*, *ideas* arise in the mind and can receive linguistic labels:

If we will observe how children learn languages, we shall find that, to make them understand what the names of simple ideas or substances for, people ordinarily *show them the thing whereof they would have them have the idea*; and then repeat to them the name that stands for it... (Locke, 1690/1964, Book 3.IX.9; italics ours)

Our question in this chapter is how far and in what ways this chain may operate in reverse, such that language causes thought to be what it is. The issues here were raised most forcefully in the writings of Benjamin Whorf and Eric Sapir in the first half of the 20th century.² According to Whorf, the grammatical and lexical resources of individual languages heavily constrain the conceptual representations available to their speakers.

We are thus introduced to a new principle of relativity, which holds that all observers are not led by the same physical evidence to the same picture of the universe, unless their linguistic backgrounds are similar, or can in some way be calibrated. (Whorf, 1956, p. 214)

This linguistic-relativistic view, in its richest form, entails that linguistic categories will be the “program and guide for an individual’s mental activity” (ibid, p. 212), including categorization, memory, reasoning, and decision making. If this is right, then the study of different linguistic systems may throw light onto the diverse modes of thinking encouraged or imposed by such systems. The importance of this position cannot be overestimated: Language here becomes a vehicle for the growth of *new* concepts—those which were not theretofore in the mind, and perhaps could not have been there without the intercession of linguistic experience. Thus, it poses a challenge to the venerable view that one could not acquire a concept that one could not antecedently entertain (Plato, 5–4th century BCE; Descartes, 1662; Fodor, 1975, *inter alia*). At the limit it is a proposal for how new thoughts can arise in the mind as a result of experience with language rather than as a result of experience with the world of objects and events.

By the 1950s the Whorf-Sapir hypothesis began to percolate into psychological theorizing, and it seemed to proponents to provide a route to understanding how cognitive categories formed and jelled in the developing human mind. A major figure in this history was Roger Brown, the great social and developmental psychologist who framed much of the field of language acquisition in the modern era. Brown (1957) performed a simple and elegant experiment

that demonstrated an effect of lexical categorization on the inferred meaning of a new word. Young children were shown a picture, for example, of hands that seemed to be kneading confetti-like stuff in an overflowing bowl. Some children were told, *Show me the sib*. They pointed to the bowl (a solid rigid object). Others were told, *Show me some sib*. They pointed to the confetti (an undifferentiated mass of stuff). Others were told, *Show me sibbing*. They pointed to the hands and made kneading motions with their own hands (an action or event). Plainly, the same stimulus object was represented differently depending on the linguistic cues to the lexical categories count noun, mass noun, and verb. That is, the lexical categories themselves have notional correlates, at least in the minds of these young English speakers.

Some commentators have argued that the kinds of cues exemplified here, for example, that persons, places, and things surface as nouns, are universal and thus can play causal roles in the acquisition of language by learners who are predisposed to find just these kinds of syntactic-semantic correlations "natural" (e.g., Baker, 2001; Bloom, 1994a; Fisher, 1996; Gleitman, 1990; Landau & Gleitman, 1985; Lidz, Gleitman & Gleitman, 2003; Pinker, 1984). Brown saw his result the other way around. He supposed that languages would vary arbitrarily in these form mappings onto conceptual categories. Those world properties thus yoked together by language would cause a (previously uncommitted) infant learner to conceive of them as meaningfully related in some ways.

In learning a language, therefore, it must be useful to discover the semantic correlates for the various parts of speech; for this discovery enables the learner to use the part-of-speech membership of a new word as a first cue to its meaning... Since [grammatical categories] are strikingly different in unrelated languages, the speakers [of these languages] may have quite different cognitive categories. (Brown, 1957, p. 5)

These ideas have continued to be explored in the cognitive literature ever since. One recent formulation states:

Instead of language merely reflecting the cognitive development which permits and constrains its acquisition, language is thought of as potentially catalytic and transformative of cognition.
(Bowerman & Levinson, 2001a, p. 13)

In the strongest interpretations, the categories of language essentially become the default categories of thought:

We surmise that language structure... provides the individual with a system of representation, some isomorphic version of which becomes highly available for incorporation as a default conceptual representation. Far more than developing simple habituation, use of the linguistic system, we suggest, actually forces the speaker to make computations he or she might otherwise not make. (Pederson et al., 1998, p. 586)

Before turning to the recent literature on language and thought, so conceived, we want to emphasize that most current contributors fall somewhere between the extremes of such views. To our knowledge, none of those who are currently advancing linguistic-relativistic themes and explanations believe that infants enter into language acquisition in a state of complete conceptual nakedness, later redressed (perhaps we should say "dressed") by linguistic information. Rather, infants are believed to possess some "core knowledge" that enters into the first categorizations of objects, properties, and events in the world (e.g., Baillargeon, 1993; Carey, 1982, 2008; Gelman & Spelke, 1981; Gibson & Spelke, 1983; Kellman, 1996; Leslie & Keeble, 1987; Mandler, 1996; Prasada, Ferenz, & Haskell, 2002; Quinn, 2003; Spelke, Breinlinger, Macomber, & Jacobson, 1992). The viable question is how richly specified this innate basis may be and how experience refines, enhances, and transforms the mind's original furnishings; and, finally, whether specific language knowledge may be one of these formative or transformative aspects of experience. To our knowledge, none of those who adopt a nativist position on these matters reject as a matter of a priori conviction the possibility that there could be effects of language on thought. For instance, some particular natural language might formally mark a category that another does not; two languages might draw a category boundary at different places; and two languages might differ in the computational resources they require to make manifest a particular distinction or category. These differences might, in turn, influence the representation or processing machinery for speech and comprehension.

We will try to draw out aspects of these issues within several domains in which commentators and investigators are currently trying to disentangle cause and effect in the interaction of language and thought. We cannot discuss it all, of course, or even very much of what is currently in print on this topic. There is too much of it (for recent anthologies,

see Bowerman & Levinson, 2001a; Gentner & Goldin-Meadow, 2003; Gumperz & Levinson, 1996; Malt & Wolff, 2010).

Border Wars: Where Does Language End and Inference Begin?

We begin with a very simple question: Do our thoughts actually take place in a specific natural language? If so, it would immediately follow that Whorf was right all along, since speakers of Korean and Spanish, or Swahili and Hopi would have to think systematically different thoughts.

There are several reasons to suppose that, if tenable at all, such a position needs to be reined in considerably. This is because, if language directly expresses our thought, it seems to make a poor job of it. Consider, for example, this sentence from the preceding section:

1. There is too much of it.

Leaving aside, for now, the problems of anaphoric reference (what is “it”?), the sentence still has at least two interpretations that are compatible with its discourse context:

- 1a. ‘There is too much written on linguistic relativity to fit into this article.’
- 1b. ‘There is too much written on linguistic relativity.’ (*Period!*)

We authors had one of these two interpretations in mind (guess which one). We had a thought and expressed it as (1) but English failed to render that thought unambiguously, leaving things open as between (1a) and (1b). One way to think about what this example portends is that language just cannot, or in practice does not, express all and only what we mean. Rather, language use offers hints and guideposts to hearers, such that they can usually reconstruct what the speaker had in mind by applying to the uttered words a good dose of common sense, *aka* thoughts, inferences, and plausibilities in the world.

The question of just how to apportion the territory between the underlying semantics of sentences and the pragmatic interpretation of the sentential semantics is, of course, far from settled in linguistic and philosophical theorizing. Consider the sentence *It is raining*. Does this sentence directly—that is, as an interpretive consequence of the linguistic representation itself—convey an assertion about rain falling *here*? That is, *in the immediate geographical environment of the speaker*? Or does the sentence itself—the linguistic representation—convey only

that rain is falling, leaving it for the common sense of the listener to deduce that the speaker likely meant raining here and now rather than raining today in Bombay or on Mars; likely too that if the sentence was uttered indoors, the speaker more likely meant *here* to convey “just outside of here” than “right here, as the roof is leaking.”³ The exact division of labor between linguistic semantics and pragmatics has implications for the language-thought issue, since the richer (one claims that) the linguistic semantics is, the more likely it is that language guides our mental life. Without going into detail, we will argue that linguistic semantics cannot fully envelop and substitute for inferential interpretation; hence, the representations that populate our mental life cannot be identical to the representations that encode linguistic (semantic) meaning.

Language Is Sketchy; Thought Is Rich

There are several further reasons to believe that thought processes are not definable over representations that are isomorphic to linguistic representations. One is the pervasive ambiguity of words and sentences. *Bat*, *bank*, and *bug* all have multiple meanings in English and hence are associated with multiple concepts, but these concepts themselves are clearly distinct in thought, as shown *inter alia* by the fact that one may consciously construct a pun. Moreover, several linguistic expressions including pronouns (*he*, *she*) and indexicals (*here*, *now*) crucially rely on context for their interpretation while the thoughts they are used to express are usually more specific. Our words are often semantically general, that is, they fail to make distinctions that are nevertheless present in thought: *uncle* in English does not semantically specify whether the individual comes from the mother’s or the father’s side, or whether he is a relative by blood or marriage, but usually the speaker who utters this word (*my uncle...*) possesses the relevant information. Indeed, lexical items typically take on different interpretations tuned to the occasion of use (*He has a square face*; *The room is hot*) and depend on inference for their precise construal in different contexts (e.g., the implied action itself is systematically different when we *open an encyclopedia**a can**an umbrella**a book* or when an instance of that class of actions is performed to serve different purposes: *open the window to let in the evening breeze**the cat*). Moreover, there are cases where linguistic output does not even encode a complete thought/proposition (*Tomorrow*, *Maybe*). Finally, the presence of implicatures and other kinds of pragmatic

inference ensures that—to steal a line from the Mad Hatter—while speakers generally mean what they say, they do not and could not say exactly what they mean.

From this and related evidence, it appears that linguistic representations underdetermine the conceptual contents they are used to convey: Language is *sketchy* compared to the richness of our thoughts (for related discussions, see Fisher & Gleitman, 2002; Papafragou, 2007). In light of the limitations of language, time, and sheer patience, language users make reference by whatever catch-as-catch-can methods they find handy, including the waitress who famously told another that “The ham sandwich wants his check” (Nunberg, 1978). In this context, *Table 8, the ham sandwich and the man seated at Table 8* are communicatively equivalent. What chiefly matters to talkers and listeners is that successful reference be made, whatever the means at hand. If one tried to say all and exactly what one meant, conversation could not happen; speakers would be lost in thought. Instead, conversation involves a constant negotiation in which participants estimate and update each others’ background knowledge as a basis for what needs to be said versus what is mutually known and inferable (e.g., Bloom, 2000; Clark, 1992; Grice, 1975; Sperber & Wilson, 1986).

In limiting cases, competent listeners ignore linguistically encoded meaning if it patently differs from (their estimate of) what the speaker intended, for instance, by smoothly and rapidly repairing slips of the tongue. Oxford undergraduates had the wit, if not the grace, to snicker when Reverend Spooner said, or is reputed to have said, “Work is the curse of the drinking classes.” Often the misspeaking is not even consciously noticed but is repaired to fit the thought, evidence enough that the word and the thought are two different matters.⁴ The same latitude for thought to range beyond established linguistic means holds for the speakers, too. Wherever the local linguistic devices and locutions seem insufficient or overly constraining, speakers invent or borrow words from another language, devise similes and metaphors, and sometimes make permanent additions and subtractions to the received tongue. It would be hard to understand how they do so if language were itself, and all at once, both the format and vehicle of thought.

Arbitrary and Inconsistent Encodings

The cases just mentioned refer to particular tokenings of meanings in the idiosyncratic interactions between people. A related problem arises

when languages categorize aspects of the world in ways that are complex and inconsistent. An example is reported by Malt, Sloman, Gennari, Shi, and Wang (1999). They examined the vocabulary used by English, Spanish, and Chinese subjects to label the various containers we bring home from the grocery store full of milk, juice, ice cream, bleach, or medicine (e.g., *jugs, bottles, cartons, boxes*). As the authors point out, containers share names based not only on some perceptual resemblances but also on very local and particular conditions, with size, contents, shape, substance, nature of the contents, not to speak of the commercial interests of the purveyor, all playing interacting and shifting roles. For instance, in present-day American English, a certain plastic container that looks like a bear with a straw stuck in its head is called “a juice box,” though it is not boxy either in shape (square or rectangular) or typical constitution (your prototypical American box is made of cardboard). The languages Malt et al. studied differ markedly in the set of terms available for this domain and also in how their subjects extended these terms to describe diverse new containers. Speakers of the three languages differed in which objects (old and new) they classified together by name. For example, a set of objects distributed across the sets of *jugs, containers, and jars* by English speakers were unified by the single label *frasco* by Spanish speakers. Within and across languages not everything square is a box, not everything glass is a bottle, not everything *not* glass is *not* a bottle, and so on. The naming, in short, is a complex mix resulting from perceptual resemblances, historical influences, and a generous dollop of arbitrariness. Yet Malt et al.’s subjects did not differ much (if at all) from each other in their classification of these containers by overall similarity rather than by name. Nor were the English and Spanish, as one might guess, more closely aligned than, say, the Chinese and Spanish. So here we have a case where cross-linguistic practice groups objects in a domain in multiple ways that have only flimsy and sporadic correlations with perception, without discernible effect on the non-linguistic classificatory behaviors of users.⁵

So far we have emphasized that language is a relatively impoverished and underspecified vehicle of expression, which relies heavily on inferential processes outside the linguistic system for reconstructing the richness and specificity of thought. If correct, this seems to place rather stringent limitations on how language could serve as the original engine and sculptor of our conceptual life. Phrasal

paraphrase, metaphor and figurative language are heavily relied on to carry ideas that may not be conveniently lexicalized or grammaticalized. Interpretive flexibility sufficient to overcome these mismatches is dramatically manifested by simultaneous translators at the United Nations who more or less adequately convey the speakers' thoughts using the words and structures of dozens of distinct languages, thus crossing not only differences in the linguistic idiom but enormous gulfs of culture and disagreements in belief and perspective.

Despite these many disclaimers, it is possible to maintain the idea that certain formal properties of language causally affect thought in more local, but still important, ways. In the remainder of this chapter we consider two currently debated versions of the view that properties of language influence aspects of perception, thinking, and reasoning. The first is that language exerts its effects more or less *directly and permanently*, by revising either the mental categories, shifting the boundaries between them, or changing their prominence ("salience"). The second is that particulars of a language exert *indirect and transient* effects imposed during the rapid-fire business of talking and understanding. The present authors believe that the latter position, which we will explicate and expand as we go along, comes closer than the former to unifying the present experimental literature, and, in essence, reunites the Whorf-inspired literature with what we might call "ordinary psycholinguistics," the machinery of online comprehension.

Use It or Lose It: When Language Reorganizes the Categories of Thought

We begin with the most famous and compelling instance of language properties reconstructing perceptual categories: categorical perception of the phoneme (Kuhl, Williams, Lacerda, Stevens, & Lindblom, 1992; Liberman, 1970; Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967; Werker & Lalonde, 1988).

Children begin life with the capacity and inclination to discriminate among all of the acoustic-phonetic properties by which languages encode distinctions of meaning, a result famously documented by Peter Eimas (Eimas, Siqueland, Jusczyk, & Vigorito, 1971) using a dishabituation paradigm (for details and significant expansions of this basic result see, e.g., Jusczyk, 1985; Mehler & Nespor, 2004; Werker & DesJardins, 1995). These authors showed that an infant will work (e.g., turn its head

or suck on a nipple) to hear a syllable such as *ba*. After some period of time, the infant habituates; that is, its sucking rate decreases to some base level. The high sucking rate can be reinstated if the syllable is switched to, say, *pa*, demonstrating that the infant detects the difference. These effects are heavily influenced by linguistic experience. Infants only a year or so of age—just when true language is making its appearance—have become insensitive to phonetic distinctions that are not phonemic (play no role at higher levels of linguistic organization) in the exposure language (Werker & Tees, 1984). While these experience-driven effects are not totally irreversible in cases of long-term second-language immersion, they are pervasive and dramatic (for discussion, see Best, McRoberts, & Sithole, 1988; Werker & Logan, 1985). Without special training or unusual talent, the adult speaker-listener can effectively produce and discriminate the phonetic categories required in the native tongue, and little more. Not only that, these discriminations are categorical in the sense that sensitivity to within-category phonetic distinctions is poor and sensitivity at the phonemic boundaries is especially acute.

When considering these findings in the context of linguistic relativity, one might be tempted to write them off as a limited tweaking at the boundaries of acoustic distinctions built into the mammalian species, a not-so-startling sensitizing effect of language on perception (Aslin, 1981; Aslin & Pisoni, 1980). Moreover, it is unlikely that the limits on perception and production imposed by early learning are absolute. After all, depending on age, talent, and motivation, they can be altered once again in subsequent learning of a second (or third, etc.) language (Werker & Lalonde, 1988).

But a more radical restructuring, specific to particular languages, occurs as these phonetic elements are organized into higher level phonological categories. For example, American English speech regularly lengthens vowels in syllables ending with a voiced consonant (compare *ride* and *write*) and neutralizes the *t/d* distinction in favor of a dental flap in certain unstressed syllables. The effect is that (in most dialects) the consonant sounds in the middle of *rider* and *writer* are indistinguishable if removed from their surrounding phonetic context. Yet the English-speaking listener perceives a *d/t* difference in these words all the same, and—except when asked to reflect carefully—fails to notice the characteristic difference in vowel length that his or her own speech faithfully reflects. The complexity of

this phonological reorganization is often understood as a reconciliation (interface) of the cross-cutting phonetic and morphological categories of a particular language. *Ride* ends with a *d* sound; *write* ends with a *t* sound; morphologically speaking, *rider* and *writer* are just *ride* and *write* with *er* added on; therefore, the phonetic entity between the syllables in these two words must be *d* in the first case and *t* in the second. Morphology trumps phonetics (Bloch & Trager, 1942; Chomsky, 1964; for extensions to alphabetic writing, see Gleitman & Rozin, 1977).

Much of the literature on linguistic relativity can be understood as adducing related reconstructions in various perceptual and conceptual domains that are mapped onto language. Is it the case that distinctions of lexicon or grammar made regularly in one's language sensitize one to these distinctions and suppress or muffle others? Even to the extent of radically and permanently reorganizing the domain? We now look at some likely further cases.

The Perception of Hue

Languages differ in their terms for color just as they do in their phonetic and phonemic inventories. A number of factors favor color variables in the study of potential influences of language on thought. First, there is a powerful tradition of psychophysical measurement in this area that allows for the creation of test materials that can be scaled and quantitatively compared, at least roughly, for difference magnitudes, discriminability, and so on. Second, the fact that humans can discriminate hundreds of thousands, if not millions, of hues, coupled with the fact that it is impossible to learn a word for each, makes this domain a likely repository of linguistic difference. Third, the case of hue appears quite analogous to the well-studied instance of learning effects on phonetic categorization, thus a plausible immediate extension in the relevant regard.

Accordingly, a very large descriptive and experimental literature has been directed toward the question of whether color memory, learning, and similarity are influenced by color category-boundaries in the languages of the world. Significant evidence supports the view that color labeling is at least partly conditioned by universal properties of perception. Berlin and Kay (1969), in a cross-linguistic survey, showed that color vocabularies develop under strong universal constraints that are unlikely to be describable as effects of cultural diffusion (for recent discussion and amplifications, see especially

Regier, Kay, Gilbert, & Ivry, 2010). Nevertheless there is considerable variance in the number of color terms encoded, so it can be asked whether these linguistic labeling practices affect perception. Heider and Oliver (1972) made a strong case that they do not. They reported that the Dugum Dani, a preliterate Papuan tribe of New Guinea with only two color labels (roughly, warm-dark and cool-light), remembered and categorized new hues that they were shown in much the same way as English speakers who differ from them both culturally and linguistically.

Intriguing further evidence of the independence of perception and labeling practices comes from red-green color-blind individuals (deutanopes; Jameson & Hurvich, 1978). The perceptual similarity space of the hues for such individuals is systematically different from that of individuals with normal trichromatic vision. Yet a significant subpopulation of deutanopes *names* hues, even of new things, consensually with normal-sighted individuals and consensually orders these hue *labels* for similarity as well. That is, these individuals do not order a set of color chips by similarity with the reds at one end, the greens at the other end, and the oranges somewhere in between (rather, by alternating chips that the normal trichromat sees as reddish and greenish; that is what it means to be color blind). Yet they do organize the color words with *red* semantically at one end, *green* at the other, and *orange* somewhere in between. In the words of Jameson and Hurvich:

the language brain has learned denotative color language as best it can from the normal population of language users, exploiting whatever correlation it has available by way of a reduced, or impoverished, sensory system, whereas the visual brain behaves in accordance with the available sensory input, ignoring what its speaking counterpart has learned to say about what it sees. (1978, p. 154)

Contrasting findings had been reported earlier by Brown and Lenneberg (1954), who found that colors that have simple verbal labels are identified more quickly than complexly named ones in a visual search task (e.g., color chips called "blue" are, on average, found faster among a set of colors than chips called "purplish blue," etc.), suggesting that aspects of naming practices do influence recognition. In a series of recent studies in much the same spirit, Gilbert, Regier, Kay, and Ivry (2006; see also Regier, Kay, & Cook, 2005; Regier, Kay, & Khetarpal, 2009) have shown that reaction time in

visual search is longer for stimuli with the same label (e.g., two shades both called “green” in English) than for stimuli with different labels (one a consensual “blue” and one a consensual “green”). Crucially, however, this was the finding only when the visual stimuli were delivered to the right visual field (RVF), that is, projecting to the left, language-dominant, hemisphere. Moreover, the RVF advantage for differently labeled colors disappeared in the presence of a task that interferes with verbal processing but not in the presence of a task of comparable difficulty that does not disrupt verbal processing (see also Kay & Kempton, 1984; Winawer, Witthoft, Frank, Wu, & Boroditsky, 2007). This response style is a well-known index of categorical perception, closely resembling the classical results for phoneme perception.

Looking at the literature in broadest terms, then, and as Regier et al. (2010) discuss in an important review, the results at first glance seem contradictory: On the one hand, perceptual representations of hue reveal cross-linguistic labeling commonalities and are independent of such terminological differences as exist within these bounds. On the other hand, there are clear effects of labeling practices, especially in speeded tasks, where within-linguistic category responses are slower and less accurate than cross-category responses. The generalization appears to be that when language is specifically mobilized as a task requirement (e.g., the participant is asked for a verbal label) or when linguistically implicated areas of the brain are selectively measured, the outcomes are sensitive to linguistic categories; otherwise, less so or not at all: Language tasks recruit linguistic categories and functions that do not come into play in nonlinguistic versions of very similar tasks.⁶ As we next show, this generalization holds as well in a variety of further domains where linguistic effects on thinking have been explored.

Objects and Substances

The problem of reference to *stuff* versus *objects* has attracted considerable attention because it starkly displays the indeterminacy in how language refers to the world (Chomsky, 1957; Quine, 1960). Whenever we indicate some physical object, we necessarily indicate some portion of a substance as well; the reverse is also true. Languages differ in their expression of this distinction. Some languages make a grammatical distinction that roughly distinguishes object from substance (Chierchia, 1998; Lucy & Gaskins, 2001). Count nouns in such languages

denote individuated entities, for example, object kinds. These are marked in English with determiners like *a*, *the*, and are subject to counting and pluralization (*a horse*, *horses*, *two horses*). Mass nouns typically denote nonindividuated entities, for example, substance rather than object kinds. These are marked in English with a different set of determiners (*more porridge*), and they need an additional term that specifies quantity to be counted and pluralized (*a tube of toothpaste* rather than *a toothpaste*).

Soja, Carey, and Spelke (1991) asked whether children approach this aspect of language learning already equipped with the ontological distinction between things and substances, or whether they are led to make this distinction through learning count/mass syntax. Their subjects, English-speaking 2-year-olds, did not yet make these distinctions in their own speech. Soja et al. taught these children words in reference to various types of unfamiliar displays. Some were solid objects such as a T-shaped piece of wood, and others were nonsolid substances such as a pile of hand cream with sparkles in it. The children were shown such a sample, named with a term presented in a syntactically neutral frame that identified it neither as a count nor as a mass noun, for example, *This is my blicket* or *Do you see this blicket?* In extending these words to new displays, 2-year-olds honored the distinction between object and substance. When the sample was a hard-edged solid object, they extended the new word to all objects of the same shape, even when made of a different material. When the sample was a non-solid substance, they extended the word to other-shaped puddles of that same substance but not to shape matches made of different materials. Soja et al. took this finding as evidence of a conceptual distinction between objects and stuff, independent of and prior to the morphosyntactic distinction made in English.

This interpretation was put to stronger tests by extending such classificatory tasks to languages that differ from English in these regards: Either these languages do not grammaticalize the distinction, or they organize it in different ways (see Lucy, 1992; Lucy & Gaskins, 2001, for findings from Yucatec Mayan; Mazuka & Friedman, 2000; Imai & Gentner, 1997, for Japanese). Essentially, these languages’ nouns all start life as mass terms, requiring a special grammatical marker (called *a classifier*) if their quantity is to be counted. One might claim, then, that substance is in some sense linguistically basic for Japanese, whereas objecthood is basic for English speakers

because of the dominance of its count-noun morphology.⁷ So if children are led to differentiate object and substance reference by the language forms themselves, the resulting abstract semantic distinction should differ cross-linguistically. To test this notion, Imai and Gentner replicated Soja et al.'s original tests with Japanese and English children and adults. Some of their findings appear to strengthen the evidence for a universal prelinguistic ontology that permits us to think both about individual objects and about portions of stuff, for both American and Japanese children (even 2-year-olds) extended names for complex hard-edged nonsense objects on the basis of shape rather than substance. Thus, the lack of separate grammatical marking did not put the Japanese children at a disadvantage in this regard.

But another aspect of the results hints at a role for language itself in categorization. For one thing, the Japanese children tended to extend names for mushy hand-cream displays according to their substance, while the American children were at chance for these items. There were also discernible language effects on word extension for certain very simple stimuli (e.g., a kidney-bean-shaped piece of colored wax) that seemed to fall at the ontological midline between object and substance. While the Japanese at ages 2 and 4 were at chance on these items, the English speakers showed a tendency to extend words for them by shape.

How are we to interpret these results? Several authors have concluded that ontological boundaries literally shift to where language makes its cuts; that the substance/object distinction works much like the categorical perception effects we noticed for phonemes (and perhaps colors; see also Gentner & Boroditsky, 2001). Lucy and Gaskins (2001) bolstered this interpretation with evidence that populations speaking different languages differ increasingly with increasing age. While their young Mayan speakers are much like their English-speaking peers, by age 9 years members of the two communities differ significantly in relevant classificatory and memorial tasks. The implication is that long-term use of a language influences ontology, with growing conformance of concept grouping to linguistic grouping. Of course the claim is not for a rampant reorganization of thought; only for boundary shifting. Thus, for displays that clearly fall to one side or the other of the object/substance boundary, the speakers of all the tested languages sort the displays in the same ways.

It may be of some importance that suitable stimuli—those falling in the border area between stuff and thing—are hard to devise and instantiate, as we will discuss further. For this and related reasons, neither the findings nor the interpretations of such experiments are easy to come by. In one attempted replication, Mazuka and Friedman (2000) failed to reproduce Lucy's effects for Mayan- versus English-speaking subjects' classificatory performance for the predicted further case of Japanese. As these authors point out, the sameness in this regard of Japanese and English speakers, and the difference in this regard between Mayan and English speakers, suggests that obtained population differences may be more cultural and educational than linguistic.

In fact, there is another interpretation of these results that does not imply that language is altering the very categories of perception and thought. Rather, the result may again be limited to the influence of linguistic categories on linguistic performances, as we have noted before for the cases of phoneme and hue perception. This time the ultimate culprit is the necessarily sketchy character of most utterances, given ordinary exigencies of time and attention. One does not say (or rarely says), "Would you please set the table that is made of wood, is 6 feet in length, and is now standing in the dining room under the chandelier?" One says instead just enough to allow reference making to go through in a particular situational context. "Just enough," however, itself varies from language to language owing to differences in the basic vocabulary. Interpretations from this perspective have been offered by many commentators. Bowerman (1996), Brown (1957), Landau, Dessaegn, and Goldberg (2009), Landau and Gleitman (1985), Slobin (1996, 2001), and Papafragou, Massey, and Gleitman (2006), among others, propose that native speakers not only learn and use the individual lexical items their language offers but also learn the *kinds* of meanings typically expressed by a particular grammatical category in their language, and they come to expect new members of that category to have similar meanings. Languages differ strikingly in their most common forms and locutions—preferred fashions of speaking, to use Whorf's phrase. These probabilistic patterns could bias the interpretation of *new words*. Such effects come about in experiments when subjects are offered language input (usually nonsense words) under conditions in which implicitly known form-to-meaning patterns in the language might hint at how the new word is to be interpreted.

Let us reconsider the Imai and Gentner (1997) object-substance effects in light of this hypothesis. As we saw, when the displays themselves were of nonaccidental-looking hard-edged objects, subjects in both language groups opted for the object interpretation. But when the world was uninformative (e.g., for softish waxy lima bean shapes), the listeners fell back upon linguistic cues if available. No relevant morphosyntactic clues exist in Japanese, and so Japanese subjects chose at random for these indeterminate stimuli. For the English-speaking subjects, the linguistic stimulus too was in a formal sense interpretively neutral: *This blicket* is a template that accepts both mass and count nouns (*this horse/toothpaste*). But here principle and probability part company. Recent experimentation leaves no doubt that child and adult listeners incrementally exploit probabilistic facts about word use to guide the comprehension process online (e.g., Gleitman, January, Nappa, & Trueswell, 2007; Snedeker, Thorpe, & Trueswell, 2001; Tanenhaus, 2007; Trueswell, Sekerina, Hill, & Logrip, 1999). In the present case, any English speaker equipped with even a rough subjective probability counter should take into account the great preponderance of count nouns to mass nouns in English and so conclude that a new word *blicket*, used to refer to some indeterminate display, is very probably a new count noun rather than a new mass noun. Count nouns, in turn, tend to denote individuals rather than stuff and so have shape predictivity (Landau, Smith, & Jones, 1998; Smith, 2001). On this interpretation, it is not that speaking English leads one to tip the scales toward object representations of newly seen referents for perceptually ambiguous items; only that hearing English leads one to tip the scales toward count-noun representation of newly heard nominals in linguistically ambiguous structural environments. Derivatively, then, count syntax hints at object representation of the newly observed referent. Because Japanese does not have a corresponding linguistic cue, subjects choose randomly between the object/substance options where world-observation does not offer a solution. Such effects can be expected to increase with age as massive lexical-linguistic mental databases are built, consistent with the findings from Lucy and Gaskins (2001).⁸

Li, Dunham, and Carey (2009) recently tested the language-on-language interpretation conjectured by Fisher and Gleitman (2002) and Gleitman and Papafragou (2005), using an expanded set of object-like, substance-like, and neutral stimuli, in the Imai

and Gentner (1997) paradigm. They replicated the prior finding in several comparisons of Mandarin and English speakers. However, they added a new task, one that, crucially, did not require the subjects to interpret the meaning of the noun stimuli. This manipulation completely wiped out the cross-linguistic effect. As so often, the implication is that it is the linguistic nature of the task that elicits linguistic categories and functions. Languages differ in their vocabulary and structural patterns, impacting the procedures by which forms resolve to their meanings. But in nonlinguistic tasks, individuals with different linguistic backgrounds are found to respond in terms of the same conceptual categories.

Spatial Relationships

Choi and Bowerman (1991) studied the ways in which common motion verbs in Korean differ from their counterparts in English. First, Korean motion verbs often contain location or geometric information that is more typically specified by a spatial preposition in English. For example, to describe a scene in which a cassette tape is placed into its case, English speakers would say, "We put the tape *in the case*." Korean speakers typically use the verb *kkita* to express the *put in* relation for this scene. Second, *kkita* does not have the same extension as English *put in*. Both *put in* and *kkita* describe an act of putting an object in a location; but *put in* is used for all cases of containment (fruit in a bowl, flowers in a vase), while *kkita* is used only in case the outcome is a tight fit between two matching shapes (tape in its case, one Lego piece on another, glove on hand). Notice that there is a cross-classification here: While English appears to collapse across tightnesses of fit, Korean makes this distinction but conflates across *putting in* versus *putting on*, which English regularly differentiates. Very young learners of these two languages have already worked out the language-specific classification of such motion relations and events in their language, as shown by both their usage and their comprehension (Choi & Bowerman, 1991).

Do such cross-linguistic differences have implications for spatial cognition? McDonough, Choi, and Mandler (2003) focused on spatial contrasts between relations of tight containment versus loose support (grammaticalized in English by the prepositions *in* and *on* and in Korean by the verbs *kkita* and *nohta*) and tight versus loose containment (both grammaticalized as *in* in English but separately as *kkita* and *nehta* in Korean). They showed

that prelinguistic infants (9- to 14-month-olds) in both English- and Korean-speaking environments are sensitive to such contrasts, and so are Korean-speaking adults (see also Hespos & Spelke, 2000, who show that 5-month-olds are sensitive to this distinction). However, their English-speaking adult subjects showed sensitivity only to the tight containment versus loose support distinction, which is grammaticalized in English (*in* vs. *on*). The conclusion drawn from these results was that some spatial relations that are salient during the prelinguistic stage become less salient for adult speakers if their language does not systematically encode them: “Flexible infants become rigid adults.”

This interpretation again resembles the language-on-language effects in other domains, but in this case by no means as categorically as for the perception of phoneme contrasts. For one thing, the fact that English speakers learn and readily use verbs like *jam*, *pack*, and *wedge* weakens any claim that the lack of common terms seriously diminishes the availability of categorization in terms of tightness of fit. One possibility is that the observed language-specific effects with adults are due to verbal mediation: Unlike preverbal infants, adults may have turned the spatial classification task into a linguistic task. Therefore, it is useful to turn to studies that explicitly compare performance when subjects from each language group are instructed to classify objects or pictures by *name*, versus when they are instructed to classify the same objects by *similarity*.

In one such study, Li, Gleitman, Gleitman, and Landau, (1997) showed Korean- and English-speaking subjects pictures of events such as putting a suitcase on a table (an example of *on* in English, and of “loose support” in Korean). For half the subjects from each language group (each tested fully in their own language), these training stimuli were labeled by a videotaped cartoon character who performed the events (*I am Miss Picky and I only like to put things on things. See?*), and for the other subjects the stimuli were described more vaguely (...and I only like to do things like this. See?). Later categorization of new instances followed language in the labeling condition: English speakers identified new pictures showing tight fits (e.g., a cap put on a pen) as well as the original loose-fitting ones as belonging to the category that Miss Picky likes, but Korean speakers generalized only to new instances of loose fits. These language-driven differences radically diminished in the similarity sorting condition, in which the word (*on* or *nohta*) was not invoked; in this case the

categorization choices of the two language groups were essentially the same.

The “language-on-language” interpretation thus unifies the various laboratory effects in dealing with spatial relations, much as it does for hue perception, and for the object-substance distinction.

Motion

Talmy (1985) described two styles of motion expression that are typical for different languages: Some languages, including English, usually use a verb plus a separate path expression to describe motion events. In such languages, manner of motion is encoded in the main verb (e.g., *walk*, *crawl*, *slide*, or *float*), while path information appears in non-verbal elements such as particles, adverbials, or prepositional phrases (e.g., *away*, *through the forest*, *out of the room*). In Greek or Spanish, the dominant pattern instead is to include path information within the verb itself (e.g., Greek *bjeno* “exit” and *beno* “enter”); the manner of motion often goes unmentioned or appears in gerunds, prepositional phrases, or adverbials (*trehontas* “running”). These patterns are not absolute. Greek has motion verbs that express manner, and English has motion verbs that express path (*enter*, *exit*, *cross*). But several studies have shown that children and adults have learned these dominant patterns. Berman and Slobin (1994) showed that child and adult Spanish and English speakers vary in the terms that they most frequently use to describe the very same picture-book stories, with English speakers displaying greater frequency and diversity of manner of motion verbs. Papafragou, Massey, and Gleitman (2002) showed the same effects for the description of motion scenes by Greek- versus English-speaking children and, much more strongly, for Greek- versus English-speaking adults. Reasonably enough, the early hypothesis from Slobin and Berman was that the difference in language typologies of motion leads their speakers to different cognitive analyses of the scenes that they inspect. In the words of these authors, “children’s attention is heavily channeled in the direction of those semantic distinctions that are grammatically marked in the language” (Berman & Slobin, 1994), a potential salience or prominence effect of the categories of language onto the categories of thought.

Later findings did not sustain so strong a hypothesis, however. Papafragou, Massey, and Gleitman (2002) tested their English- and Greek- speaking subjects on either (*a*) memory of path or manner

details of motion scenes, or (*b*) categorization of motion events on the basis of path or manner similarities. Even though speakers of the two languages exhibited an asymmetry in encoding manner and path information in their verbal descriptions, they did not differ from each other in terms of classification or memory for path and manner.⁹ Similar results have been obtained for Spanish versus English by Gennari, Sloman, Malt, and Fitch (2002). Corroborating evidence also comes from studies by Munnich, Landau, and Dosher (2001), who compared English, Japanese, and Korean speakers' naming of spatial locations and their spatial memory for the same set of locations. They found that, even in aspects where languages differed (e.g., encoding spatial contact or support), there was no corresponding difference in memory performance across language groups.

Relatedly, the same set of studies suggests that the mental representation of motion and location is independent of linguistic naming *even within a single language*. Papafragou et al. (2002) divided their English- and Greek-speaking subjects' verbal descriptions of motion according to whether they included a path or manner verb, regardless of native language. Though English speakers usually chose manner verbs, sometimes they produced path verbs; the Greek speakers varied too but with the preponderances reversed. It was found that verb choice did not predict memory for path/manner aspects of motion scenes, or choice of path/manner as a basis for categorizing motion scenes. In the memory task, subjects who had used a path verb to describe a scene were no more likely to detect later path changes in that scene than subjects who had used a manner verb (and vice versa for manner). In the classification task, subjects were not more likely to name two motion events they had earlier categorized as most similar by using the same verb. Naming and cognition, then, are distinct under these conditions: Even for speakers of a single language, the linguistic resources mobilized for labeling underrepresent the cognitive resources mobilized for cognitive processing (e.g., memorizing, classifying, reasoning, etc.; see also Papafragou & Selimis, 2010b, for further evidence). An obvious conclusion from these studies of motion representation is that the conceptual organization of space and motion is robustly independent of language-specific labeling practices; nevertheless, specific language usage influences listeners' interpretation of the speaker's intended meaning if

the stimulus situation leaves such interpretation unresolved.¹⁰

Other recent studies have shown that motion event representation is independent of language even at the earliest moments of event apprehension. Papafragou, Hulbert, and Trueswell (2008) compared eye movements from Greek and English speakers as they viewed motion events while (*a*) preparing verbal descriptions or (*b*) memorizing the events. During the verbal description task, speakers' eyes rapidly focused on the event components typically encoded in their native language, generating significant cross-language differences even during the first second of motion onset. However, when freely inspecting ongoing events (memorization task), people allocated attention similarly regardless of the language they spoke. Differences between language groups arose only after the motion stopped, such that participants spontaneously studied those aspects of the scene that their language did not routinely encode in verbs (e.g., English speakers were more likely to focus on the path and Greek speakers on the manner of the event). These findings indicate that attention allocation during event perception is not affected by the perceiver's native language; effects of language arise only when linguistic forms are recruited to achieve the task, such as when committing facts to memory. A separate study confirmed that the linguistic intrusions observed at late stages of event inspection in the memory task of Papafragou et al. (2008) disappear under conditions of linguistic interference (e.g., if people are asked to inspect events while repeating back strings of numbers) but persist under conditions of nonlinguistic interference (e.g., if people view events while tapping sounds they hear; Trueswell & Papafragou, 2010). Together, these studies suggest that cross-linguistic differences do not invade (nonlinguistic) event apprehension. Nevertheless, language (if available) can be recruited to help event encoding, particularly in tasks that involve heavy cognitive load.

Spatial Frames of Reference

Certain linguistic communities (e.g., Tenejapan Mayans) customarily use an externally referenced ("absolute") spatial-coordinate system to refer to nearby directions and positions ("to the north"); others (e.g., Dutch speakers) typically use a viewer-perspective ("relative") system ("to the left"). Brown and Levinson (1993) and Pederson et al. (1998) claim that these linguistic practices affect spatial

reasoning in language-specific ways. In one of their experiments, Tenejapan Mayan and Dutch subjects were presented with an array of objects (toy animals) on a tabletop; after a brief delay, subjects were taken to the opposite side of a new table (they were effectively rotated 180 degrees), handed the toys, and asked to reproduce the array “in the same way as before.” The overwhelming majority of Tenejapan (“absolute”) speakers rearranged the objects so that they were heading in the same cardinal direction after rotation, while Dutch (“relative”) speakers massively preferred to rearrange the objects in terms of left-right directionality. This covariation of linguistic terminology and spatial reasoning seems to provide compelling evidence for linguistic influences on nonlinguistic cognition.¹¹

However, as so often in this literature, it is quite hard to disentangle cause and effect. For instance, it is possible that that the Tenejapan and Dutch groups think about space differently because their languages pattern differently, but it is just as possible that the two linguistic-cultural groups developed different spatial-orientational vocabulary to reflect (rather than cause) differences in their spatial reasoning strategies. Li and Gleitman (2002) investigated this second position. They noted that absolute spatial terminology is widely used in many English-speaking communities whose environment is geographically constrained and includes large stable landmarks such as oceans and looming mountains. For instance, the absolute terms *uptown*, *downtown*, and *crosstown* (referring to North, South, and East-West) are widely used to describe and navigate in the space of Manhattan Island; Chicagoans regularly make absolute reference to the lake; and so on. It is quite possible, then, that the presence/absence of stable landmark information, rather than language spoken, influences the choice of absolute versus spatial-coordinate frameworks. After all, the influence of such landmark information on spatial reasoning has been demonstrated with nonlinguistic (rats; Restle, 1957) and prelinguistic (infants; Acredolo & Evans, 1980) creatures.

To examine this possibility, Li and Gleitman replicated Brown and Levinson’s rotation task with English speakers, but they manipulated the presence/absence of landmark cues in the testing area. The result, just as for the rats and the infants, was that English-speaking adults respond absolutely in the presence of landmark information (after rotation, they set up the animals going in the same

cardinal direction) and relatively when it is withheld (in this case, they set up the animals going in the same body-relative direction).

More recent findings suggest that the spatial reasoning findings from these investigators are again language-on-language effects, the result of differing understanding of the instruction to make an array “the same” after rotation. Subjects should interpret this blatantly ambiguous instruction egocentrically if common linguistic usage in the language is of “left” and “right,” as in English, but geocentrically if common linguistic usage is of “east” or “west” as in Tseltal. But what should happen if the situation is not ambiguous, that is, if by the nature of the task it requires either one of these solution types or the other? If the subjects’ capacity to reason spatially has been permanently “transformed” by a lifetime of linguistic habit, there should be some cost—increased errorfulness or slowed responding, for instance—in a task that requires the style of reasoning that mismatches the linguistic encoding. Li, Abarbanell, Gleitman, and Papafragou (2011) experimented with such nonambiguous versions of the spatial rotation tasks, yielding the finding that all cross-linguistic differences disappeared. Tseltal-speaking individuals solved these unambiguous rotation tasks at least as well (often better) when they required egocentric strategies as when they required geocentric strategies.

Flexibility in spatial reasoning when linguistic pragmatics do not enter into the task demands should come as little surprise. The ability to navigate in space is hardwired in the brain of moving creatures, including bees and ants; for all of these organisms, reliable orientation and navigation in space is crucial for survival (Gallistel, 1990); not surprisingly, neurobiological evidence from humans and other species indicates that the brain routinely uses a multiplicity of coordinate frameworks in coding for the position of objects in order to prepare for directed action (Gallistel, 2002). It would be pretty amazing if, among all the creatures that walk, fly, and crawl on the earth, only humans in virtue of acquiring a particular language lose the ability to use both absolute and relative spatial-coordinate frameworks flexibly.

Evidentiality

One of Whorf’s most interesting conjectures concerned the possible effects of evidentials (linguistic markers of information source) on the nature of

thought. Whorf pointed out that Hopi—unlike English—marked evidential distinctions in its complementizer system. Comparing the sentences *I see that it is red* versus *I see that it is new*, he remarked:

We fuse two quite different types of relationship into a vague sort of connection expressed by ‘that,’ whereas the Hopi indicates that in the first case seeing presents a sensation ‘red,’ and in the second that seeing presents unspecified evidence for which is drawn the inference of newness. (Whorf, 1956, p. 85)

Whorf concluded that this grammatical feature was bound to make certain conceptual distinctions easier to draw for the Hopi speaker because of the force of habitual linguistic practices.

Papafragou, Li, Choi, and Han (2007) investigated this proposal. They compared English (which mostly marks evidentiality lexically: “I *saw/heard/inferred* that John left”) to Korean (where evidentiality is encoded through a set of dedicated morphemes). There is evidence that such morphemes are produced early by children learning Korean (Choi, 1995). Papafragou et al. therefore asked whether Korean children develop the relevant conceptual distinctions earlier and with greater reliability than learners of English, which does not grammatically encode this distinction. In a series of experiments, they compared the acquisition of nonlinguistic distinctions between sources of evidence in 3- and 4-year-olds learning English or Korean: no difference in nonlinguistic reasoning in these regards was found between the English and Korean group. For instance, children in both linguistic groups were equally good at reporting how they found out about the contents of a container (e.g., by looking inside or by being told); both groups were also able to attribute knowledge of the contents of a container to a character who had looked inside but not to another character who had had no visual access to its content. Furthermore, Korean learners were more advanced in their nonlinguistic knowledge of sources of information than in their knowledge of the meaning of linguistic evidentials. In this case, then, learned linguistic categories do not seem to serve as “a guide” for the individual’s nonlinguistic categories in the way that Whorf and several later commentators (e.g., Levinson, 2003) have conjectured. Rather, the acquisition of linguistically encoded distinctions seems to follow (and build on) the conceptual understanding of evidential distinctions. The conceptual understanding itself appears to proceed similarly across

diverse language-learning populations. Similar data have recently been obtained from Turkish, where the acquisition of evidential morphology seems to lag behind nonlinguistic knowledge about sources of information (Ozturk & Papafragou, 2008).

Time

So far we have focused on grammatical and lexical properties of linguistic systems and their possible effects on conceptual structure. Here we consider another aspect of languages as expressive systems: their systematically differing use of certain networks of metaphor—specifically, metaphor for talking about time. English speakers predominantly talk about time as if it were horizontal (*one pushes deadlines back, expects good times ahead, or moves meetings forward*). Boroditsky (2001) reports that Mandarin speakers more usually talk about time in terms of a vertical axis (they use the Mandarin equivalents of *up* and *down* to refer to the order of events, weeks, or months). Boroditsky showed that these differences predict aspects of temporal reasoning by speakers of these two languages. In one of her manipulations, subjects were shown two objects in vertical arrangement, say, one fish following another one downward as they heard something like *The black fish is winning*. After this vertically oriented prime, Mandarin speakers were faster to confirm or disconfirm temporal propositions (e.g., *March comes earlier than April*) than if they were shown the fish in a horizontal array. The reverse was true for English speakers. Boroditsky concluded that spatiotemporal metaphors in language affect how people reason about time. She has suggested, more generally, that such systematic linguistic metaphors are important in shaping habitual patterns of thought.

However, these results are again more complex than they seem at first glance. For one thing, and as Boroditsky acknowledges, vertical metaphors of time are by no means absent from ordinary English speech (e.g., *I have a deadline coming up; this recipe came down to me from my grandmother*), though they are said to be more sporadic than in Mandarin. Other laboratories have failed to replicate the original finding (January & Kako, 2007). Moreover, Chen (2007) has disputed the phenomenon altogether, failing to find predominance of the vertical metaphor in a corpus analysis of Taiwanese newspapers. Assuming, though, that the difference does hold up in everyday speech contexts, it is a subtle cross-linguistic difference of degree, rather than a principled opposition.

In fact, the most telling finding reported in these studies is that the apparent inculcation of a generalization over a lifetime is easily erased—in fact, actually reversed—in a matter of minutes: Boroditsky explained to her English-speaking subjects how to talk about time vertically, as in Mandarin, and gave them several practice trials. After this training, the English speakers exhibited the vertical (rather than the former horizontal) priming effect. Apparently, 15 minutes of training on the vertical overcame and completely reversed 20+ years of the habitual use of the horizontal in these speakers. The effects of metaphor, it seems, are transient and fluid, without long-term influence on the nature of conceptualization or its implicit deployment to evaluate propositions in real time. Again, these results are as predicted under a processing—language-on-language—account, in which there are immediate effects on memory (here, repetition and recency effects), but no permanent reorganization of “thought.”

Number

Prelinguistic infants and nonhuman primates share an ability to represent both exact numerosities for very small sets (roughly up to three objects) and approximate numerosities for larger sets (Dehaene, 1997). Human adults possess a third system for representing number, which allows for the representation of exact numerosities for large sets, has (in principle) no upper bound on set size, and can support the comparison of numerosities of different sets as well as processes of addition and subtraction. Crucially, this system is *generative*, since it possesses a rule for creating successive integers (the successor function) and is thus characterized by discrete infinity.

How do young children become capable of using this uniquely human number system? One powerful answer is that the basic principles underlying the adult number system are innate; gaining access to these principles thus gives children a way of grasping the infinitely discrete nature of natural numbers, as manifested by their ability to use verbal counting (Gelman & Gallistel, 1978; also see Opfer & Siegler, Chapter 30). Other researchers propose that children come to acquire the adult number system by conjoining properties of the two prelinguistic number systems via natural language. Specifically, they propose that grasping the *linguistic* properties of number words (e.g., their role in verbal counting, or their semantic relations to quantifiers such as *few*, *all*, *many*, *most*; see Spelke & Tsivkin, 2001a and Bloom, 1994b; Carey, 2001, respectively) enables children

to put together elements of the two previously available number systems in order to create a new, generative number faculty. In Bloom's (1994b, p. 186) words, “in the course of development, children ‘bootstrap’ a generative understanding of number out of the productive syntactic and morphological structures available in the counting system.”

For instance, upon hearing the number words in a counting context, children realize that these words map onto both specific representations delivered by the exact-numerosities calculator and inexact representations delivered by the approximator device. By conjoining properties of these two systems, children gain insight into the properties of the adult conception of number (e.g., that each of the number words picks out an exact set of entities, that adding or subtracting exactly one object changes number, etc.). Ultimately, it is hypothesized that this process enables the child to compute exact numerosities even for large sets (such as *seven* or *twenty-three*)—an ability which was not afforded by either one of the prelinguistic calculation systems.

Spelke and Tsivkin (2001a, b) experimentally investigated the thesis that language contributes to exact large-number calculations. In their studies, bilinguals who were trained on arithmetic problems in a single language and later tested on them were faster on large-number arithmetic if tested in the training language; however, no such advantage of the training language appeared with estimation problems. The conclusion from this and related experiments was that the particular natural language is the vehicle of thought concerning large exact numbers but not about approximate numerosities. Such findings, as Spelke and her collaborators have emphasized, can be part of the explanation of the special “smartness” of humans (see also Penn & Povinelli, Chapter 27 for similar views). Higher animals, like humans, can reason to some degree about approximate numerosity, but not about exact numbers. Beyond this shared core knowledge, however, humans have language. If language is a required causal factor in exact number knowledge, this in principle could explain the gulf between creatures like us and creatures like them. In support of the dependence of the exact number system on natural language, recent findings have shown that members of the Pirahá community that lack number words and a counting system seem unable to compute exact large numerosities (Gordon, 2004).

How plausible is the view that the adult number faculty presupposes linguistic mediation? Recall

that, on this view, children infer the generative structure of number from the generative structure of grammar when they hear others counting. However, counting systems vary cross-linguistically, and in a language like English, their recursive properties are not really obvious from the outset. Specifically, until number eleven, the English counting system presents no evidence of regularity, much less of generativity: A child hearing *one, two, three, four, five, six*, and up to *eleven* would have no reason to assume—based on properties of form—that the corresponding numbers are lawfully related (namely, that they successively increase by one). For larger numbers, the system is more regular, even though not fully recursive due to the presence of several idiosyncratic features (e.g., one can say *eighteen* or *nineteen* but not *teneen* for twenty). In sum, it is not so clear how the “productive syntactic and morphological structures available in the counting system” will provide systematic examples of discrete infinity that can then be imported into number cognition.

Can properties of other natural language expressions bootstrap a generative understanding? Quantifiers have been proposed as a possible candidate (Carey, 2001). However, familiar quantifiers lack the hallmark properties of the number system: They are not strictly ordered with respect to one another and their generation is not governed by the successor function. In fact, several quantifiers presuppose the computation of cardinality of sets: for example, *neither* and *both* apply only to sets of two items (Barwise & Cooper, 1981; Keenan & Stavi, 1986). Moreover, quantifiers and numbers compose in quite different ways. For example, the expression *most men and women* cannot be interpreted to mean a large majority of the men and much less than half the women. In light of the semantic disparities between the quantifier and the integer systems, it is hard to see how one could bootstrap the semantics of the one from the other.

Experimental findings suggest, moreover, that young children understand certain semantic properties of number words well before they know those of quantifiers. One case involves the scalar interpretation of these terms. In one experiment, Papafragou and Musolino (2003) had 5-year-old children watch as three horses are shown jumping over a fence. The children would not accept *Two of the horses jumped over the fence* as an adequate description of that event (even though it is necessarily true that if three horses jumped, then certainly two did). But at the same age, they would accept *Some of the horses jumped over the*

fence as an adequate description, even though it is again true that all of the horses jumped. In another experiment, Hurewitz, Papafragou, Gleitman, and Gelman (2006) found that 3-year-olds understand certain semantic properties of number words such as *two* and *four* well before they know those of quantifiers such as *some* and *all*. It seems, then, that the linguistic systems of number and natural language quantification are developing rather independently. If anything, the children seem more advanced in knowledge of the meaning of number words than quantifiers, so it is hard to see how the semantics of the former lexical type is to be bootstrapped from the semantics of the latter.

How then are we to interpret the fact that linguistic number words seem to be crucially implicated in nonlinguistic number cognition (Gordon, 2004; Spelke & Tsivkin, 2001a, b)? One promising approach is to consider number words as a method for online encoding, storage, and manipulation of numerical information that complements, rather than altering or replacing, nonverbal representations. Evidence for this claim comes from recent studies that retested the Pirahá population in tasks used by Gordon (Frank, Everett, Fedorenko, & Gibson, 2008). Pirahá speakers were able to perform exact matches with large numbers of objects perfectly, but, as previously reported, they were inaccurate on matching tasks involving memory. Other studies showed that English-speaking participants behave similarly to the Pirahá population on large number tasks when verbal number representations are unavailable due to verbal interference (Frank, Fedorenko, & Gibson, 2008). Nicaraguan signers who have incomplete or nonexistent knowledge of the recursive count list show a similar pattern of impairments (Flaherty & Senghas, 2007). Together, these data are consistent with the hypothesis that verbal mechanisms are necessary for learning and remembering large exact quantities—an online mnemonic effect of language of a sort we have already discussed.

Orientation

A final domain that we will discuss is spatial orientation. Cheng and Gallistel (1984) found that rats rely on geometric information to reorient themselves in a rectangular space, and they seem incapable of integrating geometrical with nongeometrical properties (e.g., color, smell, etc.) in searching for a hidden object. If they see food hidden at the corner of a long and a short wall, they will search equally

at either of the two such walls of a rectangular space after disorientation; this is so even if these corners are distinguishable by one of the long walls being painted blue or having a special smell. Hermer and Spelke (1994, 1996) reported a very similar difficulty in young children. Both animals and young children can navigate and reorient by the use of either geometric or nongeometric cues; it is integrating across the cue types that makes the trouble. These difficulties are overcome by older children and adults who are able, for instance, to go straight to the corner formed by a long wall to the left and a short blue wall to the right. Hermer and Spelke found that success in these tasks was significantly predicted by the spontaneous combination of spatial vocabulary and object properties such as color within a single phrase (e.g., *to the left of the blue wall*).¹² Later experiments (Hermer-Vasquez, Spelke, & Katsnelson, 1999) revealed that adults who were asked to shadow speech had more difficulty in these orientation tasks than adults who were asked to shadow a rhythm with their hands; however, verbal shadowing did not disrupt subjects' performance in tasks which required the use of nongeometric information only. The conclusion was that speech-shadowing, unlike rhythm-shadowing, by taking up linguistic resources, blocked the integration of geometrical and object properties that is required to solve complex orientation tasks. In short, success at the task seems to require encoding of the relevant terms in a specifically linguistic format.

In an influential review article, Carruthers (2002) suggests even more strongly that in number, space, and perhaps other domains, language is the medium of intermodular communication, a format in which representations from different domains can be combined in order to create novel concepts. However, on standard assumptions about modularity, modules are characterized as computational systems with their own proprietary vocabulary and combinatorial rules. Since language itself is a module in this sense, its computations and properties (e.g., generativity, compositionality) cannot be "transferred" to other modules, because they are defined over—and can only apply to—language-internal representations. One way out of this conundrum is to give up the assumption that language is—on the appropriate level—modular:

Language may serve as a medium for this conjunction...because it is a domain-general, combinatorial system to which the representations delivered by the child's...[domain-specific]

nonverbal systems can be mapped. (Spelke & Tsivkin, 2001b, p. 84)

And:

Language is constitutively involved in (some kinds of) human thinking. Specifically, language is the vehicle of non-modular, non-domain-specific, conceptual thinking which integrates the results of modular thinking. (Carruthers, 2002, p. 666)

On this view, the output of the linguistic system just IS Mentalese: There is no other level of representation in which the information *to the left of the blue wall* can be entertained. This picture of language is novel in many respects. In the first place, replacing Mentalese with a linguistic representation challenges existing theories of language production and comprehension. Traditionally, the production of sentences is assumed to begin by entertaining the corresponding thought, which then mobilizes the appropriate linguistic resources for its expression (e.g., Levelt, 1989). On some proposals, however,

We cannot accept that the production of a sentence 'The toy is to the left of the blue wall' begins with a tokening of the thought THE TOY IS TO THE LEFT OF THE BLUE WALL (in Mentalese), since our hypothesis is that such a thought cannot be entertained independently of being framed in a natural language. (Carruthers, 2002, p. 668)

Inversely, language comprehension is classically taken to unpack linguistic representations into mental representations, which can then trigger further inferences. But in Carruthers' proposal, after hearing *The toy is to the left of the blue wall*, the interpretive device cannot decode the message into the corresponding thought, since there is no level of Mentalese independent of language in which the constituents are lawfully connected to each other. Interpretation can only dismantle the utterance and send its concepts back to the geometric and landmark modules to be processed. In this sense, understanding an utterance such as *The picture is to the right of the red wall* turns out to be a very different process than understanding superficially similar utterances such as *The picture is to the right of the wall* or *The picture is on the red wall* (which do not, on this account, require cross-domain integration).

Furthermore, if language is to serve as a domain for cross-module integration, then the lexical resources of each language become crucial for conceptual combination. For instance, lexical gaps in

the language will block conceptual integration, since there would be no relevant words to be inserted into the linguistic string. As we have discussed at length, color terms vary across languages (Kay & Regier, 2002); more relevantly, not all languages have terms for *left* and *right* (Levinson, 1996). It follows that speakers of these languages should fail to combine geometric and object properties in the same way as do English speakers in order to recover from disorientation. In other words, depending on the spatial vocabulary available in their language, disoriented adults may behave either like Spelke and Tsivkin's English-speaking population or like prelinguistic infants and rats. This prediction, although merely carrying the original proposal to its apparent logical conclusion, is quite radical: It allows a striking discontinuity among members of the human species, contingent not on the presence or absence of human language and its combinatorial powers (as the original experiments seem to suggest), or even on cultural and educational differences, but on vagaries of the lexicon in individual linguistic systems.

Despite its radical entailments, there is a sense in which Spelke's proposal to interpret concept configurations on the basis of the combinatorics of natural language can be construed as decidedly nativist. In fact, we so construe it. Spelke's proposal requires that humans be equipped with the ability to construct novel structured syntactic representations, insert lexical concepts at the terminal nodes of such representations (*left*, *blue*, etc.), and interpret the outcome on the basis of familiar rules of semantic composition (*to the left of the blue wall*). In other words, humans are granted principled knowledge of how phrasal meaning is determined by lexical units and the way they are composed into structured configurations. That is, what is granted is the ability to read the semantics off of phrase structure trees. Furthermore, the assumption is that this knowledge is not itself attained through learning but belongs to the in-built properties of the human language device.

But notice that granting humans the core ability to build and interpret phrase structures is granting them quite a lot. Exactly these presuppositions have been the hallmark of the nativist program in linguistics and language acquisition (Chomsky, 1957; Gleitman, 1990; Jackendoff, 1990; Lidz et al., 2003; Pinker, 1984) and the target of vigorous dissent elsewhere (Goldberg, 1995; Tomasello, 2000). To the extent that Spelke and Tsivkin's arguments

about language and cognition rely on the combinatorial and generative powers of language, they make deep commitments to abstract (and unlearnable) syntactic principles and their semantic reflexes. Notice in this regard that since these authors hold that *any* natural language will do as the source and vehicle for the required inferences, the principles at work here must be abstract enough to wash out the diverse surface-structural realizations of *to the left of the blue wall* in the languages of the world. An organism with such principles in place could—*independently of particular experiences*—generate and *systematically* comprehend novel linguistic strings with meanings predictable from the internal organization of those strings—and, for different but related reasons, *just as systematically* fail to understand other strings such as *to the left of the blue idea*. We would be among the very last to deny such a proposal in its general form. We agree that there are universal aspects of the syntax-semantics interface. Whether these derive from or augment the combinatorial powers of thought is the question at issue here.

Recent developmental studies from Dessalegn and Landau (2008) offer useful ways to understand the issue just raised (see also Landau et al. 2009). These investigators studied 4-year-olds' ability to keep track of two features of a visual array simultaneously: color and position. Classic work from Treisman and Schmidt (1982) has shown that such visual features are initially processed independently, so that under rapid presentation, a red "O" next to a green "L" might be reported as a green O even by adults. Young children are even more prone to such errors, often giving mirror-image responses to, for example, a square green on its left side and red on its right. Directions such as "Look very hard" or "Look! The red is touching the green" do not reduce the prevalence of such errors. But subjects told "Look! The red is on the right" improve dramatically. Landau and colleagues point out that this finding in itself isn't very surprising—except that they show that these preschoolers did not have a stable grasp of the meanings of the terms *left* versus *right*, when tested for this separately. Yet their partial, possibly quite vague, sensitivity to these egocentric spatial terms was enough to influence perceptual performance "in the moment." Two properties of these findings further support the interpretation that applies to most of the results we have reported. First, the linguistic influence is highly transient—a matter of milliseconds. Second, the

effect, presumably like those of Hermer and Spelke, is independent of *which* language is being tested. Rather, as Landau and colleagues put it, there is a momentary “enhancement” of cognitive processing in the presence of very specific linguistic labeling.

Conclusions and Future Directions

We have just reviewed several topics within the burgeoning psychological and anthropological literature that are seen as revealing causal effects of language on thought, in senses indebted to Sapir and Whorf. We began discussion with the many difficulties involved in radical versions of the linguistic “determinism” position, including the fact that language seems to underspecify thought, and to diverge from it as to the treatment of ambiguity, paraphrase, and deictic reference. Moreover, there is ample evidence that several forms of cognitive organization are independent of language: Infants who have no language are able to entertain relatively complex thoughts; for that matter, they can learn languages or even invent them when the need arises (Feldman, Goldin-Meadow, & Gleitman, 1978; Goldin-Meadow, 2003; Senghas, Coppola, Newport, & Suppala, 1997); many bilinguals as a matter of course “code-switch” between their known languages even within a single sentence (Joshi, 1985); aphasics sometimes exhibit impressive propositional thinking (Varley & Siegal, 2000); animals can form representations of space, artifacts, and perhaps even mental states without linguistic crutches (Gallistel, 1990; Hare, Call, & Tomasello, 2001). All these nonlinguistic instances of thinking and reasoning (also see Hegarty & Stull, Chapter 31) dispose of the extravagant idea that language just “is” thought.

However, throughout this chapter we have surveyed approximately half a century of investigation in many cognitive-perceptual domains that document systematic population differences in behavior, attributable to the particular language spoken. Consistent and widespread as these findings have been, there is little scientific consensus on their interpretation. Quite the contrary, recent positions range from those holding that specific words or language structures cause “radical restructuring of cognition” (e.g., Majid, Bowerman, Kita, Haun, & Levinson, 2004) to those that maintain—based on much the same kinds of findings—that there is a “remarkable independence of language and thought” (e.g., Heider & Oliver, 1972; Jameson & Hurvich, 1978). To approach these issues, it is instructive to

reconsider the following three steps that have always characterized the relevant research program:

- (1) *Identify a difference* between two languages, in sound, word, or structure.
- (2) *Demonstrate a concordant cognitive or perceptual difference* between speakers of the languages identified in (1).
- (3) *Conclude that, at least in some cases, (1) caused (2)* rather than the other way round.

Though there is sometimes interpretive difficulty at step (3)—recall Eskimos in the snow—the major problem is to disambiguate the source of the differences discovered at step (2). To do so, investigators either compare results when a linguistic response is or is not part of the task (e.g., Jameson & Hurvich, 1978; Li et al., 2009; Papafragou et al., 2008, or that do or do not interfere with simultaneous linguistic functioning (e.g., Frank et al., 2008; Kay & Kempton, 1984; Trueswell & Papafragou, 2010; Winauer et al., 2007); or where hemispheric effects, implicating or not implicating language areas in the brain, can be selectively measured (e.g., Regier et al., 2010). The cross-language differences are usually diminished or disappear under those conditions where language is selectively excluded. Traditionally, investigators have concluded from this pattern of results that language categories do not penetrate deeply into nonlinguistic thought, and therefore that the Sapir-Whorf-conjecture has been deflated or discredited altogether.

But surprisingly, recent commentary has sometimes stood this logic on its head. Interpretation of these same patterns has been to the effect that, when behavioral differences arise if and only if language *is* implicated in the task, this is evidence *supporting* the Sapir-Whorf thesis, that is, vindicating the view that language causally impacts and transforms thought. Here is L. Boroditsky (2010) in a recent commentary on the color-category literature:

...disrupting people’s ability to use language while they are making colour judgments eliminates the cross-linguistic differences. This demonstrates that language *per se* plays a causal role, meddling in basic perceptual decisions as they happen.

Thus, at first glance, investigators are in the quandary of fact-immune theorizing, in which no matter how the results of experimentation turn out, the hypothesis is confirmed. As Regier et al. (2010) put this in a recent review, such findings

... act as a sort of Rorschach test. Those who "want" the Whorf hypothesis to be true can point to the fact that the manipulation clearly implicates language. At the same time, those who "want" the hypothesis to be false can point to how easy it is to eliminate effects of language on perception, and argue on that basis that Whorfian effects are superficial and transient. (p. 179)

In the present chapter, we have understood the literature in a third way, one that situates the findings in each of the domains reviewed squarely within the "ordinary" psycholinguistic literature, as "language-on-language" effects: language-specific patterns of cognitive performance are a product of the online language processing that occurs during problem solving. These patterns are indeed transient in the sense that they do not change the nature of the domain itself (pace Whorf, 1956, and Pederson et al., 1998), but are by no means superficial. In some cases, such effects are outcomes of linguistic information handling, as these emerge online, in the course of understanding the verbal instructions in a cognitive task. For instance, because of the differential frequencies, and so on, of linguistic categories across languages, slightly different problems may be posed to the processing apparatus of speakers of different languages by what appear to be "identical" verbal instructions in an experiment (see discussion of Imai & Gentner's, 1997, results on object individuation). In other cases, linguistic information may be used online to recode nonlinguistic stimuli even if the task requires no use of language. This is particularly likely to happen in tasks with high cognitive load (Trueswell & Papafragou, 2010), because language is an efficient way to represent and store information. In neither case of linguistic intrusion does language reshape or replace other cognitive formats of representation, but it does offer a mode of information processing that is often preferentially invoked during cognitive activity (for related statements, see Fisher & Gleitman, 2002; Papafragou et al., 2002; Papafragou et al., 2008; Trueswell & Papafragou, 2010).

Other well-known findings about the role of language in cognition are consistent with this view. For example, a major series of developmental studies demonstrate that a new linguistic label "invites" the learner to attend to certain types of classification criteria over others or to promote them in prominence. Markman and Hutchinson (1984) found that if one shows a 2-year-old a new object and says, *See this one; find another one*, the child typically reaches for

something that has a spatial or encyclopedic relation to the original object (e.g., finding a bone to go with the dog). But if one uses a new word (*See this fendle, find another fendle*), the child typically looks for something from the same category (e.g., finding another dog to go with the first dog). Balaban and Waxman (1997) showed that labeling can facilitate categorization in infants as young as 9 months (cf. Xu, 2002). Beyond categorization, labeling has been shown to guide infants' inductive inference (e.g., expectations about nonobvious properties of novel objects), even more so than perceptual similarity (Welder & Graham, 2001). Other recent experimentation shows that labeling may help children solve spatial tasks by pointing to specific systems of spatial relations (Loewenstein & Gentner, 2005). For learners, then, the presence of linguistic labels constrains criteria for categorization and serves to foreground a *codable* category out of all the possible categories a stimulus could be said to belong to. Here, as well, the presence of linguistic labels does not intervene in the sense of replacing or reshaping underlying (nonlinguistic) categories; rather, it offers an alternative, efficient system of encoding, organizing, and remembering experience.

Acknowledgments

Preparation of this chapter has been supported in part by grant 5-R01-HD55498 from the National Institutes of Health to A.P. and John Trueswell and in part by grant 1-R01-HD37507 from the National Institutes of Health to L.R.G and John Trueswell.

Notes

1. "Gilead then cut Ephraim off from the fords of the Jordan, and whenever Ephraimite fugitives said, 'Let me cross,' the men of Gilead would ask, 'Are you an Ephraimite?' If he said, 'No,' they then said, 'Very well, say "Shibboleth."' If anyone said, "Sibboleth," because he could not pronounce it, then they would seize him and kill him by the fords of the Jordan. Forty-two thousand Ephraimites fell on this occasion" (Judges 12-5-6; as cited in Wikipedia).

2. Whorf's own position, and specific claims, on all the matters discussed in this chapter was often metaphorical, highly nuanced, and to some extent inconsistent across his body of work. Sometimes his concentration was on cultural differences as reflected in language rather than on language as tailor of culture. Sometimes he asserted, but sometimes rejected, the idea that particular words, word classes, or grammatical devices ("surface" facts about language) were his intended causal vehicles of mental categories and functions. Owing to this partial inconsistency, perhaps a common property of scientific views in their earliest formulations, an industry of interpreting Whorf —both by his defenders and detractors—has grown up, and it is often heated. Our aim is to explicate the theoretical positions ("Whorfianism") that are indebted in one or another way to this thinker, not to present an intellectual biography of Whorf himself.

3. We thank Jerry Fodor for discussion of these issues.

4. In one experimental demonstration, subjects were asked: *When an airplane crashes, where should the survivors be buried?* They rarely noticed the meaning discrepancy in the question (Barton & Sanford, 1993).

5. The similarity test may not be decisive for this case, as Malt, Sloman, and Gennari (2003) as well as Smith et al. (2001), among others, have pointed out. Similarity judgments as the measuring instrument could be systematically masking various nonperceptual determinants of organization in a semantic-conceptual domain, some of these potentially language-caused. Over the course of this essay, we will return to consider other domains and other psychological measures. For further discussion of the sometimes arbitrary and linguistically varying nature of the lexicon, even in languages which are typologically and historically closely related, see Kay (1996). He points out, for example, that English speakers use *screwdriver* while the Germans use *Schraubenzieher* (literally, “screwpuller”), and the French *tournevis* (literally, “screwturner”) for the same purposes; our turnpike exit-entry points are marked *exit*, whereas the Brazilians have *entradas*; and so forth.

6. These results are fairly recent, and a number of follow-up studies suggest that the picture that finally emerges may be more complicated than foreseen in Gilbert et al. For instance, Lindsey et al. (2010) report that some desaturated highly codable colors (notably, certain pinks) are not rapidly identified. Liu et al. (2009) do replicate the between-category advantage finding of Gilbert et al., but, critically, not the hemispheric advantage. If so, the suggestion is that labeling practice is penetrating to the level of nonlinguistic cognition. Roberson and colleagues adopt this very view (e.g., Roberson, 2005; Roberson, Davies, & Davidoff, 2000; Roberson, Davidoff, Davies, & Shapiro, 2005), reporting, for example, that Berinmo speakers (members of another relatively isolated Papua New Guinea tribe) were better at recognizing and remembering best examples of their own linguistic categories than color labels than the best examples of English color labels. They use such results to claim that color naming is entirely arbitrary from the point of view of perception, being solely a matter of linguistic labeling practices (for a response, see Kay & Regier, 2007).

7. This argument is not easy. After all, one might argue that English is a classifier language much like Yucatec Mayan or Japanese, that is, that all its words start out as mass nouns and become countable entities only through adding the classifiers *the* and *a* (compare *brick* the substance to *a brick*, the object). However, detailed linguistic analysis suggests that there is a genuine typological difference here; see Slobin, 2001; Chierchia, 1998; Krifka, 1995; Lucy & Gaskins, 2001, for discussion). The question is whether, since all of the languages formally mark the mass/count distinction in one way or another, the difference in particular linguistic means could plausibly rebound to impact ontology.

8. We should point out that this hint is itself at best a weak one, another reason why the observed interpretive difference for Japanese and English speakers, even at the perceptual midline, is also weak. Notoriously, English often violates the semantic generalization linking mass noun morphology with substancehood (compare, e.g., *footwear*; *silverware*; *furniture*).

9. Subsequent analysis of the linguistic data revealed that Greek speakers were more likely to include manner of motion in their verbal descriptions when manner was unexpected or non-inferable, while English speakers included manner information regardless of inferability (Papafragou et al. 2006). This suggests that speakers may monitor harder-to-encode event components and choose to include them in their utterances when especially

informative. This finding reinforces the conclusion that verbally encoded aspects of events vastly underdetermine the subtleties of event cognition. As Brown and Dell had shown earlier (1987), English actually shows the same tendency, but more probabilistically: English speakers are less likely to express an inferable instrument, for example, to say, “He stabbed him with a knife” than a noninferable one (“He stabbed him with an ice cutter”).

10. In another demonstration of this language-on-language effect, Naigles and Terrazas (1998) asked subjects to describe and categorize videotaped scenes, for example, of a girl skipping toward a tree. They found that Spanish- and English-speaking adults differed in their preferred interpretations of new (nonsense) motion verbs in manner-biasing (*She's kradding toward the tree* or *Ella está mecanando hacia el árbol*) or path-biasing (*She's kradding the tree* or *Ella está mecanando el árbol*) sentence structures. The interpretations were heavily influenced by syntactic structure. But judgments also reflected the preponderance of verbs in each language—Spanish speakers gave more path interpretations, and English speakers gave more manner interpretations. Similar effects of language-specific lexical practices on presumed verb extension have been found for children (Papafragou & Selimis, 2010a).

11. It might seem perverse to hold (as Levinson and colleagues do) that it is “lacking ‘left,’” rather than “having ‘east,’” that explains the navigational skills of the Mayans, and the relative lack of such skills in speakers of most European languages. The reason, presumably, is that all languages have and widely use vocabulary for geocentric location and direction, so to point to one language’s geocentric vocabulary would not account for the presumptive behavioral difference in navigational skill. Therefore, by hypothesis, it must be the mere presence of the alternate vocabulary (of body-centered terms) that’s doing the damage. Here L. Boroditsky (2010) makes this position explicit: “For example, unlike English, many languages do not use words like ‘left’ and ‘right’ and instead put everything in terms of cardinal directions, requiring their speakers to say things like ‘there’s an ant on your south-west leg.’ As a result, speakers of such languages are remarkably good at staying oriented (even in unfamiliar places or inside buildings) and perform feats of navigation that seem superhuman to English speakers. In this case, just a few words in a language make a big difference in what cognitive abilities their speakers develop.”

12. Further studies show that success in this task among young children is sensitive to the size of the room—in a large room, more 4-year-olds succeed in combining geometric and landmark information (Learmonth, Nadel, & Newcombe, 2002). Also, when adults are warned about the parameters of the task, they are able to fall back on alternative representational strategies (Ratliff & Newcombe, 2008). Moreover, it is claimed that other species (chickens, monkeys) can use both types of information when disoriented (Gouteux, Thinus-Blanc, & Vauclair, 2001; Vallortigara, Zanforlin, & Pasti, 1990).

Thinking in Societies and Cultures

Tage S. Rai

Abstract

Rather than focusing on cross-cultural differences in cognition, this chapter focuses on how being born into and living in any large sociocultural group is deeply intertwined with thinking. I begin by discussing the ways in which thinking in societies and cultures is heavily distributed across people, time, and technology. This selective review focuses primarily on research on distributed and extended cognition, social and transactive memory, and cognitive anthropology and cultural transmission. The second part of the chapter addresses the question of whether cultural evolution is linked to cognitive evolution in humans. In particular, I will ask to what extent our minds are predisposed to acquire knowledge relevant for succeeding in culture, and how this possibility changes our view of the role of culture in cognition. I will conclude the chapter by proposing a division between micropsychological and macropsychological levels of analysis in psychology, and I will suggest research questions that this perspective is uniquely suited to address.

Key Words: macropsychology, distributed cognition, cognitive anthropology, cultural transmission, cultural evolution, social biases, social learning, enculturation, group psychology, social media

Introduction

Without men, no culture, certainly; but equally, and more significantly, without culture, no men. (Geertz, 1973, p. 49)

Although it may be unintended, the disciplinary term “culture and cognition” implies a clean distinction between minds and the sociocultural contexts within which minds exist and must operate. Similarly, reviews of culture and cognition typically focus on *cross-cultural differences* in thinking, such as the differences in attention, categorization, causal attribution, or causal reasoning reported between individualistic (independent, analytic) cultures and collectivistic (interdependent, holistic) cultures (for recent comprehensive reviews of this literature, see Heine & Ruby, 2010; Lehman, Chiu, & Schaller, 2004; Markus & Kitayama,

1991; Nisbett, 2004; Nisbett & Norenzayan, 2002; Nisbett, Peng, Choi, & Norenzayan, 2001; Segall, Lonner, & Berry, 1998; Triandis, 1989). In this chapter, I would like to question the distinction between culture and cognition, while considering basic and often overlooked ways in which our thinking is inextricably linked to life in societies and cultures (see Fessler & Machery, in press; Fiske et al., 1998).

Just as there are interactions between the cell and the individual mind, there are interactions between the individual mind and the social group, such that the cognitive processes of both are influenced by the existence of the other (Brown, Collins, & Duguid, 1989; Hutchins, 1995a; Lave & Wenger, 1991). What I term “macropsychology”—the complexity of human cognition that emerges in sociocultural groups—concerns how living and being born into

any human culture changes the way we think, what we think about, and how our minds have evolved.

For our purposes, I will define human societies simply as large groups of socially interacting individuals. Notably, modern societies are often characterized by high levels of access to technology, which as I address later, has significant downstream effects on cognition. Although historically contested (Lug-hod, 1991), I will define culture simply as the set of shared meanings, knowledge, and practices that are transmitted within societies across generations. Culture is embodied in a society's objects, tools, language, artifacts, rituals, technologies, and media. Note that the entire body of culture is not shared by everyone within a society. Issues of communication and physical access will prevent everyone from participating in all aspects of culture, while issues of trust and legitimization will create cultural barriers to sharing information between subgroups within a society. As far as a definition of "thinking," I will focus on how cognition within societies and cultures is characterized by "thinking for doing" (Fiske, 1992), wherein processes such as memory, reasoning, and decision making occur in the service of navigating social-relational interactions.

Rather than providing an exhaustive review of all of the ways in which thought and culture are intertwined, my goal in this chapter is to map out the research terrain so as to highlight key areas for future study, and to spur research on the intersection of thought and culture. In particular, I will draw on relevant research in cognitive anthropology and theories of distributed cognition, social neuroscience and theories of cultural evolution and transmission, and sociological and psychological approaches to cognition in social groups. Much of this work is captured under similar headings, such as distributed, situated, extended, and embodied cognition; or social, collective, transactive, and collaborative memory. Although relevant for thinking about group cognition, I will not focus in great detail on the vast literature documenting social biases in individual cognition, such as social influences on eyewitness memory (Loftus & Hoffman, 1989) or the effects of stereotypes on performance (Steele & Aronson, 1995). Instead, I will only consider social biases that capture emergent properties at the level of the group, such as research on group polarization or conformity. I will also not focus on proposed instances of culture or tool use in other mammals, as it is simply not on the same scale as that of humans (see Penn & Povinelli, Chapter 27). Nor will I

consider in detail research on artificial intelligence, or the swarm intelligence evident in colonies of ants, schools of fish, or flocks of birds, because my focus in this chapter is restricted to human thinking and how it has been affected by social life. Through this selective review, I hope to shed light on how the advent of society connected through culture generates macropsychology by distributing thinking across people, time, and technology.

By reviewing the distributed nature of cognitive processes such as thinking, knowing, reasoning, learning, remembering, and decision making, it will become apparent that living in societies connected by culture is not only necessary for acquiring specific kinds of knowledge (e.g., how to perform an initiation rite or how to dress for the festival), but that it is crucial for *producing* human cognition in arguably its most important respects. Specifically, culturally produced cognition enables us to build on and recombine the ideas of others by distributing cognitive processes, generating collective representations, and selecting for cognitive abilities that are advantageous to individuals living in social groups. At the same time, conditions or events that affect the social group will have major implications for individual-level thinking, reasoning, knowledge, and preferences. With this perspective in mind, we can ask two sets of interrelated questions.

1) How does participation in societies and cultures facilitate a division of cognitive labor across people, time, and technology? How is information represented and transmitted in this system and what are its consequences?

2) How has individual thinking adapted specifically for learning and succeeding in a sociocultural setting, both in terms of brain evolution and the cognitive capacities we are predisposed to develop? Would the removal of culture alter cognitive processes or the informational content informing those processes, or both? Is such a hypothetical state even possible?

To examine these questions, I will consider the nature of individual knowledge and how we leverage the expertise of others, how knowledge is accumulated and transmitted via social learning and cultural evolution, the sensitivity of our thinking to social sources of information and the impact of group changes on our thinking, how technology augments our memory capacity and processing capabilities, and the ways in which our minds may be specifically adapted for learning culture.

I will conclude the chapter by discussing how a fuller understanding of the relationship between culture and thought can transform the nature of psychological inquiry and give rise to quite promising new avenues of research into both individual and group psychology. In particular, I will suggest that we must examine the emergent macropsychology of social groups, as cognitive processes cannot be reduced to the aggregate of individual psychologies. At the same time, we will have to bolster studies of individual psychology with an understanding of the socio-cultural contexts in which it developed. Within this framework, observational and descriptive research outside of the laboratory will be required in order to inductively develop and test theory against real-world behavior. Guiding questions will include how individual thinking is embedded in culture, how we should represent cognitive processes at the level of the group, in what ways we may be specifically attuned to learning and thinking with others, and the ways in which thinking sometimes occurs independent of knowledge.

Cognition Through Culture

For socially marginalized, otherwise quite intelligent adolescent boys (i.e., “nerds”), there is no better pastime than imagining how great life would be if they could travel back in time. Just as the Connecticut Yankee awoke in King Arthur’s court following a blow to the head (Twain, 1889), they too would reemerge from the lockers they were stuffed in to find a preindustrial Camelot that they could rule with their modern knowledge and superior intellect. Unfortunately, for the nerds, what they fail to realize is that they—and people in general—actually don’t know how to do much of anything *completely on their own*. Rather, a given individual, no matter how intelligent, knows incredibly little.

Thinking Distributed Across People

Even an expert on modern firearms, such as the Connecticut Yankee, would be helpless without any idea as to how to produce necessary raw materials, such as lead or gunpowder, from scratch. Similarly, I know how to turn on a switch, but I don’t have any deep understanding of how my television or my microwave works, let alone the myriad causal processes that interact between my home, a power plant, and the earth’s magnetic field (is this even involved?) to generate electricity.

What about a relatively simple device, such as a zipper? In any deep sense, do you have any idea how

exactly a zipper “zips”? In a series of experiments, Keil (2003, 2006, 2010; Rozenblit & Keil, 2002) has documented our lack of explanatory understanding. In one study with *graduate students at Yale*, participants were asked to write detailed explanations for everyday artifacts. It was found that explanations of even simple objects such as zippers or piano keys were quite shallow. At the same time, their confidence in their explanatory knowledge was extraordinarily high (Rozenblit & Keil, 2002).²

If we understand so little and fail to realize it, how do we succeed? Keil (2003, 2006) has argued that we overcome our shallow understanding by successfully leveraging the knowledge of other people. Such a situation is familiar to scientists, who often succeed not by knowing everything themselves, but by knowing who to consult. In support of this view, Keil (2010) has found that children as young as 8 years of age can distinguish categories on the basis of their likelihood to have experts (e.g., hammers used by miners vs. hammers with red handles).

Wegner (1987; also see Hollingshead, 1998) has found that romantic couples leverage each other’s expertise by dividing the work of remembering between each other, a process he refers to as “transactive memory.” When tested together, the extent to which participants will remember new information depends in part on the expertise *their partner* has in the knowledge domain. Transactive memory systems have also been investigated in the context of production in work teams in both short-term (Liang, Moreland, & Argote, 1995) and long-term tasks (Austin, 2003). It has been found that training groups together on a task (e.g., building a transistor radio) can increase memory for the procedure and subsequent performance at test. Such transactive memory processes likely include encoding of information as well. When a member of your transactive memory system encounters information of which they know it would be important for you to be aware, they can encode that information and transmit it to you at a later time. They can even encode the source of that information so that you can engage in deeper level processing of the information on your own (Wegner, 1987).

In contrast, studies of “collaborative memory” have typically argued that remembering in groups inhibits memory function. These studies have shown that although social groups working together do recall more than a single individual, they recall less than a group of individuals working separately (Weldon & Bellinger, 1997). However, there are

two causes for possible concern with this line of inquiry. First, it disregards the fact that “pooling” the responses of individuals working separately is itself social in nature, requiring a hierarchical distribution of responsibilities that may occur in many real-life collaborative efforts. Second, although groups of individuals working separately on a single small task may outperform groups working together, groups working together will have the ability to distribute their cognitive efforts across several large tasks and build on the efforts of each other over time to accumulate and transmit a much greater shared body of knowledge.

Representation and Transmission Across Time

Living in social groups greatly enhances the cognitive capacity of a given individual because we can rely on others for both additional memory and information processing, without having to learn or remember nearly so much on our own. Information transmitted from others provides a sort of scaffolding upon which individual learning can build. In turn, individual learning can lead to modifications in previous knowledge, behaviors, and practices. Thus, our modern knowledge actually reflects an accumulation of information socially transmitted across generations (Henrich & McElreath, 2003; Richerson & Boyd, 2005; Tomasello, 1999).

To build on the contributions of other people and to consolidate their knowledge into chunks of information that we can understand, we need culture to *mediate* our access to this shared body of knowledge (Cole, 1995; Vygotsky, 1978). Drawing on schema theories, D’Andrade (1981) argued that we employ cultural schemas to facilitate use of this shared body of knowledge by organizing the information into usable chunks or scripts imbued with meaning, such that access to one part of the cultural model and its meaning (e.g., walking into a restaurant) will activate the rest of the cultural model (e.g., wait to be seated, open menu, and order food). Importantly, because of the distributed nature of thinking, individuals involved in a situation will never have access to all of the information, but they will share enough knowledge to coordinate, much as in Keil’s (2010) example of expert knowledge. Thus, I may have no knowledge of what a waiter does with my order, but both the waiter and I know what our roles and responsibilities are.

The mechanisms by which people in a social group acquire culturally mediated knowledge from

others are varied, but perhaps the most important is learning through observation and subsequent imitation, processes by which individuals actively attempt to reproduce behaviors they have seen (Lancy, 1996; Tomasello, 1999). The classic study of observational and imitative modeling was Bandura, Ross, and Ross’s (1963) experiment in which they found that children were more likely to engage in aggressive behaviors toward a doll if they had previously observed an adult engaging in such behaviors. In naturalistic settings, observational and imitation-based learning is evident in the guided participation characteristic of apprenticeship in non-Western cultures (Brown et al., 1989; Lave & Wenger, 1991). In these situations, there is little explicit teaching by masters. Rather, apprentices observe masters, imitate their actions without complete understanding, and slowly gain mastery themselves as they take on greater responsibilities over time (e.g., when Daniel-san unknowingly learns karate by helping Mr. Miagi fix up his house).

Experimental investigations into how these learned behaviors are transmitted and modified over time have focused on the development of strategies within “micro-societies” (Caldwell & Millen, 2008). In these studies, participants are removed and replaced from groups as they try to design basic artifacts in order to simulate generational change. For example, in one study groups of participants were tasked with constructing paper airplanes that could travel as far as possible. At any given time, some participants were constructing airplanes while others observed and asked questions of them. Over time, those who constructed their airplanes tested them and were subsequently replaced by those who observed them, with new observers entering the scene. Completed airplanes were kept available with their recorded distances for all subsequent group members, such that all participants had a historical record of all previous attempts. This process was meant to simulate vertical transmission across generations, in which a given learner has access to the knowledge and efforts of previous generations.

Caldwell and Millen found that within a 10-person group, the performance of airplanes significantly improved across generations: on average, the paper airplane produced by the tenth participant traveled nearly three times further than the airplane produced by the first participant. The similarity of airplane designs within a group, as assessed by a separate group of naïve raters, was closer between airplanes of successive generations than between generations

that were farther apart, as would be expected if transmission with gradual modification was occurring. Similarity was also closer among airplanes from the same group than between airplanes from different 10-person groups, suggesting a process analogous to cultural variation took place. However, similarity between different groups increased over time; paper airplanes made by the eighth, ninth, and tenth participants in the groups were more similar to their counterparts in the other groups than those made by earlier participants, suggesting a process of convergent evolution toward objectively more efficient designs (Caldwell & Millen, 2008; also see Griffiths, Kalish, & Lewandowsky, 2008).

Culturally mediated social learning via observation, imitation, or other mechanisms generally makes sense when it is difficult to learn things on your own.³ Moreover, we do not copy just anyone, but rather we are biased toward learning from *particular* others. For example, children are often biased toward horizontal imitation of same-age or slightly older children rather than vertical imitation of parents, likely because other children are the models from whom they would have the most to learn in many cases (Harris, 1995). Similarly, we may be biased toward copying the successful and conforming to the majority. Copying successful models rather than learning yourself is generally advantageous when individual learning is difficult, and when there is a large amount of variation in the abilities between the successful and the unsuccessful (Henrich & Gil-White, 2001). Success-biased transmission was evident in my (failed) attempts to copy and incorporate Michael Jordan's fade-away jumper into my basketball game as a child. Similarly, conforming to the majority may be more advantageous than individual learning when learning is difficult because conformity is roughly equivalent to basing actions on a large sample (Henrich & Boyd, 1998). Conformity-biased transmission is evident in odd fashion trends, such as my regrettable but effective attempts to copy the use of flannel shirts during the early 1990s. Finally, it is likely that we also biased toward selectively copying people to whom we are connected by social relationships, such as friends and family members as opposed to strangers (Fiske, 1991).

Coconstruction, Sampling, and Isolation

COCONSTRUCTION OF KNOWLEDGE

With the advent of language, processes of observation and imitation have been augmented by the learning of oral narratives. In such situations, knowledge

is reproduced and modified with each telling to facilitate even greater maintenance and accumulation of knowledge over time (Boyer, 1992; Sperber, 1985). In modern contexts, such oral transmission is codified in the coconstruction of history; our collective memory of the past (Halbwachs, 1950; Olick & Robbins, 1998; Zerubavel, 1996). Specifically, history is coconstructed by recombining the individual memories of large groups of people to form a narrative from which later generations may learn. Due to our lack of direct access to the past events recounted in the narrative, history is continually reconstructed in response to the needs of the present (Schwartz, 1991). For example, Welzer (2010) has found that when German grandchildren interview their grandparents about World War II, they actively change various aspects of their grandparents' narrative to satisfy their own psychological need to deal with a collective trauma. These alterations are mutually supported by members of the younger generation and transmitted horizontally within the younger generation to reconstruct history into a new, modified version of itself. Because of this coconstructive nature of history, it cannot be reduced to individual memory, and it must instead be considered a collective representation (Halbwachs, 1950)—an invention made possible by individuals living together in culturally connected societies.

SAMPLING BIASES

One basic consequence of learning so much from other people is that many of our beliefs and attitudes are largely a product of where we grew up. Latane (1981, 1996) has argued that because people close to you will naturally have more impact on your learning, shared beliefs and attitudes will begin to cluster in physical space, and sets of different beliefs will begin to correlate with each other, in a process he refers to as "dynamic social impact." Latane and Bourgeois (1996) have demonstrated that differential sampling of beliefs leads to clustering of beliefs among the groups that are sampled, correlations among different beliefs within these groups, consolidation of minority groups, and some level of diversity even when everyone attempts to be in the majority.

The potentially adverse impact of relying on sampling rather than individual learning is evident in studies of information cascades (Anderson & Holt, 1997). In an information cascade, if the first few individuals make a particular judgment or express a particular belief, subsequent individuals will copy

their actions even if doing so contradicts their own beliefs. Specifically, if my own calculation supports hypothesis A, but the *expressed* judgments of everyone before me support competing hypothesis B, then I will weigh their expressed judgments as evidence for competing hypothesis B and may express a judgment in favor of hypothesis B in spite of my own calculations. Such a process can generate a cascade of conformity in which all subsequent individuals support the competing hypothesis, even if their own individual calculations support a different hypothesis (also see Asch, 1955).

The errors that can result from misrepresentations of other actors' internal beliefs are also evident in research on group polarization (Isenberg, 1986; Moscovici & Zavalloni, 1969) and pluralistic ignorance (Miller & Prentice, 1994). Group polarization refers to the tendency of group decisions to be more extreme than the average decisions that would have been made by individuals. For example, in jury decision making, awards of damages following group discussion become either significantly more severe or more lenient than the average decisions made by individuals (Bray & Noble, 1978). In cases of pluralistic ignorance, members of a group express public views that differ from their inner views. They fail to express their inner views because they assume that everyone else's inner views correspond to their public views and worry about the social costs of publicly dissenting. For example, Miller and Prentice argued that pluralistic ignorance can lead members of juvenile gangs who did not harbor extreme antisocial attitudes when they first joined to "act tough" to match their perceptions of everyone else's positions. As a consequence of this process, all the gang members may pursue antisocial behavior that none of them would have preferred individually.

Inventions of modern societies, such as prediction games and markets, can offset some of the risks of information cascades, pluralistic ignorance, and group polarization. In prediction games and markets, large groups of individuals make predictions about the likelihood of events ranging from sports victories to presidential winners (Wolfers & Zitzewitz, 2004). It has been argued that these large groups of individuals making predictions are more accurate in the aggregate than any expert due to the inherent advantages of large samples over small ones (Surowiecki, 2005). The key is for individuals to make their predictions independently so as to avoid the problem of information cascade, and to make their decisions anonymously so as to avoid the social

costs that lead to pluralistic ignorance. Surowiecki argued that when prediction markets have failed, such as in the case of stock market bubbles, it has been because the conditions of independence and anonymity were not satisfied. As I will touch on later, the ability to draw on the wisdom of crowds in making judgments that are superior to individuals requires culturally mediated information technologies that are themselves products of living in modern societies.

COSTS OF ISOLATION

Perhaps more intriguing than the cognitive consequences of participating in a social group are the cognitive consequences of being cut off from the group. Wegner (1987) hypothesized that the cognitive impairments reported by recent divorcees may not be the result of psychological trauma, but rather may actually reflect the loss of an integral part of a transactive memory system. Specifically, if romantic couples naturally and implicitly divide the work of remembering between them, it may take time for former partners to reallocate resources to areas that were once outside of their cognitive responsibilities. Similarly, analyses of poverty have argued that low-socioeconomic status (SES) individuals lack access to the extensive environmental and interpersonal supports that people in high-SES environments rely on for everyday cognition. As a consequence, living poor in America is akin to a chronic state of thinking under divided attention, a condition known to severely impair cognitive processing (Bertrand, Mullainathan, & Shafir, 2004).

Historical examinations of rapid population change have also demonstrated the consequences of changes to the group on cognition. For instance, when discovered by Europeans, Tasmanians only employed about 24 simple tools with regularity. In contrast, the aboriginal Australians 200 kilometers away, who used to be connected to Tasmania via a land bridge, used hundreds more tools that were much more complex, including specialized spears and nets for hunting and trapping prey. Moreover, the archaeological record suggests that tools in Tasmania were more complex 10,000 years earlier (just before the land bridge to Australia was engulfed by the ocean) than at the time of initial European contact (Henrich, 2004). Henrich cites these changes as evidence that tools did not merely stop developing once the island became isolated from mainland Australia. Rather, it seems that a culturally accumulated body of knowledge related to tool use was gradually

lost once the number of individuals over whom knowledge could be distributed and from which it could be learned was greatly reduced.

Thoughts Extended Into Technology

Would you still like to know how a zipper works? Go to <http://science.howstuffworks.com/innovation/everyday-innovations/zipper.htm>.

Rozenblit and Keil (2002) interpreted their participants' overconfidence as an error in the participants' metacognitive awareness of their own knowledge given the shallow explanations they were able to provide in the experiment. However, their overconfidence may indicate that rather than stating the actual explanatory knowledge available to them *in their heads*, the participants were in fact reporting whether they would be able to find the answer through a process of search involving various social technologies. As the aforementioned Internet link exemplifies, much of our available knowledge is actually not inside any individual's head; rather, it is now recorded in various culturally mediated written, electronic, or oral media that participants can easily access.

Importantly, this fact raises an interesting question as to whether Rozenblit and Keil's (2002) participants actually made a metacognitive error, and by extension, whether they actually had shallow explanatory knowledge. If we do not define knowledge as restricted to the memory storage of an individual mind, but instead include external culturally mediated memory retrieval such as going to a library, surfing the Internet, or consulting experts who can perform their own searches, then participants' explanatory understandings may have been quite rich. Similarly, should we consider a person who has corrective glasses to have poor vision, or a person with a hearing aid to have poor hearing? From a practical standpoint, does it make sense to test students' ability to hold information in their head, or should exams be "open-book" in the same way that students are now allowed to use calculators on most mathematics tests?

In their work on the extended mind hypothesis, Clark and Chalmers (1998) have emphasized this broader conception of cognition, which includes artifacts and objects in the world that can unite the knowledge of large groups of individuals. Inventions such as writing and computers have enabled us to massively augment our long-term memory as well as facilitate our working memory, as in "carrying" processes during mathematical operations,

spatial tasks requiring rotation, or writing out our thoughts during brainstorming. For example, Clark and Chalmers argued that if two people were trying to get somewhere and one memorized the location while the other wrote it down in a notebook always on his or her person, both could be said to be utilizing their memories and have merely stored the information in different locations. External cognitive processes are often faster than cognitive processes inside the head. For example, in the game "Tetris," pressing the rotate button repeatedly until the correct configuration appears may be faster than mentally rotating the object yourself (Kirsh & Maglio, 1994). According to Clark and Chalmers, if we redefine cognition as extended into environmental supports, then we can actually think of processes such as writing as alternative forms of thinking. (For other reviews of embodied and extended cognition, see Anderson, 2003; Wilson, 2005.)

In a similar vein, Hutchins (1995b) argued that the distribution of cognitive tasks across individuals and objects, and the specialization of work it enables, is critical to the success of complex cognitive tasks such as landing a plane. For example, pre-calculated informational readouts ("speed cards") detail the speed a plane should travel given its gross weight in order to land successfully. According to Hutchins, speed cards and other similar technologies should not be thought of as long-term memory aids, because people cannot change the information on the speed card and because its existence enables pilots to engage in different cognitive processes, such as spatial cognition tasks. Rather, the speed card is the long-term memory for the cognitive system of the plane and its crew, of which an individual pilot is merely one part (also see Hutchins, 1995a).

Recently, social-collaborative technologies such as Wikipedia have distributed cognitive processing in ways never thought possible. Kittur and Kraut (2008) have argued that whereas before there were significant costs and losses of information in the process of collaboration, Wikipedia has reduced these costs through its ability to maintain fidelity of the knowledge built across individuals, allowing them to build on each other's efforts.⁴ The up side of such collaboration is that the quality of work written and rewritten by several people is uniformly higher than the efforts of a single individual. Thus, the level of quality of Wikipedia articles is equivalent to traditional encyclopedias, and the highest quality Wikipedia articles have had the most editors. This process of having large groups edit and reedit each

other's work can be considered a form of group-level thinking in which rough ideas are gradually modified into final forms.

In this framework, culturally mediated technologies have enabled the individual mind to become part of ever-expanding cognitive networks that solve complex problems no individual mind could solve on its own (Hutchins, 1995a). Perhaps most intriguing are cases where we have actually outsourced our thinking to technology. For example, the "genius" feature in Apple's iTunes takes pre-established preferences and uses them to generate new preferences. Via access to the preferences of a large group of individuals, iTunes can compute correlations among preferences for different types of music. With this information, it can form categories and subsequently perform inferences to identify new music for us (Brooks, 2007). It should be noted that societies and cultures vary considerably in their access to information technology. As touched upon earlier in the context of poverty, some cultures cannot afford to provide access, others restrict it, and others do not trust the people in control of it. Do such cultures know less? To what extent do some cultures overly rely on technology, thus being exposed to misinformation?

Cognition for Culture

The result of the culturally mediated distribution of thinking across people, time, and technology, is that a given individual *never needs to know*. Rather, the "cognitive division of labor" (Wilson & Keil, 1998) has changed cognition at the individual level by enabling individuals to focus their attention on specialized tasks that can complement others in the service of group goals. In the following sections, I will consider the possibility that living in societies connected by culture may have actually altered the evolution of our minds and the cognitive processes they perform.

Evolution of Cultural Cognition

If thinking is incredibly interconnected with social living, then it may be possible that our minds have coevolved with the emergence of large social group living (Richerson & Boyd, 2005; Tomasello, 1999). In terms of the evolution of neural systems, we know that in primates as compared to other species, the neocortex has grown disproportionately to the rest of the brain (Dunbar, 1993; see Morrison & Knowlton, Chapter 6). Importantly, the energetic costs of building larger brains likely required a greater

proportion of meat and fat in our diet, which in turn was likely made possible by socioculturally mediated inventions such as cooking and improvements in hunting (Richerson, Boyd, & Henrich, 2010).

It has been hypothesized that selection for changes to neocortex occurred in part to support social learning and the acquisition of culturally transmitted information (Henrich & McElreath, 2003). Support for this view is based on data indicating that across primates, neocortex size relative to body size is correlated with many aspects of complex social group living, including the size of the social group (Dunbar, 1992) and the propensity for social learning (Reader & Laland, 2002; for a review, see Dunbar & Shultz, 2007).

In terms of particular neural systems, functional imaging studies have revealed that dorsomedial prefrontal cortex and the medial parietal cortex are tonically deactivated by engaging in general cognitive and reasoning tasks when compared to the resting baseline activation, as opposed to the baseline activation established by a control condition.⁵ In contrast, these areas are activated beyond the resting baseline when participants view social-relational interactions, suggesting both that these areas function to process social relations, and that thinking about social relationships is what we do most of the time (Iacoboni et al., 2004). Similarly, one key to succeeding in social groups may be the ability to infer the inner mental states of others when observing their behavior. This process, referred to as "mindreading," may also support our capacities for observational and imitation-based learning (Gallese & Goldman, 1998; Rizzolatti & Craighero, 2004; but see Lillard, 1998).

In primates, it has been found that mirror neurons located primarily in the ventral premotor area fire both when performing a goal-directed action (e.g., grasping an object) and when observing another individual performing the same action. Importantly, these neurons will not fire if the action of the observed individual is not goal directed, for example, if the person is grasping at nothing (Rizzolatti & Craighero, 2004). Iacoboni et al. (2005) extended this work to humans by demonstrating that mirror neuron systems uniquely fired when participants viewed scenes for which differential interpretations of the actor's intentions were possible. It has been hypothesized that the mirror neuron system in humans has adapted beyond that of other primates to form the basis for a sophisticated simulation-based mindreading mechanism, necessary for successful social interaction (Gallese & Goldman, 1998).

Social-Functional Aspects of Thought and Predispositions to Learn Culture

If our minds have coevolved with culture, it is possible that some of our most basic cognitive functions have adapted specifically for succeeding in social groups, and that we are predisposed to acquire socially relevant skills without extensive learning. In the broader cognitive framework sketched in this chapter, natural selection can be understood as “learning encoded on a long timescale,” because it can select for early acquisition of particular psychological tendencies and preferences over time if there is stability in the relevant behavioral contexts across generations.

For example, if skills such as imitation or mind-reading are recurrently adaptive, then there may be selective pressure toward evolving predispositions for early acquisition of these skills. Meltzoff and Moore (1977) found that young infants can mimic the mouth gestures of people they see, suggesting an evolved predisposition to imitate other people. Gergely, Bekkering, and Kiraly (2002) have found that as early as 14 months of age, infants appear to be aware of the goal-directed nature of actions. When 14-month-old infants observed a model turn off a light with her head when her hands were free, the infants were likely to imitate the model’s head action in turning off the light. However, infants who observed the model using her head when her hands were occupied were significantly less likely to imitate this head action, suggesting that the infants had inferred that the only reason the model used her head was because her hands were occupied. Similarly, Onishi and Baillargeon (2005) have demonstrated that even 15-month-old infants can pass a nonverbal version of the false belief task, in which participants must infer whether another actor knows the location of a toy.

More extreme social-functional theories have argued that language evolved as a consequence of living in larger social groups, which required mechanisms for tracking the histories of the numerous social relationships that developed (Dunbar, 1996); or that reasoning evolved as an argumentative tool to convince others to support our positions (Mercier & Sperber, 2010). Although direct evidence for these theories is lacking, there is some indirect evidence. By studying transmission chains, in which participants pass information along to each other in sequence, Mesoudi, Whiten, and Dunbar (2006) demonstrated a bias toward transmitting and maintaining social information compared to

equivalent nonsocial information. Regarding reasoning, Mercier and Sperber (2010) argued that the ubiquity of reasoning errors supported their hypothesis regarding its argumentative functions. From this perspective, “errors” such as confirmation bias or examples of motivated reasoning (see Evans, Chapter 8; Molden & Higgins, Chapter 20) indicate that individuals do not reason in order to discover truth, but rather that reasoning is instead adapted to persuade listeners of our point of view. However, it should be noted that the mere existence of such biases does not constitute strong evidence for a social-functional view of reasoning, as they are also quite compatible with a Bayesian rational account of argumentation (see Hahn & Oaksford, Chapter 15; Rai & Holyoak, 2011).

Alternative social-functional theories of cognition with stronger support are Relational Models Theory (Fiske, 1991, 1992) and Relationship Regulation Theory (Rai & Fiske, 2011). According to Relational Models Theory, particular patterns of social interaction are stable across generations, and as a consequence we have evolved particular social-relational schemas for constituting and successfully navigating our social relationships. For example, “authority-ranking” relations are ubiquitous in societies and are typically constituted iconically through indices of magnitude, such as size or height, with greater magnitudes being associated with higher positions in the hierarchy. Whereas Relational Models Theory provides a taxonomy of the dominant social relationships that exist across cultures and how they emerge in ontogeny, Relationship Regulation Theory specifies the distinct moral motives and actions that have evolved to successfully maintain and regulate those relationships. For example, authority-ranking relations are motivated by “hierarchy,” which requires that subordinates respect and defer to superiors, who in turn are required to lead, guide, direct, and protect subordinates. (See Waldmann, Nagel, & Wiegmann, Chapter 19, for a review of work on moral judgment.)

Relational Models Theory predicts that people are predisposed to acquire certain social-relational schemas early in development and Relationship Regulation Theory predicts that people are predisposed to acquire corresponding moral motives. Thomsen et al. (2011) found that by 10 months of age, infants show greater surprise when they see a larger anthropomorphized block physically “bow” and defer to a smaller anthropomorphized block than vice versa, controlling for nonsocial factors.

As smaller and larger size are constitutive of subordinate and superior positions in authority-ranking relations, and as the hierarchy motive requires that subordinates defer to superiors, this finding suggests that even preverbal infants have expectations regarding appropriate social behavior in authority relationships, without having received explicit teaching. Similarly, infants as young as 8 months of age prefer a puppet that harmed a previously antisocial puppet to a puppet that helped that same puppet (Hamlin, Wynn, Bloom, & Mahajan, *in press*). This finding suggests that our minds are not innately predisposed toward specific moral actions, such as a prohibition against intentional harm (Haidt, 2007; Hauser, 2006); rather, we are predisposed to acquire expectations and motives regarding the correct conduct of social relationships without explicit teaching. Although “core knowledge” has been proposed in nonsocial domains such as intuitive physics or folk biology (Carey & Spelke, 1994), we are only now beginning to consider that the mind may also be predisposed toward early acquisition of social-relational knowledge necessary for successful living in sociocultural groups.

An Illusory Distinction

There is no such thing as a human nature independent of culture. Men without culture... would be unworkable monstrosities (Geertz, 1973, pp. 48–49).

Within classical formulations of psychology, a distinction has often been cast between what are considered conceptually important basic universal cognitive “processes,” such as perception, reasoning, decision making, and memory, and what are considered relatively unimportant learned “content” that informs those processes and varies across cultures. Thus, the Azande may believe in witchcraft, but it is not because they have engaged in cognitive processes fundamentally different from those of Westerners. Rather, their beliefs are due to what they have been taught; they find confirmation of their beliefs via the same reasoning biases that Westerners exhibit (Evans-Pritchard, 1937/1976). Conceptualized in terms of an analogy between the mind and an information-processing computer, cognitive processes represent underlying “computations,” whereas cultural content represents the “inputs” on which the computations are performed (Block, 1995). Different inputs will lead to different “outputs,” but the computation remains unchanged

and is therefore the fundamental object of study for investigators of cognition.

Nisbett and colleagues (reviewed in Nisbett, 2004; Nisbett et al., 2001) have challenged this view through their research into cross-cultural differences in cognition between individualistic (independent, analytic) and collectivist (interdependent, holistic) cultures. In line with contemporary theories of Bayesian rational reasoning and the importance of prior beliefs (see Griffiths, Tenenbaum, & Kemp, Chapter 3), they have contended that inputs into cognition are fundamental to cognitive processing because they determine what cognitive processes individuals will engage in. For example, one widely documented difference is between the “analytic” reasoning styles of individualist Westerners and the “holistic” reasoning styles of collectivist Easterners. Under this formulation, ecological and historical factors have led people in Western societies to assume direct cause-effect relations and consequently place greater emphasis on focal objects, whereas people in Eastern societies are more prone to assume that actions occur in a field of forces and consequently emphasize the wider context within which actions take place. In contrast to the Azande example, Nisbett et al. (2001) argue that due to these different implicit theories and epistemologies of the world, Easterners and Westerners will actually engage in different cognitive processes. For example, when viewing a scene, Easterners focus their attention on background images and have better memory for those images than Westerners, who in turn demonstrate the opposite pattern by focusing their attention on focal images in the foreground.

By Nisbett et al.’s (2001) own admission, their position is “at the same time less radical and more radical than the assertion that basic processes differ across cultures” (p. 306). On the one hand, they have suggested that culture does affect process in a profound way because the different theories and epistemologies learned in different cultures trigger different processes. On the other hand, they are still operating within the traditional conceptualization of a separation between content and process. They have simply argued for an additional computational step of selecting among multiple alternative cognitive processes in which an individual might engage. Cultural inputs that differ across cultures bias which cognitive processes are pursued. In this framework, culture is still operationalized as that which is different between two groups; it serves as a latent variable that can be used to explain additional variance, in

the same manner that social psychologists might use race or gender.

Although I agree that prior beliefs have been underemphasized and are certainly sensitive to culture, based on the research reviewed in this chapter I would like to push further by suggesting a blurrier (perhaps even nonexistent) distinction between process and content (Geertz, 1973). Living in large social groups connected by culture has selected for vast changes in neural systems and led to specialized psychology for succeeding in societies and cultures. Consequences include the evolution and development of cognitive capabilities specifically relevant to grasping implicit cultural meanings, including observational learning and imitation as well as biases that favor attending to social-relational information and thinking about social relationships. These cognitive capabilities have allowed us to build and inhabit more complex societies over time, enabling the distribution of knowledge across people, time, and technologies so that a given individual needs to know and think about incredibly little in order to function successfully.

In this framework, we cannot simply strip away culture to see what cognitive capacities are left. We will find relatively little remaining, as much of the human mind has adapted specifically for functioning in societies and cultures. Rather, we must investigate cognition in the context of the modes of thought produced by evolving and living in societies and cultures.

Conclusions and Future Directions

My aim in this chapter has been to raise some basic questions about how thinking is manifested within societies and cultures. In so doing, I have suggested that we should shift our attention toward examining cognitive processes at the level of the social group and more fully integrate analyses of the sociocultural environment into psychological theorizing. The promise of this approach is that it may provide insights into cognition that could never be attained if we focused only on the cognitive processes that lend themselves to a view of individual minds working in isolation.

In modern economics there is a distinction between microlevels and macrolevels of analysis that captures the idea that patterns and causal relations operating at the level of large groups and societies cannot simply be reduced to the aggregate principles underlying the actions of individuals. Rather, there are emergent properties of groups that must

be analyzed using different methods and theories. Within psychology, research on cognition has been dominated by investigations into the processes that occur within an individual mind studied in isolation. The research discussed in this chapter can be interpreted as a proposal for establishing a division between such micropsychology and the macropsychology discussed in this chapter. This division is based on the recognition that individual minds are part of larger cognitive networks, which have emergent psychological properties that cannot be reduced to individual psychological processes alone. In this framework, we will have to consider how social ecologies impact patterns of social relations, generating cultural histories that in turn produce particular patterns of cognition at both the microlevel of individuals and the macrolevel of groups.

This new model of research will require that we be willing to leave the laboratory and inductively develop our theories based on real-world observation of everyday social interaction (Rai & Fiske, 2010). For example, at the micropsychological level, cognitive dissonance (Festinger & Carlsmith, 1959), which was interpreted in terms of the anxiety felt by individuals who act contrary to their beliefs, proposed that people will change their beliefs to align with their actions in order to reduce anxiety. For such a process to occur, individuals presumably must believe that actions are freely chosen, that their choices imply preferences that are stable across time and reflect their character, that they have control over and are thus responsible for the outcome of events, and that good people make consistent choices. However, none of these assumptions are cross-culturally universal (Fiske et al., 1998). Not coincidentally, Japanese participants do not display dissonance reduction in the free-choice paradigm (Heine & Lehman, 1997). By integrating an understanding of the individual's psychological embeddedness within a sociocultural context, we will be able to generate stronger causal theories of behavior as well as use cultural differences as a test bed for assessing these theories.

At the macropsychological level, areas of cognitive investigation that have heretofore been concentrated in disciplines outside of psychology, such as analyses of collective memory in sociology, cultural transmission in evolutionary anthropology, social-collaborative technologies in computer science, distributed cognition of complex tasks, and the consequences of biological changes in response to the sociocultural environment, become principal objects of

psychological inquiry. Particular questions to address will focus on how knowledge is represented at the group level. For example, many scientists wish to discover what memory is “in the brain.” But what is memory “in the group”? How will we describe it? In this chapter I have suggested that technologies such as computers or books can be thought of as external memory storage. But what about aspects of our environment, such as landmarks or a worn path in the wilderness? I may have no deep understanding of how to get to where I wish to go, but I know if I follow the path I will get there. Should we consider the knowledge to be encoded into the path, or is the path simply a heuristic that my individual mind exploits?

Of course, it is unlikely that all knowledge is distributed. Indeed, there likely are instances in which no one actually knows (or has ever known, even in an unconscious fashion), and yet thinking occurs without knowledge. For example, some practices and traditions may have initially occurred at random, but then were maintained and transmitted over time because they served some function of which their progenitors were unaware. One question to consider is how much of our cognition reflects such thinking without knowledge.

Finally, single nucleotide polymorphisms in our genes are highly susceptible to local changes in the environment (see Green & Dunbar, Chapter 7). Their incidence has increased drastically in humans over the last 10,000 years, most likely due to rapid population growth that occurred as a consequence of the cultural evolution of large social group living (Cochran & Harpending, 2010). Although in its early stages and quite speculative, recent work suggests that differences in gene expression as a result of polymorphisms are linked to differences in psychological functioning across cultures, raising the question of whether differences in gene expression may be occurring as a function of cultural change (Kitayama & Uskul, 2011).

Acknowledgments

Preparation of this chapter was supported by the UCLA Center for Society and Genetics. I thank Clark Barrett, Patricia Cheng, Daniel Fessler, Alan Fiske, Keith Holyoak, the UCLA Reasoning Lab, the UCLA Relational Models Theory lab, and the UCLA Experimental Biological Anthropology Lab for their valuable comments on an earlier draft.

Notes

1. Note that my use of *macropsychology* and *micropsychology* is quite different from that of Fiske (1991) and from conceptions directly tied to economics (Katona, 1979).

2. To rule out the “arrogant Yale graduate student” hypothesis, the results were replicated with non-Ivy league undergraduates.

3. Although not the focus of this chapter, both individual and social learning are necessary for cumulative cultural evolution to evolve.

4. Wikipedia is an interesting example. Although it may have originated in a very free-flowing manner, it now has layers of higher level editing. Similar hierarchical structures may also emerge in other forms of social collaboration.

5. Studies that reveal “activation” in these areas in response to general cognitive tasks are actually reporting *less deactivation* from the resting baseline compared to control tasks, such as staring at a fixation point.

Development of Quantitative Thinking

John E. Opfer and Robert S. Siegler

Abstract

For understanding development of quantitative thinking, the distinction between nonsymbolic and symbolic thinking is fundamental. Nonsymbolic quantitative thinking is present in early infancy, culturally universal, and similar across species. These similarities include the ability to represent and compare numerosities, the representations being noisy and increasing logarithmically with actual quantity, and the neural correlates of number representation being distributed in homologous regions of frontoparietal cortex. Symbolic quantitative thinking, in contrast, emerged recently in human history, differs dramatically across cultural groups, and develops over many years. As young children gain experience with symbols in a given numeric range and associate them with nonverbal quantities in that range, they initially map them to a logarithmically-compressed mental number line and later to a linear form. This logarithmic-to-linear shift expands children's quantitative skills profoundly, including their ability to estimate positions of numbers on number lines, to estimate measurements of continuous and discrete quantities, to categorize numbers by size, to remember numbers, and to estimate and learn answers to arithmetic problems. Thus, while nonsymbolic quantitative thinking is important and foundational for symbolic numerical capabilities, the capacity to represent symbolic quantities offers crucial cognitive advantages.

Key Words: numerical cognition, number representation, mathematical thinking, symbols, cognitive development

Quantitative thinking is central to human life. Whether the situation involves a child recalling which blocks provided her with the most candies on previous Halloweens, a Londoner telling the time by counting the tolls of Big Ben, or a candidate using polls to predict results of an upcoming election, quantitative thinking is important for learning from the past, monitoring the present, and planning for the future.

Quantitative thinking plays an important role in the lives of other animals as well. To project the outcome of a future fight, prides of lionesses compare their pridenumbers to the number of distinct roars they hear in rival packs (McComb, Packer, & Pusey, 1994). Similarly, to learn optimal foraging

locations, animals in the wild encode the relative number of food items they have found previously in various locations (Davis, 1993).

The existence of such quantitative abilities makes sense from an evolutionary perspective. Being deprived of a sense of *how many* would deprive an animal of any rationality in its judgments and decisionmaking. Rational choices among alternative strategies and courses of action would be rendered impossible.

Given the importance of quantitative thinking, it is unsurprising that representations of quantity are a universal property of human cognition. Quantitative representations are present from early infancy (Cordes & Brannon, 2008a; Feigenson, Dehaene, &

Spelke, 2004) and share striking similarities across human cultures that provide radically different cultural and linguistic experiences (Butterworth et al., 2008; Gordon, 2004; Pica, Lemer, Izard, & Dehaene, 2004). Moreover, early-developing quantitative representations play a central role in learning a wide range of other quantitative skills that have emerged more recently in human history, such as symbolic arithmetic and algebra (Ifrah, 2000).

The central distinction among numerical capabilities that organizes this review, one that is highly correlated with the distinction between early-developing and later-developing quantitative skills, is that between nonsymbolic and symbolic capabilities. Nonsymbolic capabilities are ones in which numerical properties are implicit; for example, when sets of 7 and 5 dots are presented, the facts that one set has 7, the other has five, and the first set has more objects than the second are all implicit. In contrast, symbolic capabilities are ones in which the numerical properties are explicitly expressed as written Arabic numerals, spoken words, or written words (e.g., “7” or “seven”). Nonsymbolic and symbolic numerical processing differ in many ways. Nonsymbolic processing of numbers is widespread across species; symbolic numerical processing appears to be unique to humans (aside from a small number of primates that have participated in laboratory experiments). Nonsymbolic processes emerge in infancy; symbolic processing does not emerge until later in childhood. Nonsymbolic processing is approximate; symbolic processing allows precision. Moreover, symbolic processing of numbers shows wide variations among different cultures and historical periods, whereas variation in nonsymbolic processing is less marked.

One reason to be interested in the development of quantitative abilities is that findings from this area often shed light on general theoretical issues in cognitive development. These issues include the potential existence of innate representational abilities, the extent to which early-developed capacities are sufficient to support the development of later abilities, and whether experience creates new representational resources or selects among preexisting ones for use in novel contexts. Among the reasons why studies of quantitative abilities have been so fruitful is that such studies permit a degree of mathematical precision that is much more typical of psychophysics than of studies of children’s concepts in other areas (e.g., theory of mind, biology, and moral development), thereby allowing researchers to test models

that generate competing quantitative predictions. An equally important reason for the rapid expansion of this area is that valuable practical applications for improving children’s mathematical understanding have arisen from the theoretical work.

Within the distinction between nonsymbolic and symbolic quantitative thinking, we focus on three main questions: (1) What quantitative abilities exist in infancy that provide the foundation for later, more advanced abilities; (2) How are later abilities continuous, and how are they discontinuous, with these early emerging abilities; and (3) How do developmental changes in these abilities affect other aspects of quantitative thinking, such as mental arithmetic?

Nonsymbolic Quantitative Thinking

Foundations of Quantitative Thinking in Infancy

Three key issues arise in studying the early foundations of human nonsymbolic quantitative abilities. First, at what point in development do children reliably *discriminate* among quantities that differ in number and *represent* the number of entities in a set? Second, in early development, what mental mechanisms initially represent numerical values? Third, at what point in development can children *mentally manipulate* numbers (as measured, for example, by their ability to recognize impossible arithmetic transformations)? It turns out that all of these abilities are present early in infancy.

DISCRIMINATION OF NUMERICAL QUANTITIES

Without the ability to perceive the difference between two sets that differ only in number, it would be impossible to understand the similarity of sets that have only number in common (cross-modal mapping), to distinguish between possible and impossible arithmetic transformations of sets of objects (nonsymbolic arithmetic), to link numeric symbols to their approximate or exact referents (estimation, counting), or to engage in economic transactions. For these reasons, research on the development of numerical cognition begins with efforts to establish the capacities (and limits) of infants’ discrimination among quantities.

Infants’ Discrimination Among Numbers of Objects

A consistent finding in research on development of quantitative abilities is that human infants notice changes in number in sets of 1–3 objects (Starkey & Cooper, 1980; Starkey, Spelke, & Gelman, 1983; Strauss & Curtis, 1981). In one early study of

infants' numerical capacities and a number of later ones, researchers observed a spontaneous preference for the larger set when two sets differed in number by a factor of 2 or more, even with very large sets (e.g., 128 versus 32 elements in Fantz & Fagan, 1975; 32 versus 16 in Xu, Spelke, & Goddard, 2005; 16 versus 8 in Lipton & Spelke, 2003). In other studies, investigators used habituation paradigms in which infants were repeatedly presented a particular number of objects until their looking time decreased, and then they were presented with a different number of objects. Recovery of looking time to novel stimuli (dishabituation) was observed when the ratio between original and novel sets was 2:1 or 3:2 (2 versus 3 in Strauss & Curtis, 1981; 8 versus 4 in Xu, 2003). The earliest signs of this kind of numerical discrimination appeared in 21- to 44-hour-old neonates, who—having been habituated to a display of 2 (or 3) dots—recovered interest when shown 3 (or 2) dots (Antell & Keating, 1983).

Findings from studies of infants' discrimination of sets of objects suggest three general conclusions. First, at all ages, the number required to discriminate between two relatively large sets (i.e., 4 or more members) is not an absolute number but rather a ratio (e.g., discrimination of 4 versus 8 objects is typical at ages where discrimination of 8 versus 12 objects is not). Rather, as in the Weber-Fechner psychophysical function, *the probability of discrimination is proportional to the difference in the logarithms of the numbers*, where, for example, $\ln(32)-\ln(16) = \ln(16)-\ln(8) = \ln(8)-\ln(4) > \ln(12)-\ln(8) = \ln(6)-\ln(4)$. Second, the difference in logarithms required to discriminate between numbers decreases with age. Thus, older infants discriminate ratios that younger infants do not (Cordes & Brannon, 2008b). Finally, for very small numbers (i.e., 3 or less), the probability of discrimination is uniformly high, higher than would be predicted from considering the differences in logarithms alone. Thus, discriminating 2 versus 3 is easier for infants than discriminating 4 versus 6.

Infants' discrimination of auditory sequences (Lipton & Spelke, 2003; vanMarle & Wynn, 2009), temporal intervals (Brannon et al., 2008; vanMarle & Wynn, 2006), events (Wynn, 1996; Wood & Spelke, 2005,) and collective entities (Wynn et al., 2002) conforms to these generalizations about number discrimination. To cite one example, the Weber-Fechner law applies to discriminations among number of sounds. When Lipton and Spelke (2003) familiarized 6-month-old infants to a sequence of 8 or 16 sounds,

infants more often turned their heads to hear a novel number of sounds (16 or 8) than to hear the original number of sounds. As with objects, the ratio of the sets is what matters; 6-month-olds discriminate between 32 and 16, 16 and 8, and 8 and 4 sounds, but not between 4 and 6 or 8 and 12 sounds (Lipton & Spelke, 2004; Xu, 2003; Xu et al., 2005). Also as with objects, the difference in logarithms required to discriminate between two numbers of sounds decreased with age: Older infants discriminated ratios (e.g., 4:6) that younger infants did not (Lipton & Spelke, 2003). And as with objects, discrimination of very small numbers of sounds is consistently high, higher than would be expected from considering the ratio in isolation. When 4-day-old infants were presented multisyllabic utterances, discriminations between 2 and 3 syllables were more likely than between 4 and 6 (Bijeljac-Babic, Bertoni, & Mehler, 1993).

DO INFANTS REPRESENT NUMBER PER SE?

Whenever infants react to changes in a stimulus, a number of possible mechanisms might give rise to the reaction. In the case of numerical discrimination, different mechanisms might process numbers of discrete entities than other quantitative dimensions that often are correlated with number of discrete entities, such as summed area of the objects or their contour length. Because numerical and non-numerical parameters are inextricably linked in sets of objects, it is sometimes impossible to uniquely identify the factors that allowed infants to dishabituate to a display within a specific experiment (Mix, Huttenlocher, & Levine, 2002). Thus, infants' ability to discriminate sets of items that differ in number may not necessarily mean that infants possess mental mechanisms that code number per se. In the next two sections, we examine this issue, first by reviewing whether infants' sensitivity to nonnumerical features of sets is sufficient to explain their ability to discriminate between sets that differ numerically, and then by examining evidence from cross-modal mapping studies that we view as decisive on this issue.

Nonnumerical Cues to Numerical Quantity

One class of nonnumerical cues that might cause an infant to dishabituate to a novel number of objects is continuous quantitative cues, such as surface area, volume, and contour length. A number of investigators have posited that discrimination among values of these continuous dimensions, rather than of number as such, explains findings that others have interpreted as indicative of numerical

discrimination abilities (Clearfield & Mix, 1999, 2001; Feigenson, Spelke, & Carey, 2002; Gao, Levine, & Huttenlocher, 2000; Mix, Huttenlocher, & Levine, 2002). In an important challenge to early research on infants' numerical abilities, Clearfield and Mix (1999) habituated 6-month-olds to a series of stimuli that shared a set size (e.g., three objects) and a constant cumulative contour length. Infants were then presented a dishabituation trial, either with number held constant and cumulative contour length changed or vice versa. Infants responded as if they detected the change in contour length but not the change in number. Results of subsequent studies indicated that infants' discrimination of surface area resembles that of the Weber-Fechner psychophysical function, with novelty preference increasing linearly with the ratio of the surface areas, a result that paralleled previous findings with discrete objects (Clearfield & Mix, 2001). One interpretation of these results (e.g., Mix et al., 2002; Newcombe, 2002) is that young infants do not represent number and instead respond solely to nonnumerical properties of the set.

On the other hand, several considerations suggest that nonnumerical cues are insufficient to account for infants' ability to discriminate sets of objects. First, when nonnumerical properties of a large set of objects (e.g., eight or more) are varied in the habituation display while number is held constant, infants in the test phase of the procedure reliably dishabituate when shown a set with a novel number of objects that shares nonnumerical properties of the habituation sets (Brannon, Abbott, & Lutz, 2004; Brannon, Lutz, & Cordes, 2006; Xu & Spelke, 2000). If infants were sensitive only to the nonnumerical properties of a set, this pattern of results would not occur. Second, discriminating nonnumerical values of a set is often more difficult for infants than discriminating the numbers of objects in the set (Brannon et al., 2004; Cordes & Brannon, 2008b, 2009). In Brannon et al.'s (2004) study, for example, 6-month-olds detected a two-fold change in number after being habituated to a five-fold change in surface area of the objects, but failed to detect a two-fold change in surface area of the objects after being habituated to a five-fold change in their number. Third, the similarity of findings on visual and auditory stimuli cannot be explained by spatial dimensions, such as contour length and surface area, which do not apply to sounds. Thus, rather than number being detected as a last resort, it seems more likely that infants

simultaneously track the number of discrete objects in a set and the nonnumerical characteristics of those objects. Consistent with this interpretation, combining auditory and visual cues to number improves the Weber-Fechner ratio that infants can discriminate over that which they can discriminate on the basis of visual cues alone (Jordan, Suanda, & Brannon, 2008).

Numerical Representation in Infants: Evidence From Cross-Modal Mapping

When infants are habituated to a display of eight objects or eight tones and then recover interest in a display of four objects or four tones, is it because they recognize that the "eighthness" of the habituation displays had been violated by the "fourness" of the test displays? This question is crucial because it gets at the heart of whether infants have a concept like "four" or "eight," as when adults generalize the word "four" to four votes, four belltolls, and four candies. To determine whether infants also have an abstract concept to which adults and older children would sensibly apply number words, researchers have tested infants' ability to generalize across numerical groups that—like candies and bell-tolls—are perceived by different sensory modalities (Izard, Sann, Spelke, & Streri, 2009; Jordan & Brannon, 2006; Kobayashi, Hiraki, & Hasegawa, 2005; Lourenco & Longo, 2010). An important feature of these cross-modal mapping tests is that they obviate objections that infants' reactions are driven only by nonnumerical features of the input—contour length usually increases with the number of candies, but it doesn't increase with the number of bell tolls. Similarly, temporal length of a sequence of bell tolls generally increases with number of tolls but not with objects' contour length.

In cross-modal mapping studies, infants were initially reported to look longer at a set of 2–3 objects that matched the number of sounds that were played simultaneously (Starkey, Spelke, & Gelman, 1983). However, subsequent studies reported no such preference (Mix et al., 1997) or a reversed preference (Mix et al., 1997; Moore et al., 1987). In all cases, the effect sizes were quite small, leading to the hypothesis that the contradictory findings were due to participants on the tails of a distribution whose means were in the middle (Mix et al., 2003).

Recent studies, however, have reported robust evidence of cross-modal number matching for sets of 2–3 s in 6-month-olds (objects and tones in Kobayashi et al., 2005; faces and voices in Jordan & Brannon, 2006) and of larger sets in

2-day-olds (Izard et al., 2009). An interesting feature of Izard et al. (2009) is that newborns' looking time was greater when viewing congruent displays (4 syllables/4 objects or 12 syllables/12 objects) than incongruent displays (4 syllables/12 objects or 12 syllables/4 objects). The difference in that study between congruent and incongruent displays was nearly identical for another three-fold change in number (6 vs. 18), and both differences were much greater than those evoked by a two-fold change in number (4 vs. 8). These findings are thought provoking, because they suggest that when newborns represent number in different modalities, their number representations are subject to the same ratio dependence observed in number discrimination within a single modality.

Origins of the Mental Number Line

If infants are capable of representing the number of items in a set, how might they do it? An important proposal for how this occurs—the mental number-line hypothesis—came from findings on number matching in nonhuman animals (Mechner, 1958; Platt & Johnson, 1971; for review, see Boysen & Capaldi, 1993).

PARALLELS BETWEEN INFANTS' AND NONHUMAN ANIMALS' NUMERICAL MAGNITUDE PROCESSING

To examine rats' matching of number of physical actions to a criterion number (i.e., the number of actions rewarded on previous trials), Mechner (1958) and Platt and Johnson (1971) developed paradigms in which food was dispensed to a rat after it had pressed a lever a criterion number of times and then stopped pressing the lever, either in order to press another lever (Mechner, 1958) or to enter a feeding area (Platt & Johnson, 1971). Results of the two studies were similar, with the modal number (and standard deviation) of lever presses increasing with the criterion number (4, 8, 12, and 16). To ensure that the rats were estimating the number of lever presses, rather than the time since the trial had started, subsequent studies varied the degree of food deprivation imposed on the rats, on the logic that the hungriest rats would press the lever faster than the less-hungry rats (which they did). Speed of bar pressing did not affect matching of bar presses to the criterion number; the hungry rats still pressed the lever the same *number* of times as the less-hungry rats for each criterion number (Mechner & Guevrekian, 1962).

The similarity of rats' numerical processing to that of infants can be seen in the rats' pattern of errors. Specifically, the likelihood of pressing the lever a given number of times in response to a particular criterion number decreased *as a function of the difference in the two numbers' logarithms*. For example, as in the previously described studies of human infants, Mechner found that rats were more likely to confuse 6 with 4 lever presses than to confuse 8 with 4, and rats were more likely to confuse 16 with 12 than 8 with 4. As Gallistel (1993) wrote, "It is as if the rat represented numerosity as a position on a [logarithmic!] mental number line (that is, a continuous mental/neural quantity or magnitude), using a noisy mapping process from numerosity to values on this continuum, so that the one and same numerosity would be represented by somewhat different mental magnitudes (positions on the number line) on separate occasions" (p. 215).

Why might a "mental number line" (illustrated in Fig. 30.1) be useful for thinking about infants' and nonhuman animals' encoding of number? One reason is that the mental number line provides a nonverbal mechanism for a true number concept, thereby accounting for prelinguistic infants' (and other animals') ability to generalize across perceptual modalities (Dehaene, 1992). If infants automatically convert the sight of six apples or the sound of six tones (Fig. 30.1, bottom panel, "Stimuli") to the same position on a mental number line (Fig. 30.1, middle panel, "Mental Number Line"), then—long before they learn conventional verbal counting—they could recognize an equivalent "sixness" of the two sets, to which a written or oral symbol ("six" or "6") could later be associated.

The mental number line metaphor is also useful for illustrating how number discrimination follows the Weber-Fechner law. That is, if mental magnitudes increase logarithmically with actual numeric value (as numbers on a slide rule), then numeric intervals on the lower end of the number line (like 1 and 2) are further apart and—given noisiness in the mapping—easier to discriminate than the same intervals at higher ends of the range, due to reduced overlap of signals.

The idea that the mapping of quantities to the number line is noisy provides an interesting way to think about what changes in infants' development. If the noisiness of the mappings to the logarithmic number line decreases with age, then the difference in logarithms required to discriminate any two quantities would also decrease with age. Thus, a

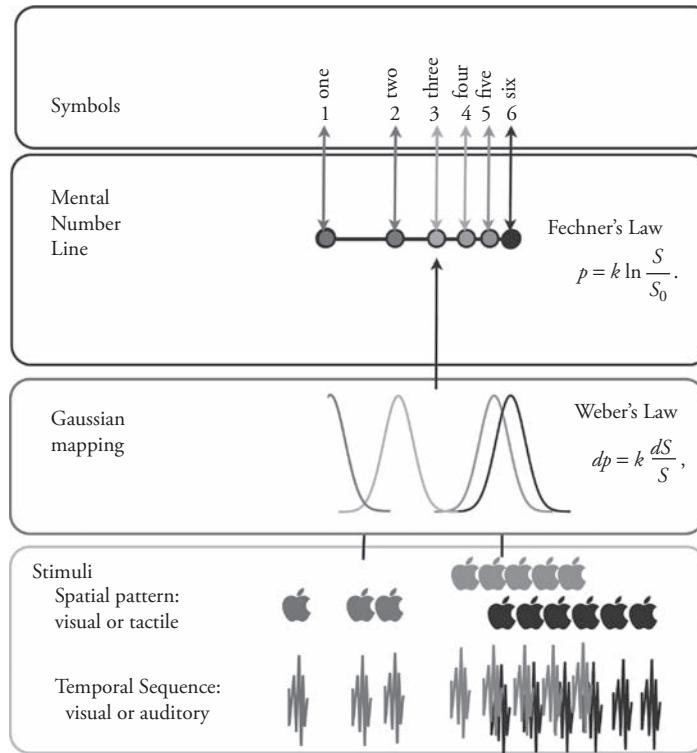

Fig. 30.1 Illustration of a logarithmically-scaled mental number line. See color figure.

logarithmically-scaled mental number line provides a simple way to conceptualize the numerical abilities of infants, how those abilities are limited by the Weber-Fechner Law, and how those abilities change with age and experience.

THE NEURAL BASIS OF THE MENTAL NUMBER LINE

What physical mechanisms generate the findings that are explained metaphorically by the mental number line construct? An idea that proved prescient was formulated by Dehaene and Changeux (1993). Working from the pattern of errors and solution times in numerosity discrimination studies that we reviewed earlier, as well as Dehaene's own research on symbolic number comparison in human adults, Dehaene and Changeux proposed the existence of innate numerosity detectors, that is, neural units that directly code numerosity (cf. "numerons" in Gelman & Gallistel, 1978).

In the Dehaene-Changeux model, objects of various sizes and locations are initially presented to a retina-like module (or to echoic auditory memory in the case of sounds), and then normalized for size and location on an intermediate topographical map of object locations. Number is registered from a

map of numerosity detectors that sum all outputs from the intermediate topographical map of object locations. An important feature of such a mechanism is that the internal representation of numerosity would be highly correlated with the number of objects in a set, regardless of their physical characteristics. Additionally, simulations that embodied the model revealed that the activations evoked by different input numerosities overlapped with one another, with the degree of overlap being proportional to the difference between the logarithms of the numerosities. In this way, the performance of the Dehaene-Changeux neural model suggested explanations of the experimental findings from newborns and rats, and it provided a powerful theoretical model for how a mental number line might be realized.

Independent empirical support for a neural mechanism like that hypothesized by Dehaene and Changeux (1993) came from a series of later findings by Nieder, Miller, and colleagues (for a review, see Nieder, 2005). These investigators obtained single-cell recordings of neural activity as an awake animal (a macaque monkey) tracked the number of objects in a set. In a typical task, a set of N objects (dots in various positions, configurations, and sizes)

was presented to the monkey in a sample display, a brief delay was imposed, and then a test display of objects was presented that had either the same number of objects as, or a different number than, the original display. The monkey's task was to respond if the number in the test display matched the number in the sample display.

Like the hypothetical "numerons" in the Dehaene-Changeux model, many neurons were found to be tuned to a particular numerosity (Nieder & Merten, 2007; Nieder & Miller, 2003, 2004). These neurons maintained their numerical selectivity in the face of variation in the position, size, and configuration of the objects in the display (Nieder, Freedman, & Miller, 2002). For example, some neurons were found to show peak firing for a set of one, other neurons peak responding at a set size of two, others at three, and so on, all the way to numbers in the 30s (which were the highest numbers tested). These neurons were involved in numerical memory as well as perception: When the monkey saw a set of four objects that then was hidden and the monkey had to maintain a representation of the number in memory, the fourneurons maintained their activity more than competing neurons did.

Furthermore, the tuning curves of these neurons showed Gaussian variability on a logarithmic scale (as in Fig. 30.1). This means that neurons that peaked when four objects were presented to the monkey would also respond (somewhat less) if three or five objects were presented, and they would respond much less when 1 or 10 objects were presented. Consequently, when the monkey needed to judge whether he was being shown a new number or an old number of objects, accuracy was linked to the difference in logarithms between the two numbers. Thus, collectively, the number-tuned neurons identified by Nieder and colleagues formed a physical basis for the Weber-Fechner law.

These number-tuned neurons were most abundant in the lateral prefrontal cortex (PFC) and in the fundus of the intraparietal sulcus (IPS) (Nieder & Miller, 2004). Neurons in the IPS are thought to code number first, because these neurons required shorter latencies on each trial to become numerosity selective than did PFC neurons (Nieder & Miller, 2004). Based on previous work showing that posterior parietal cortex (PPC) and PFC are functionally interconnected (Cavada & Goldman-Rakic, 1989; Chafee & Goldman-Rakic, 2000; Quintana, Fuster, & Yajeya, 1989), it also seems likely that numerical information first encoded in PPC might

be conveyed directly or indirectly to the PFC, where the signals are amplified and maintained to gain control over behavior. Finally, in a remarkable similarity to the mental number line metaphor, the number-tuned neurons in PPC were found to be so intermingled with neurons that code for line length that number- and length-sensitive neurons were sometimes under the same electrode tip (Tudusciuc & Nieder, 2009)! Thus, the distribution and timing of activation of number-selective neurons suggests that the most likely site for a neural "mental number line" is a frontoparietal circuit.

Could the mental mechanism serving infants' representation of number be the same ones serving monkeys' numerical representations? Because obtaining single-cell recordings requires neurosurgical implantation of electrodes, obtaining directly equivalent measures in human infants is unethical. Therefore, to obtain unobtrusive measures of human infants' neural coding of number, Izard and colleagues (2008) obtained event-related potentials from 3-month-old infants while they were presented with a succession of sets that either changed in number but not object type (e.g., from 4 ducks to 12 ducks) or in object type but not number (e.g., from 4 ducks to 4 balls). The study was designed so that most sets had the same number and type of objects (e.g., repeatedly presenting nonidentical images of 4 ducks). Occasionally, however, a test image appeared that broke this regularity in either number, object identity, or both. The brain response to this disruption was recorded in order to measure the event-related potential (ERP). Across different groups of infants, the numeric changes were 2 versus 3, 4 versus 8, or 4 versus 12.

In all cases, the ERPs revealed that infants' brains detected both types of changes (number and object). To examine the underlying circuitry, the investigators used a source reconstruction method that was based on a model of the infants' cortical folds. This analysis suggested that whereas the infants' left occipitotemporal cortex responded to object novelty, the infants' right parietal cortex responded to numerical novelty, like the corresponding area of the monkeys studied by Nieder.

This method for localizing infants' neural activity is admittedly coarse, due to the relatively poor spatial resolution of electroencephalography (EEG). However, the results were quite similar to those observed in adults and 4-year-olds in studies using more spatially precise functional magnetic resonance imaging (fMRI) methods (Cantlon, Brannon, Carter,

& Pelpfrey, 2006; Piazza, Izard, Pinel, Bihan, & Dehaene, 2004). In these studies, too, regions of the occipitotemporal area reacted to changes in object identity but not to changes in number, whereas posterior parietal regions reacted to changes in number but not to changes in object identity. Both EEG and fMRI data are consistent with the conclusion that number is among the dimensions that are quickly extracted when processing visual stimuli.

Arithmetic in Infancy: Travels on the Mental Number Line

An important property of a number line is that it makes basic addition and subtraction trivial. That is, traveling four spaces forward from four registers the sum of four and four; traveling four spaces back from eight registers the difference between eight and four, and so on.

Therefore, if infants possess a mental number line and encode numerical values of stimuli, they should register sums and differences of numeric quantities (at least approximately). This hypothesis led Wynn (1992) to conduct a series of experiments on infants' arithmetic capacities. To test ability to compute $1 + 1$, for example, Wynn recorded infants' looking times as they watched one object appear to be placed behind an opaque screen and then another object added to it behind the screen. When the screen dropped, seeming to reveal the arithmetically impossible event $1 + 1 = 1$, infants looked longer than when the screen dropped and revealed an outcome consistent with the arithmetically realistic event $1 + 1 = 2$. To be sure that this difference in looking wasn't caused by infants simply preferring to look at one object rather than two, Wynn also examined two objects initially seeming to be placed behind a screen and one object then seeming to be removed. In this situation, infants looked longer when they were shown the arithmetically impossible event of two objects being present after one seemed to be removed, rather than the arithmetically realistic event of one being present. This pattern of findings has since been replicated by other investigators (Koechlin, Dehaene, & Mehler, 1997; Simon, Hespos, & Rochat, 1995).

Testing the idea that infants correctly registered the outcome of the arithmetic operation and were surprised by the arithmetically impossible event, Berger, Tzur, and Posner (2006) collected EEG recordings of infants' brain activity during presentation of correct and incorrect arithmetical operations. In addition to replicating Wynn's finding of

infants looking longer at the seemingly impossible number of objects, infants' brain activity indicated an error detection process in the arithmetically impossible condition. Specifically, the topography and frequency (θ -band effects) of the infants' brain activity were quite similar to what had been found previously in adults when they observe or make responses that they know are wrong, though the error detection signal emerged more slowly in infants than in adults.

An alternative to Wynn's interpretation was that the source of infants' surprise was not violation of their *numeric* expectations but rather a violation of their expectations about objects (Simon, 1997; Uller, Carey, Huntley-Fenner, & Klatt, 1999). In this account, babies used the appearance of the objects to track their individual identities and were surprised when a new individual—not a new number—appeared or went missing. This is a reasonable distinction: When determining whether everyone is present in a small research group, for example, the professor might notice that Tom is missing from the normal attendees of Tom, Dick, and Harry, without bothering to encode how many people were present. As we have seen, infants' abilities to compare sets of four or fewer objects is much greater than would be expected by a mental number line; thus, a subitizing mechanism for tracking small numbers of objects (Kahneman, Treisman, & Gibbs, 1992; Scholl & Leslie, 1999; Trick & Pylyshyn, 1994) might explain infants' error detection on this task.

One way to test whether babies' *numeric* expectations are violated by arithmetically impossible events is to test whether this surprise is also evident when babies witness arithmetically impossible transformations of large sets, where all the individuals couldn't be represented through subitizing (McCrink & Wynn, 2004). Consistent with Wynn's original interpretation that infants were surprised by the numerical outcome, when 9-month-old babies were confronted with arithmetic transformations of large sets (e.g., $5 + 5 = 10$ versus $5 + 5 = 5$, or $10 - 5 = 5$ versus $10 - 5 = 10$), they also looked longer at the arithmetically impossible events than the arithmetically possible ones.

One reason why infants might look longer at the "impossible" outcome is that a logarithmically compressed mental number-line representation supports babies' ability to register approximate sums and differences. If adding n_2 to n_1 involves traveling n_2 spaces forward from n_1 on the mental number line, then babies would arrive at the position

$\log(n_1) + \log(n_2)$, which would be a considerable overestimation of the actual result. Conversely, subtraction through traversing a mental number line would yield a considerable underestimation of the actual results. From this perspective, babies would have no doubt found $5 + 5 = 5$ surprising because they would have experienced it as $\log(5) + \log(5)$ and thus expected to see $\log(25)$!

Consistent with this compressed mental number-line interpretation, McCrink and Wynn (2009) reported that 9-month-old babies' expectations of arithmetic transformations overestimate the results of additive operations and underestimate the results of subtractive operations. Thus, when babies were initially shown a sequence of events equivalent to $6 + 4$, they looked significantly longer when the raised screen revealed 5 objects than when it revealed 20 objects. Similarly, when babies were shown a sequence equivalent to $14 - 4$, they looked significantly longer when the raised screen revealed 20 objects than when it revealed 5. In the same study, the infants looked equally long at 20 objects as 10 at the end of the first example, and looked as long at 5 objects as at 10 at the end of the second example. McCrink and Wynn (2009) explained these findings in terms of "operational momentum." In particular, they suggested that infants moved too far in a positive direction along the mental number line when they added sets of dots and too far in a negative direction when they subtracted sets of dots because they didn't know where to stop their travel along the mental number line.

Another possibility is that the results reflected the infants using logarithmically compressed representations of numerical quantity. In particular, the arithmetically impossible events (e.g., $6 + 4 = 20$; $14 - 4 = 5$) that babies looked at as much as the correct answers were those answers predicted by the view that the infants were mentally representing the problem on a logarithmically compressed mental number line.

Changes Beyond Infancy in Nonsymbolic Numerical Processing

NUMERICAL DISCRIMINATION

Infants' discrimination between sets of objects that differ in number predicts several features of older children's and adults' performance on similar, nonverbal numerosity discrimination tasks. Recall the conclusion that the probability of infants' discrimination was related to the difference between the logarithms of the number of objects in the

two sets. When prevented from counting sets of objects (e.g., through tight time limits or interpolated tasks), older children's and adults' reaction times show the same pattern. For example, the time required for children and adults to select the larger set is proportional to the logarithm of the distance between the numbers of objects in the two sets, both for sets of less than 10 objects (Buckley & Gillman, 1974; Huntley-Fenner & Cannon, 2000) and for sets of 10 or more objects (Birnbaum, 1980; Piazza et al., 2004; Ratcliff, Love, Thompson, & Opfer, 2012).

Another conclusion from infants' performance was that the difference in logarithms needed to discriminate the number of objects in two sets decreases with age. The relation between set size and solution times shows the same pattern in childhood. The time required to discriminate between two numbers that are close together decreases from early childhood to later childhood to adulthood (Ratcliff et al., in press). The "internal Weber fraction," which indicates the difference in ratios needed to reliably discriminate set sizes, has proved useful for quantifying this type of developmental change (Izard et al., 2008; Piazza et al., 2004). Piazza et al. (2010) reported an exponential decline in the internal Weber fraction from an average of 0.34 for kindergarteners, down to 0.25 for 10-year-olds, to 0.15 for adults. Similarly, Halberda and Feigenson (2008) reported internal Weber fractions of 0.38 for kindergarteners and 0.11 for adults. Interestingly, individual differences in Weber fractions within an age group are correlated with the students' math achievement test scores (Halberda, Mazzocco, & Feigenson, 2008). This pattern supports the hypothesis that the precision of the mental number line is foundational to other quantitative skills.

A third conclusion from studies of infants' numerical abilities is that infants' discrimination of very small numbers of objects is consistently higher than would be expected from considering the Weber fractions in isolation. The same is true for older children's and adults' solution times on similar problems. That is, the time required to judge the greater of two sets of three or fewer objects is uniformly low, much lower than would be expected given their ratios alone (Chi & Klahr, 1975; Mandler & Shebo, 1982; Oyama, Kikuchi, & Ichihara, 1981; Trick & Pylyshyn, 1994).

The similarities in performance among infants, older children, and adults suggest that the process of numerosity discrimination is similar, with all

groups accessing the mental number-line representation. This hypothesis is consistent with findings of substantial overlap between the regions in the intraparietal sulcus that are activated by infants, younger children, older children, and adults when comparing numerosities (Castelli, Glaser, & Butterworth, 2006; Piazza et al., 2004; Piazza, Mechelli, Price, & Butterworth, 2006; Piazza, Pinel, Le Bihan, & Dehaene, 2007).

DEVELOPMENT OF NONSYMBOLIC ARITHMETIC BEYOND INFANCY

To examine the development of nonsymbolic arithmetic beyond infancy, McCrink, Dehaene, and Dehaene-Lambertz (2007) showed adults several hundred videos of two successive sets of dots and asked them to approximate their sum or difference by choosing one of two sets of dots. As with infants, adults almost always overshot the correct outcomes on addition problems, as if they had moved “too far” along the mental number line, whereas they almost always undershot the correct outcomes on the subtraction problems, again moving too far on the mental number line in the other direction. In addition, the researchers found that from adults’ modal response, the distribution of other responses tapered off as a function of the ratio of the true and alternative quantities, just as would be predicted by Weber-Fechner’s law. To illustrate the magnitude of this error, the presented subtraction problem of $32 - 16 = 8$ was judged to be correct approximately 60% of the time, which is quite a radical departure from moving along a linearly scaled mental number line.

Development of Symbolic Quantitative Thinking in Childhood and Beyond

In the previous section, we reviewed evidence that a logarithmically-compressed mental number line is a powerful construct for understanding nonsymbolic representations of numerical magnitude, that the construct provides a good analogy to the way that the brain codes numerosity, and that the hypothesis accounts for prominent features of infants’, older children’s, and adults’ nonsymbolic arithmetic capacities.

In this section, we examine the extent to which early-developing, nonsymbolic representations of quantity serve as a foundation for later-developing, symbolic ones. As we will show, on some tasks, the logarithmic function translating symbolic numeric quantities into a subjective representation is preserved from early childhood through adulthood.

We will also see that new ways of thinking about number emerge with age and experience with symbolic expressions of numbers, thereby preparing children to acquire more complex quantitative skills. The new and old numerical representations coexist after the new forms are acquired, with their use varying with the situation and with the child’s numerical experience and mathematical aptitude. Evidence for these ideas comes largely from tasks such as number-line estimation that require participants to translate between alternative quantitative representations, at least one of which is inexact and at least one of which is a symbolically expressed number. Finally, we examine the influence of internal representations of number on uses of those representations in symbolic arithmetic, their relation to overall mathematical achievement, and ways in which research on the mental number line has led to effective instructional interventions.

Numerical Symbols on the Mental Number Line

How do children learn to use the symbols of the decimal system to think about quantities? And how does mastery of this symbol system expand their mathematical capabilities? Early in the learning process, numeric symbols—like the Arabic numerals in Diester and Nieder’s study—are meaningless stimuli for young preschoolers. For example, 2- and 3-year-olds who count flawlessly from 1–10 have no idea that $6 > 4$ and $8 > 6$, regardless of whether the number symbols are spoken or written, nor do children of these ages know how many pennies to give an adult who asks for 4 or more (and very early on, not even how many to give an adult who asks for 1–3) (Le Corre & Carey, 2007; Le Corre, Van de Walle, Brannon, & Carey, 2006; Sarnecka & Carey, 2008).

As young children gain experience with the symbols in a given numerical range and associate them with nonverbal quantities in that range, they initially map them to a logarithmically-compressed mental number line (Berteletti, Lucangeli, Piazza, Dehaene, & Zorzi, 2010; Booth & Siegler, 2006; Geary, Hoard, Nugent, & Byrd-Craven, 2008; Opfer, Thompson, & Furlong, 2010; Siegler & Booth, 2004; Siegler & Opfer, 2003; Thompson & Opfer, 2010). Over a period that typically lasts 1–3 years for a given numerical range (0–10, 0–100, or 0–1000), their mapping changes from a logarithmically compressed form to a linear form, in which subjective and objective numerical values increase

in a 1:1 fashion. Use of linear magnitude representations occurs earliest for the numerals that are most frequent in the environment, that is, the smallest whole numbers (Berteletti, Lucangeli, Piazza, Dehaene, & Zorzi, 2010), and it gradually is applied to increasingly large numbers (Siegler, Thompson, & Opfer, 2009). In this section, we first examine this process of learning representations of symbolic numbers as it applies to numerical magnitude comparison and then as it applies to number-line estimation; after this, we examine the consequences of individual differences in these numerical representation processes and interventions that promote the growth of linear representations.

SYMBOLIC NUMBER COMPARISON

When 3-year-olds from middle-income backgrounds or 4- and 5-year-olds from low-income backgrounds are presented numerical magnitude comparison problems involving the numbers 1–9 in symbolic form, their performance is near chance (Ramani & Siegler, 2008; Siegler & Robinson, 1982). In contrast, by kindergarten or first grade, most children are highly accurate on these numerical comparison problems with Arabic numerals. Their solution times, and those of older children and adults, are subject to the same Weber-Fechner law that characterizes numerical comparisons of nonsymbolic stimuli, such as dot arrays (Buckley & Gillman, 1974; Moyer & Landauer, 1967; Sekuler & Mierkiewicz, 1977), with the time required to select the larger of two numbers being inversely proportional to the logarithm of the distance between the numbers being compared. Thus, the time required to select the larger of 3 and 5 is less than the time required to compare 5 and 7, and the time required to select the larger of 30 and 50 is less than the time required to compare 50 and 70 (Dehaene, 1989). This finding suggests that Arabic numerals automatically activate the same mental number-line representation that encodes nonsymbolic numerosity (as in Fig. 30.1).

Consistent with this idea, fMRI studies have revealed that even very brief presentations of number symbols evoke number-related activation in the intraparietal cortex of educated adults (Naccache & Dehaene, 2001). The systems for representing nonsymbolic and symbolic numbers appear to be closely linked. In addition to the physical overlap, if not identity, between the systems, habituation of one leads to habituation of the other. Thus, after adaptation to 17, 18, or 19 dots, dishabituation (as

measured by fMRI activations) is observed when the Arabic numeral 50 is presented, but not when the numeral 20 is presented (Piazza et al., 2007). These results suggest that—at least in educated adults—populations of neurons in parietal and prefrontal cortex are activated by both nonsymbolic numerosities and by number symbols. Put another way, the mental number line appears to link symbolic and nonsymbolic numerical representations.

Given that the invention of Arabic numerals only dates back a few thousand years (Ifrah, 2000), it is implausible that the brain evolved specifically to handle them. More likely, the link between the two systems arises through learning during childhood. To investigate how this learning process might occur, Diester and Nieder (2007) trained two monkeys to associate Arabic numerals with the numerosity of multidot displays. After the training, a large proportion of PFC neurons encoded numerical values, irrespective of whether the numbers had been presented to the monkeys in the form of dots or Arabic numerals. Moreover, these neurons exhibited similar tuning functions, with activity falling with increasing numerical distance from the neuron's "preferred" numerical value. Over the course of training, numeral-numerosity associations progressively shifted from the PFC to the IPS.

A similar pattern may exist in human development (Ansari et al., 2005; Houdé, Rossi, Lubin, & Joliot, 2010; Rivera, Reiss, Eckert, & Menon, 2005). The distance effect observed in monkey's PFC neurons has also been observed in the PFC of preschool children. Moreover, with age and experience, neural activation in response to numerical stimuli shifts to posterior parietal areas, particularly in the left hemisphere, much as the numeral-numerosity associations shifted to IPS during the later stages of training among the monkeys studied by Diester and Nieder (2007). Together, these results suggest that the PFC might be the first cortical area to link numerals to the mental number line, and that with age and experience, the IPS is increasingly involved in linking numerals with the numerosities for which they stand.

NUMBER-LINE ESTIMATION

An alternative method that has been developed to examine the development of representations of numerical magnitudes is the number-line estimation task (Siegler & Opfer, 2003). On this task, participants are shown a blank line flanked by a number at each end (e.g., 0 and 1,000) and asked

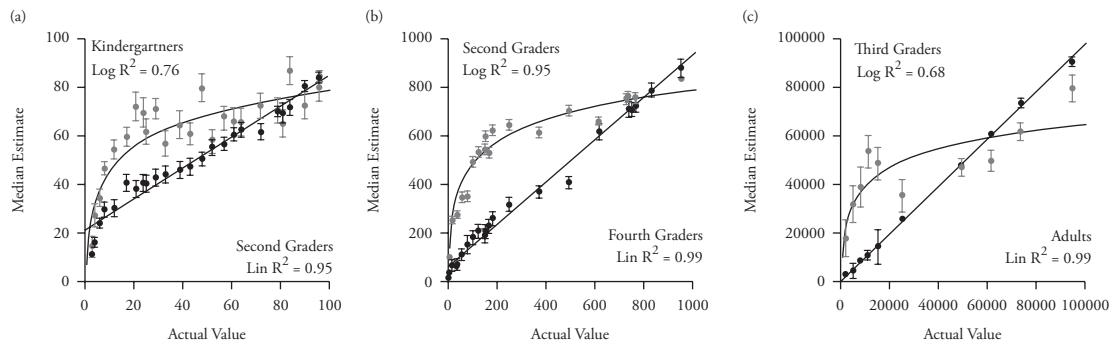

Fig. 30.2 Development of number-line estimation across three scales.

where a third number (e.g., 150) would fall on the line. This task is particularly revealing about representations of numerical magnitude because it transparently reflects the ratio characteristics of the number system. Just as 150 is twice as large as 75, the distance of the estimated position of 150 from 0 should be twice as great as the distance of the estimated position of 75 from 0. More generally, estimated magnitude (y) should increase linearly with actual magnitude (x), with a slope of 1.00, as in the equation $y = x$.

Across a number of cross-sectional studies using this number-line estimation task (Booth & Siegler, 2006; Laski & Siegler, 2007; Opfer & DeVries, 2008; Opfer & Siegler, 2007; Siegler & Booth, 2004; Siegler & Opfer, 2003; Thompson & Opfer, 2008, 2010), a systematic difference between younger and older children's estimates has been evident: Younger children's estimates of numerical magnitude typically follow Fechner's law ($y = k \times \ln x$) and increase logarithmically with actual value (Fig. 30.2). In contrast, older children's estimates for the same range of numbers increase linearly with actual value.

This developmental sequence emerges at different ages with different numerical ranges (Fig. 30.2). It occurs between preschool and kindergarten for the 0–10 range, between kindergarten and second grade for the 0–100 range, between second and fourth grade for the 0–1,000 range, and between third and sixth grade for the 0–100,000 range (Berteletti, Lucangeli, Piazza, Dehaene, & Zorzi, 2010; Opfer & Siegler, 2007; Siegler & Booth, 2004; Thompson & Opfer, 2010). Thus, as shown in Figure 30.2A, on the 0–100 number-line estimation task, the logarithmic function fit kindergartners' estimates better than did the linear function, but the linear function fit second graders' estimates better than did the logarithmic function. The same transition occurs roughly

a year later for children with mathematical learning difficulties (Geary, Hoard, Byrd-Craven, Nugent, & Numtee, 2007). The timing of the changes corresponds to the periods when children are gaining extensive exposure to the numerical ranges: through counting during preschool for numbers up to 10, through addition and subtraction between kindergarten and second grade for numbers through 100, and through all four arithmetic operations in the remainder of elementary school.

How might these changes occur? One clue came from the estimates of sixth graders and adults in Siegler and Opfer (2003). The median estimates of both groups increased linearly with numeric value, but the variability of estimates for both was smallest near the *quartiles* on the number line, as if these older children and adults mapped numbers like 0, 250, 500, 750, and 1,000 to 0, 1, 2, 3, and 4—that is, numbers that other studies indicated they already represent linearly (Chi & Klahr, 1975; Siegler & McGilly, 1989; Siegler & Robinson, 1982). This observation suggested that children might map early-developing linear representations of numerical magnitudes to guide their learning about the magnitudes of less familiar, larger numerals, a process that might be aided through children learning about fractions and percentages in third through fifth grade.

To test this idea about how the logarithmic-to-linear shift occurs, we conducted three microgenetic studies that allowed us to examine changes in numerical estimation on a trial-to-trial basis (Opfer & Siegler, 2007; Opfer & Thompson, 2008; Thompson & Opfer, 2008). In these studies, we used an experimental manipulation to help students who initially used logarithmic representations to adopt a linear representation. Specifically, we provided children with feedback on their estimates of numbers

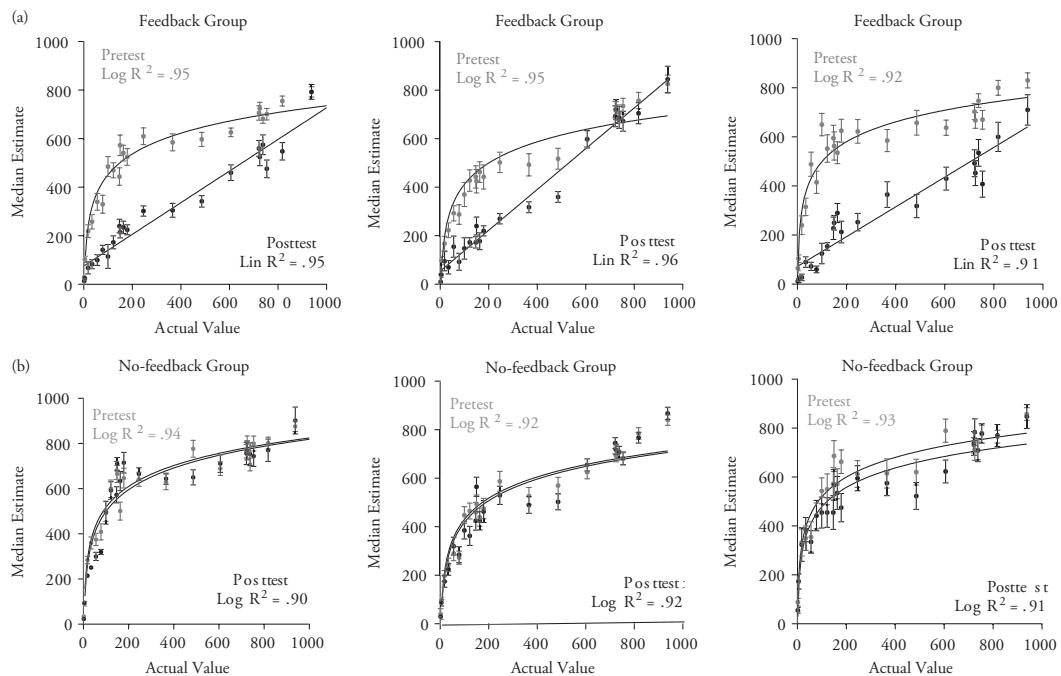

Fig. 30.3 Estimation of numeric magnitudes in response to limited feedback. (a) Across three studies (L-R: Opfer & Siegler, 2007; Opfer & Thompson, 2008; Thompson & Opfer, 2008), logarithmic-to-linear shifts in estimation occurred from pretest (gray circles) to posttest (black circles) when children were given feedback on their estimates for a few numbers around 150. (b) Across the same studies, very little change in logarithmic estimation patterns occurred when children were not given feedback on their estimates.

around 150, the point where the logarithmic and linear functions that pass through 0 and 1,000 are most discrepant. The idea was that this feedback would be highly salient, due to it indicating that the children's estimates were far from correct, and that the experience would lead children to draw an analogy between what the feedback indicated about the correct placement of 150 on a 0–1,000 number line and their existing knowledge of the correct placement of 15 on a 0–100 number line. After receiving feedback on their estimates of numbers around 150, second graders in all three studies provided estimates that increased linearly with actual value (Fig. 30.3A). This representational change was evident in differences in the median estimates of the treatment groups on pretest and posttest, with pretest estimates being best fit by logarithmic functions and posttest estimates being best fit by linear functions. Providing feedback regarding correct placements at other numerical values, such as 725, also increased the linearity of estimates, but change occurred more slowly and to a somewhat lesser extent (Opfer & Siegler, 2007). Consistent with the interpretation that this change came about through

a process of analogy, when children were given an opportunity to compare (1) the placement of 15 cherries on a line flanked by 0 and 100 cherries, and (2) the placement of 1,500 on a line flanked by 0 and 10,000, children quickly apprehend the similarity of the two situations and use it to improve their estimates of the larger numbers (Thompson & Opfer, 2010).

As is evident in Figure 30.3, second graders' newly adopted linear representation spanned the entire 0–1,000 range and was not simply a "local fix" to the numbers near 150. This effect across the entire numerical range was consistent with the view that the numerical magnitude representation has psychological reality as a coherent unit, rather than simply being a convenient way of summarizing data. Moreover, like an analogical insight (e.g., Gick & Holyoak, 1983; see Holyoak, Chapter 13), the shift occurred abruptly, much more abruptly than what had been observed in studies of transitions in related areas such as addition and numerical insight problems (e.g., Siegler & Jenkins, 1989; Siegler & Stern, 1998). Often, feedback on a single trial was sufficient to yield a shift from a logarithmic to a linear

pattern of estimates (Opfer & Siegler, 2007; Opfer & Thompson, 2008; Thompson & Opfer, 2008).

The finding of new symbolic representations arising through analogies to representations of similar relations in simpler contexts is widely evident in cognitive development (for a review, see Gentner, 2010). Such analogy-based representational change is important, because it suggests a potential solution to a problem that is endemic to the mental number-line representation discovered by Nieder and colleagues. The problem is that it seems as though one would simply run out of “numerons” to represent large numbers. Do people and other animals possess neurons that fire more in response to seeing 1,582 dots than in response to 1,583? However, if learners can map small numbers to large ones, they would gain the ability to use the relations among small number representations to represent relations among larger magnitudes (as when adults mapped 250-500-750-1,000 to 1-2-3-4 or $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, 1 or to 25%, 50%, 75%, and 100%). If this occurs at the neural level (and in some sense it must), then having a limited number of numerons imposes no inherent limit on the number of numeric magnitudes that could be represented.

MEASUREMENT AND NUMEROSITY ESTIMATION

To examine the generality of the developmental transition revealed by the number-line task, several studies have tested whether similar changes are evident in estimates of line lengths and numbers of discrete objects (measurement estimation and numerosity estimation) (Booth & Siegler, 2006; Laski & Siegler, 2007; Thompson & Siegler, 2010). On the measurement estimation task, children saw an extremely short line, labeled “1 zip;” a long line, labeled “1,000 zips;” and a number indicating the length of a line (in zips) that should be drawn. Children drew a line to approximate the desired length, then were asked to draw a line of a different number of zips, and so on. On the numerosity estimation task, children saw a computer screen that depicted one box with 0 dots, one with 1,000 dots, and a third, initially empty, box that could be filled with the desired number of dots by placing the cursor in the “increase” box or the “decrease” box and holding down the mouse until the desired number of dots was reached (the time limit was too short for the children to count the dots).

On each task, the same logarithmic-to-linear shift that had been observed with number-line estimation was observed (Booth & Siegler, 2006; Thompson

& Siegler, 2010). On the measurement estimation task in Booth and Siegler (2006), for example, the variance accounted for by the best-fitting linear function increased with age (from 85% to 98%), whereas the variance accounted for by the best-fitting logarithmic function decreased with age (from 91% to 74%). Furthermore, individual second graders’ measurement estimates were more likely to be better fit by the logarithmic function than by the linear function (70% vs. 30%), whereas fourth graders’ estimates were more likely to be better fit by the linear function than by the logarithmic function (78% vs. 22%). Similarly, the percentage of children for whom the linear function provided the better fit on the numerosity estimation task increased from 43% to 82%, whereas the percentage of children for whom the logarithmic function provided the better fit decreased from 57% to 18%.

NUMBER CATEGORIZATION

To examine whether the logarithmic-to-linear transition extended beyond estimation tasks, Laski and Siegler (2007) presented 5- to 8-year-olds with a numerical categorization task. Children were told that 1 was a “really small number” and that 100 was a “really big number” and then were asked to categorize numbers between 1 and 100 as “really small,” “small,” “medium,” “big,” or “really big.” Each child’s categorization of each number was assigned a numerical value ranging from 1 for the “really small” category to 5 for the “really big” category. Then, the mean value for the categorizations of each number was computed, and the fit of linear and logarithmic functions to the mean categorization scores for the full set of numbers was calculated.

Kindergartners’ mean categorizations of the numbers were better predicted by the best-fitting logarithmic function than by the best-fitting linear function. In contrast, second graders’ mean categorizations were (nonsignificantly) better predicted by the best-fitting linear function than by the best-fitting logarithmic function. The same change was evident for the number-line task. Moreover, the linearity of individual children’s number-line estimation and categorization patterns was highly correlated, providing additional evidence for the generality of the logarithmic-to-linear transition in representations of numerical magnitudes.

If number-line estimation and categorization reflect the same underlying numerical representation, then experience that leads to improved number-line estimation might transfer to numerical

categorization. To test this hypothesis, Opfer and Thompson (2008) presented kindergartners who initially produced number-line estimates that were more logarithmic than linear with feedback designed to improve the linearity of number-line estimates and tested both number-line estimation and categorization. As expected, after the feedback experience, the linear function provided a better fit to the mean category judgments of children who received feedback on their number-line judgments than for those who did not receive such feedback. Thus, the change from a logarithmic to a linear representation on the number-line task extended to the categorization task, even without any feedback on that task.

Symbolic Arithmetic in Childhood

Linear representations of numerical magnitudes also are important for symbolic arithmetic abilities, both for approximating answers and for learning exact sums. One source of evidence regarding approximations to correct sums comes from Gilmore, McCarthy, and Spelke's (2007) study of preschoolers' estimates of answers to arithmetic problems that they had not yet encountered in school. The investigators presented 5- and 6-year-olds with problems such as "Sarah has 21 candies, she gets 30 more, John has 34 candies—who has more?" To insure that the preschoolers understood the symbols that were being used, the problems were simultaneously presented both orally—as spoken numerals—and in writing, as Arabic numerals.

Despite the fact that the preschoolers had received no training with numbers of that size, they spontaneously performed better than chance (60%–75%). This was true regardless of their socioeconomic origins. Performance was still approximate, however, and depended on the ratio of the two sums that the children were choosing between, a signature of the Weber-Fechner law.

Other evidence for the relation between the linearity of numerical magnitude representations and arithmetic knowledge comes from positive relations between the linearity of first through fourth graders' estimates on number line, measurement, and numerosity tasks on the one hand and the accuracy of their estimates of answers to two digit plus two digit addition problems on the other (Booth & Siegler, 2006). Yet other correlational evidence comes from positive relations in first graders' linearity of number-line estimates and the number of single digit addition problems that the children

answered correctly (Booth & Siegler, 2008; Geary et al., 2007).

In addition to this correlational evidence, linear representations of numerical magnitude also play a causal role in arithmetic learning. Booth and Siegler (2008) pretested firstgraders' number-line estimation and retrieval of answers to 13 addition problems, ranging in difficulty from $1 + 4$ to $49 + 43$. Then, children were trained on the easiest 2-digit + 2-digit problems that they had answered incorrectly on the pretest. All children were presented with each of these addition problems three times, with feedback regarding the correct answer being provided after each presentation.

A randomly chosen half of the children were also presented with analog linear representations of the addends and sum. This manipulation was intended to inculcate a linear representation of the numbers in the addition problems and ideally of numbers in the 0–100 range more generally. Children in this experimental condition saw a number line with 0 at one end and 100 at the other, then saw the first addend represented by a red bar just above the line, then the second addend represented by a blue bar just below the line, and then the sum represented by a purple bar straddling the line. Thus, if the problem was $43 + 49$, the red bar would be 43% of the number line's length, the blue bar 49% of its length, and the purple bar 92% of its length. The logic was that seeing the linear representations of the addends and sums along the number line would allow children to encode the numerical magnitudes more accurately and thus help them retrieve the answers to the problems.

Presentation of the analog representations of the addends and sum along the number line was causally related to arithmetic learning; it increased the number of addition problems correctly recalled on the posttest and also improved the linearity of the children's number-line estimates. Moreover, the effect of the experimental manipulation was even stronger for measures of the closeness of addition errors to the correct sum than for the number of correct sums, supporting the view that activating the linear representation was the means through which the experimental manipulation produced its effect. If this mechanism were not involved, why else would children who were presented with the analog representations of the addends and sums increasingly advance incorrect answers that were close to the sum and decreasingly produce answers that were far from it? Similarly, randomly assigning

preschoolers to play a linear numerical board game, rather than a color board game, has been found to increase preschoolers' learning of answers to arithmetic problems (Siegler & Ramani, 2009). Thus, linear magnitude representations are both causally and relationally related to arithmetic learning.

RELATIONS BETWEEN NUMERICAL MAGNITUDE REPRESENTATIONS AND OVERALL MATHEMATICS PROFICIENCY

Both nonsymbolic and symbolic numerical magnitude representations have been found to be related to standardized mathematics achievement test performance. Halberda et al. (2008) found that accuracy of nonsymbolic number comparison was positively related to achievement test scores in mathematics, but not to other domains of the school curriculum. Similarly, Holloway and Ansari (2008) found that individual differences in the distance effect during symbolic number comparison among children aged 6 to 8 years is related to mathematics achievement but not reading achievement.

Moreover, the linearity of number line, measurement, and numerosity estimation, as well as of numerical categorization, have been related to mathematics achievement test performance (Booth & Siegler, 2006, 2008; Laski & Siegler, 2007); and children with mathematical learning difficulties, as defined by low mathematics achievement test scores, often generate logarithmic patterns of estimates for several years beyond the time when other students have adopted linear representations for the same numerical range (Geary et al., 2007; Geary et al., 2008). Thus, linear representations of numerical magnitudes seem related to general as well as specific numerical competencies.

THEORETICALLY-BASED EDUCATIONAL INTERVENTIONS

Research on the centrality of the mental number line in numerical knowledge suggested an educational intervention that has proved highly effective with low-income preschoolers. The intervention began with the question, "How do children develop a linear representation of numerical magnitudes?" Experience with counting likely contributes, but such experience is insufficient for children to construct linear representations of numerical magnitudes, as indicated by the previously described dissociation between counting knowledge and magnitude comparison of the numbers that can be counted.

One common activity that was hypothesized by Siegler and Booth (2004) to help children generate linear representations is playing linear, number board games—that is, board games with linearly arranged, consecutively numbered, equal-size spaces (e.g., *Chutes and Ladders*.) These board games provide multiple cues to numbers' magnitudes. The greater the number in a square, the greater: (a) the distance that the child has moved the token, (b) the number of discrete moves of the token the child has made, (c) the number of number names the child has spoken, (d) the number of number names the child has heard, and (e) the amount of time since the game began. Thus, children playing the game have the opportunity to relate the number in each square to the time, distance, and number of manual and vocal actions required to reach that number.

To test whether playing number board games promotes number sense, Ramani and Siegler (2008; Siegler & Ramani, 2008, 2009) randomly assigned 4- and 5-year-olds from low-income backgrounds to play either a number board game or a color board game. At the beginning of each session, children in the number board condition were told that on each turn, they would spin a spinner that would point to "1" or "2," that they should move their token that number of spaces, and that the first player to reach the end would win. Children in the color board condition were told that on each turn, they would spin a spinner that could point to different colors, that they should move their token to the nearest square with the same color as the one to which the spinner pointed, and that the first player to reach the end would win. The experimenter also told children to say the numbers (colors) on the spaces through which they moved. Thus, children in the number board group who were on a 3 and spun a 2 would say, "4, 5" as they moved their token. Children in the color board group who were on green and spun a "blue" would say "purple, blue." If a child erred or could not name the numbers or colors, the experimenter correctly named them and then had the child repeat the names while moving the token. The preschoolers played the number game or the color game about 20 times over four 15-minute sessions within a 2-week period; each game lasted about 3 minutes.

Playing the number board game led to dramatic improvements in the low-income preschoolers' number-line estimates. Accuracy of number-line estimation, magnitude comparison, counting, and numeral identification increased from pretest to posttest among children who played the number

board game. Gains remained present on a follow-up 9 weeks later. In contrast, there was no change in the accuracy of estimates of children who played the color board game (Ramani & Siegler, 2008; Siegler & Ramani, 2009). Playing the game also improved the children's learning of subsequently presented addition problems (Siegler & Ramani, 2009).

Conclusions and Future Directions

Quantitative thinking, ranging from the ability to choose the greater of two sets of a few objects to the ability to project arithmetic transformations with very large numbers, is central to the lives of humans and other animals. In this chapter, we have argued that despite quantitative thinking playing important roles in the lives of both humans and other animals, there is also a fundamental distinction present between two kinds of quantitative thinking—nonsymbolic and symbolic—and that this distinction is essential to understanding what develops in human quantitative thinking.

On nonsymbolic quantitative tasks, similarities between human and nonhuman quantitative thinking pervade many levels of analysis. In a wide range of species and age groups (*1*) there is a capacity to mentally represent and compare the approximate number of objects or events in sets; (*2*) mental representations of nonsymbolic numeric quantities are noisy and increase logarithmically with actual quantity, leading to the speed and accuracy of comparison depending on the ratio of the two numbers, and (*3*) the neural correlates of nonsymbolic number representation are distributed in regions of frontoparietal cortex that overlap greatly across species and age groups from infants to adults. A common cognitive mechanism—a logarithmically compressed “mental number line”—also appears to underlie thinking about nonsymbolic quantities in people and other animals.

Nonsymbolic quantitative thinking, however, has important limitations. Nonsymbolic representations of quantitative properties of sets greater than three or four objects are inexact, making impossible activities such as economic transactions that require precision (Furlong & Opfer, 2009). Lack of symbols also makes it impossible to communicate numerical properties to other minds (e.g., that there are 12 sheep in one herd but 18 in another). Furthermore, without symbols, it is impossible to preserve numerical information over time, as when recording tallies of livestock in a ledger, and it is impossible to track small but important changes, for example, gradual increments in the size of a herd. Moreover, mentally

adding or subtracting nonsymbolic quantities of any substantial size yields extremely noisy estimates that preclude many characteristic human activities, such as deciding on a fair exchange involving numerous specific items. Thus, while the capacity to represent and compare nonsymbolic quantities is important, and provides a basis for symbolic numerical capabilities, the capacity to represent symbolic quantities offers crucial cognitive advantages.

This theoretical contrast between nonsymbolic and symbolic quantitative abilities provides a useful way to approach development of quantitative thinking. Numeric symbols were invented relatively recently in human history, making it implausible that the brain evolved specifically to handle them; they must be learned through prolonged interaction with the environment. Consistent with this perspective, nonsymbolic quantitative thinking emerges early in infancy and shows little variation among children of different cultural backgrounds. In contrast, symbolic quantitative thinking emerges much later, typically in preschool among middle and upper class groups in developed societies and even later among less affluent groups in those societies. Indeed, numerical symbols are used only for a few small whole numbers among children in adults in less developed societies, such as some indigenous Amazonian populations (Dehaene, Izard, Spelke, & Pica, 2008). For all of these reasons and many more, the distinction between nonsymbolic and symbolic quantitative thinking is fundamental to describing and understanding the development of quantitative thinking.

As we have seen, children's learning of the decimal system and the meaning of the symbols within it occurs over many years through substantial observation of adults and older children, direct instruction from teachers and parents, extensive practice, and surmounting misunderstandings and forming new understandings. Early in the learning process, numerical symbols are meaningless stimuli for young preschoolers. For example, 2- and 3-year-olds who count flawlessly from 1–10 have no idea that 6>4, nor do children of these ages know how many pennies to give an adult who asks for 4 or more. As young children gain experience with the symbols in a given numerical range and associate them with nonverbal quantities in that range, they initially map them to a logarithmically compressed mental number line. Over a period that typically lasts 1–3 years for a given numerical range (0–10, 0–100, or 0–1,000), children's mapping of symbolically expressed numbers to nonverbal representations changes from a

logarithmically compressed form to a linear form. In the linear representation, subjective and objective numerical values increase in a 1:1 fashion. Use of linear magnitude representations occurs earliest for the numerals that are most frequent in the environment, that is, the smallest whole numbers, and is gradually extended to increasingly large numbers.

The logarithmic-to-linear shift in children's representations of symbolic quantities expands children's quantitative thinking profoundly. It improves (1) children's ability to estimate the positions of numbers on number lines, (2) to estimate the measurements of continuous and discrete quantities, (3) to categorize numbers according to size, (4) to remember numbers they have encountered, and (5) to estimate and learn the answers to arithmetic problems. These abilities are crucial for learning mathematics, resulting in the use of linear representations of number being highly correlated with skill at arithmetic and overall mathematics achievement. Especially important, educational interventions aimed at inculcating linear representations have broad and sustained effects on mathematics performance and learning. In contrast, interventions aimed at improving nonsymbolic quantitative abilities (e.g., Räsänen, Salminen, Wilson, Aunio, & Dehaene, 2009) have proved less effective in leading to positive educational outcomes.

A final contrast between development of nonsymbolic and symbolic quantitative thinking is worth highlighting as an important direction for future research. Although much is known about the neural substrate of nonsymbolic quantitative abilities, and a reasonable amount is known about its development, little is known about several remaining issues concerning symbolic numerical capabilities: (1) What are the neural substrates for acquiring the ability to think about symbolic numerical quantities? (2) How do the neural correlates of symbolic number representation change with age and experience? (3) How does a limited set of neurons represent the magnitudes of a much larger set of symbolic numeric quantities, including those expressed by integers, fractions, and ordinals? and (4) What mechanisms for representing symbolic number are affected by the various developmental disorders (e.g., William's syndrome) that are marked by difficulties with mathematics?

Visuospatial Thinking

Mary Hegarty and Andrew T. Stull

Abstract

Visuospatial thinking includes thinking about space at the smaller scale of objects and at the larger scale of environments. It also includes situations in which we use visuospatial representations to think about nonspatial entities. At the scale of objects, this chapter reviews the types of representations and processes that underlie object recognition and categorization, the nature of visuospatial mental images of objects, and how these are processed in interactions with objects and in reasoning and problem solving. At the scale of environments, we examine the nature of environmental spatial representations and the processes that operate on these to keep us oriented in space, to reorient ourselves when we are lost, to learn the layout of new environments, and to plan routes through familiar environments. Finally, the chapter reviews how spatial representations are used metaphorically, to think about nonspatial entities, in language, reasoning, and graphics.

Key Words: imagery, navigation, spatial updating, cognitive maps, spatial metaphors, diagrams, graphs

Introduction

When we find our way back to our parked car at the end of the day, think about how to rearrange the furniture in our living room, or read a graph, we are engaging in visuospatial thinking. Visuospatial thinking is central to many scientific domains and professions. For example, chemists think spatially when they develop models of the structure of molecules to understand their reactive properties, geologists think spatially when they reason about the physical processes that form mountains and canyons, and architects think spatially when they design a new house. Visuospatial thinking involves thinking about the shapes and arrangements of objects in space and about spatial processes, such as movement and deformation. It also involves maintaining a representation of our location and orientation with respect to the larger environment, updating how that changes as we move through space, and planning routes. Finally, it includes thinking with

spatial representations of nonspatial entities, such as spatial metaphors, diagrams, and graphs.

Theories of cognition recognize the centrality of visuospatial thinking. For example, in working memory theories, one of the most fundamental distinctions is between visuospatial versus verbal working subsystems (Baddeley & Lieberman, 1980; Shah & Miyake, 1996). Similarly, in research on intelligence, spatial visualization was identified as one of the seven primary mental abilities (Thurstone, 1938) and is one of Gardner's (2004) multiple intelligences. Spatial thinking is fundamental for survival and is not uniquely human (see Penn & Povinelli, Chapter 27). Animals keep a record of their position and orientation in the environment, find their way back to their nests at the end of the day, and often demonstrate feats of spatial intelligence that exceed those of humans (Muller & Wehner, 1988). Pigeons can recognize objects from novel perspectives (Friedman, Spetch, & Ferrey, 2005). Crows

use tools and cache food throughout their environments, locating it several months later (Emery & Clayton, 2004).

The title of this chapter is visuospatial thinking, reflecting the fact that vision is the primary sense by which we sense spatial properties of the world, and research on visuospatial thinking has traditionally focused on thinking with visual perceptions and images. However, not all visual properties are spatial properties. For example, the shape and location of an object are spatial properties, but its color and brightness are not. Furthermore, spatial properties are not just sensed by vision. We can sense shapes of objects by haptic exploration, locate people by hearing their voices, and update our location in the environment by integrating body-based senses, and there is growing evidence that spatial representations are often multimodal or amodal (e.g., Avraamides, Loomis, Klatzky, & Golledge, 2004). While focusing on visuospatial thinking, our chapter will also address how other perceptual modalities and motor processes allow humans to think about space.

We interact with space in different ways at different scales. Montello (1993) distinguishes between *figural* space, which is small in scale relative to the body and external to the individual (e.g., the space of objects); *vista* space, which is projectively as large or larger than the body and contains the individual but can be visually apprehended from a single place (the space of rooms or scenes); and *environmental* space, which is apprehended over time by moving through the environment (the space of buildings, towns, or cities). Spelke and Kinzler (2007) distinguish between four core knowledge systems, including an object system that represents the cohesion of object properties and mechanical interactions between objects and a spatial system for representing the geometry of the environment (their other two proposed core systems represent agents and their goal-directed actions, and number, respectively). Previc (1998) proposed four realms for spatial behaviors: peripersonal (near-body space), focal extrapersonal (the space of visual search and object recognition), action extrapersonal (orienting in topographically defined space), and ambient extrapersonal (orienting in earth fixed space).

In this chapter, we distinguish between spatial thinking at two broad scales of space: (1) small-scale or object-based space, which includes activities such as imagining object transformations and planning interactions with objects, and (2) large-scale or environmental space, which includes activities

such as learning the layout of a new environment, or planning a route. Spatial thinking at both scales involves perceiving spatial properties, maintaining spatial representations in working memory, and transforming those representations. However, we interact differently with the world at these scales. We manipulate objects within reach of our bodies (peripersonal space) but not objects outside of that space. These scales typically involve different frames of reference; in our interactions with objects, we generally think of ourselves as stationary while the objects move, whereas in our interactions with environments we think of ourselves as moving and the environment as stationary. Moreover, there is evidence for dissociations between spatial thinking at these two scales of space, in both individual differences (Hegarty, Montello, Richardson, Ishikawa, & Lovelace, 2006) and in terms of neural systems. Object-based transformations such as mental rotation depend primarily on areas in the superior parietal cortex (Zacks, 2008), whereas environmental spatial tasks depend on a network of brain regions in the medial temporal cortex, parietal cortex, and retrosplenial cortex (Byrne, Becker & Burgess, 2007; Epstein, 2008).

Another distinction that we make in this chapter is between thinking about space and using space to think. Visuospatial thinking includes situations in which we use spatial representations to think about other entities, both abstract and concrete. For example, we follow the path of life, feel “down” when we are sad, and climb the corporate ladder (Lakoff & Johnson, 1980). We also use spatial representations to reason, for example, when we represent premises in a reasoning problem as Euler circles (Stenning & Oberlander, 1995) or use diagrams, maps, and graphs, which enable us to “use vision to think” (Card, Mackinlay, & Schneiderman, 1999).

This chapter is therefore divided into three main sections. The first two address thinking about space, at the smaller scale of objects and the larger scale of environments, respectively. The third section is about using space to think. They correspond loosely to what a recent National Research Council report (2006) refers to as thinking about space, thinking in space, and thinking with space.

Thinking About Space: The Space of Objects

In considering visuospatial thinking at the scale of objects, we first briefly review the types of representations and processes that underlie object recognition

and categorization. We then examine the nature of visuospatial mental images and how these are used when we interact with objects and in more complex processes of reasoning and problem solving.

Recognizing and Categorizing Objects

Recognizing and categorizing objects in the external world are not trivial tasks, which may not seem obvious given the speed and apparent ease with which we accomplish them (Thorpe, Fize, & Marlot, 1996). Recognition of an object involves edge detection, figure-ground perception, and binding of features such as color, contrast, and shading into a common form that is understood to be a three-dimensional object. The complexity of this process is compounded when considering that the image of an object on the retina is not likely to be identical on any two occasions because of differences in viewpoint, distance, and so on (Hayward, 2003; Lawson, 1999). Categorization adds further complexity, because there is great variability of size, shape, and texture within members of a single category. For example, our ability to categorize armchairs, office chairs, and kitchen chairs as chairs requires considering some features of the object while ignoring others.

MODELS OF OBJECT RECOGNITION

Visuospatial cognitive processes are central to the long-standing debate over the mechanisms by which objects are recognized (Biederman, 1987; Hayward, 2003; Tarr & Pinker, 1989). One class of object recognition model, structural description models (also known as viewpoint invariant models) (Hayward, 2003), posits that viewed objects are recognized by comparing them to schematic viewpoint invariant representations based on either their principal axes (Marr & Nishihara, 1978) or the spatial relationship between component parts (i.e., volumetric primitives called geons) (Biederman, 1987). These models predict that time and accuracy to recognize a previously viewed object will not be affected by viewpoint differences as long as the invariant features and their spatial relationships are visible.

A second class of model, referred to as view-based or view-dependent models, posits that recognition involves the comparison of a two-dimensional projection or image encoded from the observed viewpoint with a previously encoded two-dimensional image stored in memory and retrieved based on common features (Tarr & Pinker, 1989). This class of models specifies that multiple views of the object,

influenced by the observer's experience with that object, are stored in memory. To recognize an object from an unfamiliar view, an analog normalization process is proposed to transform the stored image to match the percept (Humphreys & Riddoch, 1984; Lawson, 1999; Lawson & Humphreys, 1999). These models predict that recognition time and accuracy will be proportional to the angular difference between the stored and viewed image.

Given that there is evidence for both viewpoint-dependent and viewpoint-independent recognition performance under different circumstances, object-recognition researchers have begun to develop hybrid models (e.g., Foster & Gilson, 2002; Hayward, 2003; Hummel, 2003; Vanrie, Willems, & Wagemans, 2001). For example, Graf and colleagues (Graf, 2006, 2010; Graf, Kaping, & Bülthoff, 2005) have proposed a model in which the stored representation is schematic, as in structural description models, but viewpoint dependent, as in view-based models; and it is this schematic representation, rather than a two-dimensional visual image, that is transformed by an analog transformation when the view to be recognized is different from the stored view. The primary support for this model is the *congruency effect*, which is that sequentially presented objects are faster to recognize if their main axes are aligned, even for objects of dissimilar categories and form (Gauthier & Tarr, 1997; Jolicoeur, 1990, 1992).

Extending this idea, transformation of a perceptual coordinate system may also account for the similarities between object recognition and categorization. Graf (2010) proposes that recognition involves comparing the stimulus percept with the memory representations after Euclidian transformations (i.e., rotation, size, and displacement), whereas categorization involves additional non-Euclidian transformations that deform or morph the percept of an object to match a stored representation. In this light, the physical space of an object, the perceptual space encoded from the stimulus, and the representational space stored in memory might share a topological structure and object recognition and categorization might be based on common neural processes (Panis, Vangeneugden, & Wagemans, 2008).

Imagining Objects

PERCEPTUAL CHARACTERISTICS OF IMAGES

In contrast with object recognition and categorization, visual imagery refers to the experience of visualizing something that is not physically present, so that

there is no corresponding sensory input to the cognitive system. The experience of having a visual image feels similar to the experience of seeing. For example, most people report that they experience imagery when answering questions such as “how many windows are in your home?” Objective measures also reveal several parallels between imaging and seeing. The time to answer questions about objects in a mental image is correlated with the relative size of those objects, as if one has to “zoom” into the image to see the details of the object’s appearance (Kosslyn, 1980). Time to scan between objects in a mental image is also related to the distance between these objects, just as it takes more time to scan between objects that are farther apart when looking at a real scene (Finke & Pinker, 1983; Kosslyn, Ball, & Reiser, 1978).

Despite these similarities, there are also important differences between mental images and visual percepts. Images are generally less vivid and detailed (Chambers, 1997). Images are also internally organized so that it is easier to “see” certain subcomponents of images than others. For example, it is easier to see a triangle than a parallelogram in an image of the Star of David (Reed, 1974). Furthermore, people cannot always reinterpret patterns in images as well as they can reinterpret them in pictures (Chambers & Reisberg, 1985, 1992), although some ambiguous figures can be reinterpreted (Finke, Pinker, & Farah, 1989) and reinterpretation can be an important cognitive process in creative thinking (Finke, 1989).

THE IMAGERY DEBATE

While the phenomenology of visual imagery is not at issue, there has been much debate in psychology about the nature of the internal representations that underlie the experience of mental imagery (for recent reviews, see Kosslyn, Thompson, & Ganis, 2006; Pylyshyn, 2003). According to Kosslyn et al. (2006), mental images reflect a distinct type of internal representation, a *depictive* representation, in which the representation resembles the object represented, parts of the representation depict parts of the object, the shapes of these parts and their spatial relationships correspond to the shapes and spatial relationships of the represented objects, and so on. In contrast, Pylyshyn (2003) proposes that what distinguishes images is their content, not their format. According to his view, there is no reason to postulate a separate form of representation underlying imagery and when we experience mental imagery, we are simulating what something would look like, based on *tacit knowledge*, or what we have come

to know about the appearances of objects from our visual experiences, but our conscious experience of an image may arise from representations that are not themselves depictive.

NEURAL BASIS OF IMAGERY

In recent years, the imagery debate has been fueled by findings that both primary and secondary visual cortex are activated during many imagery tasks (Kosslyn & Thompson, 2003). These cortical areas are topographically mapped such that specific neurons represent specific areas of space. Thus, representations in these cortical areas are depictive, in the sense that parts of the cortical representation correspond to parts of the represented object. The patterns of activation in these areas during imagery have been shown to mimic perception. For example, when people view objects that subtend smaller visual angles, activation is more posterior in primary visual cortex than for larger percepts. The same is true when people construct smaller versus larger images (Kosslyn, Alpert, Thompson, & Maljkovic, 1993). Similarly, patients with brain lesions that affect visual perception are also impaired in visual imagery (Farah, 1988), and hemispatial neglect patients ignore the same areas of space in perception and imagery (Bisiach & Luzatti, 1978).

Although many imagery tasks activate early visual cortex, not all do so. A recent review of neuroimaging studies (Kosslyn & Thompson, 2003) revealed three characteristics of studies in which activation was found in these areas: (1) the task involved inspecting high-resolution details of images, (2) the task required the visualization of shapes, and (3) the measurement technique was particularly sensitive. These results highlight that not all visual imagery tasks have the same demands. Some imagery tasks, such as answering questions about the shapes of letters or the colors of objects require people to inspect details of the appearance of objects and are accompanied by activation of primary visual cortex. Other imagery tasks, such as mental rotation or making judgments about the spatial locations of objects activate parietal rather than visual cortex and can be performed as well by congenitally blind as by sighted people, suggesting that they may rely on multimodal or amodal representations rather than specifically “visual” representations.

Interestingly, individual-difference studies also suggest dissociations between ability to perform these *visual* and *spatial* tasks (Kozhevnikov, Blazhenkova, & Becker, 2010). There are large individual differences

in vividness of visual imagery, first studied by Galton (1883) when he asked people to imagine their breakfast table. There are also large individual differences in ability to imagine spatial transformations of images, as measured by spatial ability tests (Hegarty & Waller, 2005). But these individual differences dimensions are uncorrelated (Kosslyn, Brunn, Cave, & Wallach, 1984). The dissociation between visual and spatial aspects of mental images is thought to reflect a division of labor in the visual system between a ventral, *object* properties pathway (otherwise known as the “what” subsystem) that projects from the occipital to the inferior temporal lobe, and a dorsal, *spatial* properties pathway, otherwise known as the “where” subsystem (Ungerleider & Mishkin, 1982) or the “how” subsystem (Goodale & Milner, 1992) that projects from the occipital lobe to the posterior parietal lobe.

TRANSFORMATIONS OF IMAGES

Thinking and reasoning about objects often involves mentally transforming images. While there are many ways in which we can transform images, by adding or subtracting parts, size scaling of parts of the image, and so on, most research on this topic has focused on mental rotation of images, so we will consider this transformation in detail. When people are asked to judge whether the two objects in Figure 31.1 depict the same object or are mirror images of each other, the time taken to answer this question is linearly related to the angular difference in orientation between the two objects, suggesting that people mentally rotate a visual image of one of the forms into congruence with the other (Shepard & Metzler, 1971). This rotation process was proposed to be analog such that when objects are mentally rotated, they are imagined at all intermediate orientations between the start and final orientation (Cooper, 1976; Cooper & Shepard, 1984). For example, if people are interrupted during the mental rotation process, and their rate of mental rotation is known, they show no additional time to respond to a stimulus that matches the amount of rotation that should have occurred at the time of the interruption. Early studies also suggested that mental rotation is holistic. Thus, differences in complexity of two-dimensional shapes did not affect rotation times (Cooper & Podgorny, 1976). However, later studies suggested that the lack of a complexity effect might have occurred because the task could be accomplished by rotating only a subset of the stimulus information (Folk & Luce, 1987; Yuille & Steiger, 1982) and that rotation is piecemeal when the full

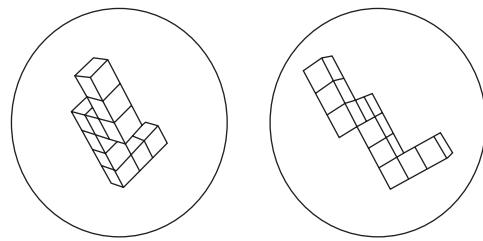

Fig. 31.1 Example of a trial in a mental rotation study.

complexity of the stimulus needs to be considered or the stimuli are less novel (Bethell-Fox & Shepard, 1988). Eye fixation studies also suggested a piecemeal strategy (Just & Carpenter, 1976).

Mental rotation strategies and performance are affected by individual differences in spatial ability. For example, in a cube comparison task, Just and Carpenter (1985) found that when the most direct rotation is around an axis that is nonorthogonal to the axes of the object, high-spatial individuals rotate around this axis, whereas low-spatial individuals perform a sequence of rotations around orthogonal axes. Other research has shown that rotations around axes that are orthogonal to axes of the object and environment are generally easier than rotations around nonorthogonal axes (Pani, 1993; Pani, William, & Shippey, 1995). In summary, the literature on mental rotation suggests that while mental rotation involves analog imagery, other factors such as familiarity with the objects, experience with the task, and spatial ability enable more analytic strategies that can be used in conjunction with imagery to simplify the imagery process.

IMAGERY OF HANDS AND INTERACTIONS WITH OBJECTS

Our hands are our primary tool for exploring and modifying objects and, therefore, they play a special role in visuospatial cognition (Halligan, Fink, Marshall, & Vállar, 2003). Time to rotate an image of a hand is not linearly related to angle of displacement (cf. Shepard & Metzler, 1971). Rather, the constraints of real hand movement affect the response time and more time is required to imagine rotations of hands through orientations that are biomechanically awkward (Parsons, 1987a, 1987b, 1994; Sekiyama, 1982). Observing hand rotation also facilitates motor imagery (Conson, Sarà, Pistoia, & Trojano, 2009), and this facilitation is specific to the stimulus (hands) and motion (rotation).

Other research suggests that mental rotation shares representations and processes with planning

and executing physical interactions with objects (Wohlschläger, 2001). Manual rotation facilitates mental rotation of objects if the directions of the two rotations are congruent and interferes when the directions of the rotations are incongruent (Wexler, Kosslyn, & Berthoz, 1998; Wohlschläger & Wohlschläger, 1998; but see Sack, Lindner, & Linden, 2007). Furthermore, actions when using a tool facilitate mental rotation even when the action is not a rotation. For example, pulling the string wrapped around a spool (a linear translation action) facilitates mental rotation of an object lying on the spool (Schwartz & Holton, 2000). Finally, the motor cortex is engaged when participants imagine rotating an object with their hand, but not when they do not imagine their hand as the agent (Kosslyn, Thompson, Wraga, & Alpert, 2001).

More generally, the locations of hands in space affect how we allocate attention, whether the hands belong to the viewer, another human, or are disembodied hand-shaped objects (Reed, Grubb, & Steele, 2006). This biased attention is more evident in the graspable region (in front of the hand) than other regions equally close to the hands or tools (e.g., back of the hand) (Reed, Betz, Garza, & Roberts, 2009). In fact, the actions that we can perform within reach of our hands help to divide the space that surrounds our body. The space that is in reach (peripersonal space) is dissociable and handled by different neural systems than the space that is outside our reach (extrapersonal space), but peripersonal space is based on the potential for action rather than being a fixed size. For example, it is smaller for amputees with restricted reach (Makin, Wilf, Schwartz, & Zohary, 2009) and is expanded to include the space surrounding tools that extend actionable space (Berti & Frassinetti, 2000; Carlson, Alvarez, Wu, & Verstraten, 2010; Halligan et al., 2003; Macaluso & Maravita, 2010; Maravita & Iriki, 2004). In summary, imagery, motor planning, and attention are interacting cognitive processes unified because of the presence of our hand in the actionable space around our body.

Imagery in Complex Spatial Tasks

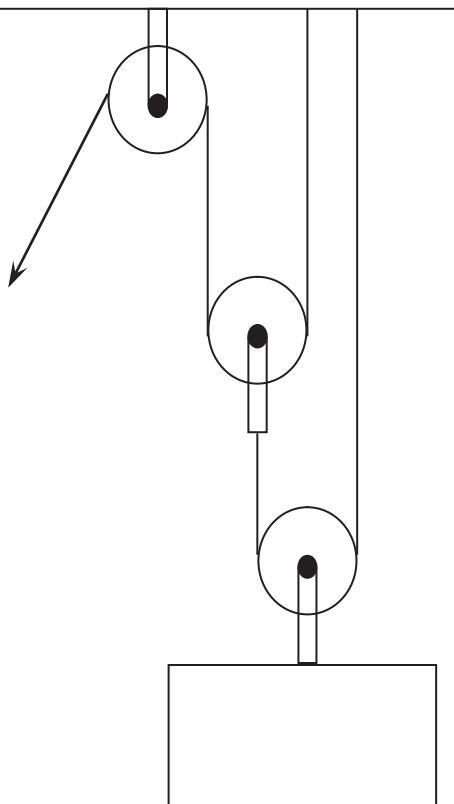

Although a great deal of research has examined how we imagine basic spatial transformations, and mental rotation in particular, the visuospatial tasks that we carry out in everyday life involve imagining more complex spatial transformations. They often require imagining a series of spatial transformations, as when we assemble a piece of furniture

(Tversky et al., 2007) or rearrange the furniture in our living room. Similarly, in diagnosing faults in your car engine, mechanics have to imagine different motions (rotations, translations, ratcheting, etc.) of many components, and scientists have to imagine complex spatial transformations when they reason about flying balls and spinning gyroscopes, or justify the relationship between molecular structure and chemical reactivity (Stieff, 2007). These do not just involve mentally rotating one rigid object (as in measures of mental rotation). In these situations, it appears that analog mental imagery transformations are augmented by analytic processes, including task decomposition and rule-based reasoning.

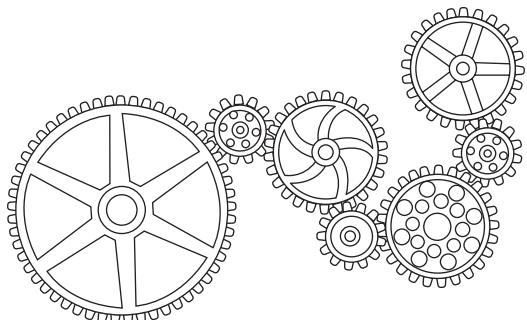

TASK DECOMPOSITION

One way in which people augment analog imagery processes in visuospatial thinking is by task decomposition. They mentally simulate complex motions piecemeal rather than holistically. For example, if you pulled on the rope of the pulley system illustrated in Figure 31.2a, all of its parts would move together. However, Hegarty (1992) showed that people infer the motion of a mechanical system like this by decomposing the task into a sequence of relatively simple interactions (e.g., how the motion of a rope causes a pulley to rotate) and inferring the motion of one component at a time. The time taken to verify how a component moved was thus proportional to its position in this causal chain.

At the same time, several lines of evidence suggest that people often use imagery transformation processes in mechanical reasoning when they imagine each “link” in the causal chain, rather than merely applying verbally encoded rules. Visuospatial working memory loads interfere more with mechanical reasoning tasks like the pulley problem than do verbal working memory loads (Sims & Hegarty, 1997). Similarly, mechanical reasoning interferes more with visuospatial than with verbal memory loads, suggesting that mechanical reasoning depends on representations in visuospatial working memory (cf. Logie, 1995). When asked to “think aloud” while they infer how parts of a machine work, people tend to express their thoughts in gestures rather than in words (Hegarty, Mayer, Kriz, & Keehner, 2005; Schwartz & Black, 1996; see also Goldin-Meadow & Cook, Chapter 32), and asking people to trace an irrelevant spatial pattern while reasoning about mechanical systems impairs their reasoning (Hegarty et al., 2005). In summary, mechanical

a. Pulley System

b. Gear System

Fig. 31.2 Examples of pulley and gear systems. In mechanical reasoning problems, one might be asked which direction the lower pulley moves (clockwise or counterclockwise) when the rope is pulled or one might be told that the large gear on the left is moving clockwise and asked to predict the direction of the right uppermost gear.

reasoning involves first decomposing the task into one of inferring the motion of individual components and then using mental image transformations to simulate the motion of each component in order of the causal chain of events (Hegarty 1992, 2004).

AUGMENTATION BY RULE-BASED REASONING

Another way in which imagery-based processing is augmented by more analytic thinking is that it sometimes leads to the induction of regularities, so that rule-based reasoning takes over. For example, take the gear problem in Figure 31.2b. When Schwartz and Black (1996) asked people to solve problems like this, participants' gestures indicated that people initially mentally simulated the motion of the individual gears, but on the basis of these simulations, they discovered the simple rule that any two interlocking gears move in opposite directions. Participants then switched to a rule-based strategy, but they reverted to the mental simulation strategy again when given a novel type of gear problem. Replacing simulation-based reasoning with rule-based reasoning was also observed in problem solving with diagrams in organic chemistry (Stieff, 2007; Stieff & Raje, 2010) and in psychometric tests of spatial ability (e.g., Hegarty, 2010; Lohman, 1988). In these situations, it has been proposed that imagery strategies are domain-general problem-solving heuristics used by novices, whereas rule-based analytic strategies are discovered during task performance or instruction and are more evident in expert problem solving (Schwartz & Black, 1996; Stieff, 2007; Stieff, Hegarty, & Dixon, 2010). However, experts also use mental simulation in novel situations in which their rules are inadequate (e.g., too narrow for the situation at hand), and in some domains such as algebra, the development of expertise is characterized by a shift from more abstract rule-based thinking to simulation-based thinking (e.g., Goldstone, Landy, & Son, 2010), so the development of expertise might be best seen as a process of developing the least effortful strategies, whether imagistic or analytic, for different tasks.

REVEALING IMPLICIT KNOWLEDGE

Research on mechanical reasoning and problem solving has suggested that an important function of imagery may be to “reveal” or make available knowledge about properties such as the shapes of objects or motion constraints that is otherwise tacit or implicit. For example, consider the problem in

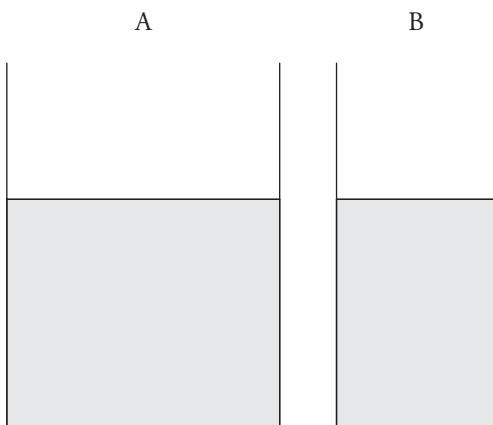

Fig. 31.3 Water Pouring Problem (Schwartz & Black, 1999). The water level in the two glasses is the same. If you start to rotate the two glasses at the same rate (degrees of rotation per second), in which glass will the water start pouring out first? A or B?

Figure 31.3, which people had to judge the angle at which water would pour out of two glasses, a fat glass and a thin glass. People perform very poorly on this task when they answer on the basis of explicit knowledge. However, when they close their eyes and rotate an imaginary glass to indicate the answer, they can almost always correctly judge that water will start pouring out of the fat glass first, and there is no systematic relationship between their answers when they are and are not instructed to use imagery (Schwartz & Black, 1999). Visualizing the situation reveals knowledge of which the person was otherwise unaware. The same process seems to occur when we take a mental walk to “discover” how many windows are in our house. Furthermore, when imagery is externalized as gesture, it can also reveal knowledge to others, and observing one’s own gestures might also reveal implicit knowledge to oneself, and this is one possible way in which gesture enhances thinking (see Goldin-Meadow & Cook, Chapter 32). In these situations, it seems that the knowledge was there to begin with, but because it was initially linked to our perceptual experience, it may take an act of mental imagery or simulated physical action to make it available to our thought processes.

In summary, simulating spatial transformations using visual imagery is an important strategy in tasks such as mental rotation, mechanical reasoning, and chemistry problem solving, but in each of these cases, more analytic strategies are also used. These can involve decomposing the problem, such that less information needs to be visualized at a time, abstracting nonspatial information, and the

application of rules to generate an answer or eliminate answer choices. One possibility is that mental imagery transformations are effortful processes, and the best spatial thinkers are those who augment visualization with more analytic strategies, using these analytic strategies when they can, so that they rely less on effortful imagery processes.

Thinking About Space: The Space of Environments

The ability to navigate in the world is a fundamental cognitive function. Navigation is necessary for finding our way in familiar environments, learning the layouts of new places, and planning routes to distant locations. Navigation can be based on external spatial representations such as maps and on internal spatial representations derived from sensory experience. It is a multisensory process in which information needs to be integrated and manipulated over time and space. Vision provides us with direct information about spatial attributes of the environment, such as its general shape, and the objects therein. However, in most natural environments, not all relevant features can be seen from a single vantage point. Therefore, keeping track of one’s location and orientation is crucial if we are to integrate all relevant features into a comprehensive representation, so that navigation also depends on perceiving self-motion.

Wolbers and Hegarty (2010) provide an overview of the sensory cues, perceptual and cognitive processes, and spatial representations involved in most forms of human and animal navigation. The sensory cues include cues in the environment, such as landmarks (e.g., a distinctive building), global orientation cues (e.g., the sun), the geometric structure of the environment (e.g., the network of streets in a city), and symbolic representations (e.g., maps or verbal directions). They also include self-motion perception based on vestibular and proprioceptive cues, and optic flow. The perceptual and cognitive processes that act on these sensory cues include space perception, self-motion perception, computing distances and directions to unseen places, and imagining shifts in perspective or reference frame. Wayfinding and navigation can also depend on executive processes such as selection and maintenance of navigational goals or choice of a navigation strategy (e.g., depending on familiar routes versus global orientation cues). Finally, navigation depends on a variety of spatial representations, including online or short-term representations that are available

when one is navigating in an environment and more enduring offline or long-term memory representations. We first discuss the nature of these representations and then review the perceptual and cognitive processes that operate on them to keep us oriented in space, to reorient when we are disoriented or lost, to learn the layout of new environments, and to plan routes through familiar environments.

Spatial Representations in Orientation and Navigation

Orientation and navigation in the environment rely on two types of spatial representations, egocentric and allocentric representations. Egocentric representations encode the distances and directions to objects and features in the environment with respect to the self, are relatively precise, and depend on areas of the parietal cortex (Byrne et al., 2007). They are primarily online spatial representations that are active in working memory when we are actually in and oriented to an environment.

Allocentric representations encode the locations of objects in the environment with respect to other objects or features of the environment, and they are thought to depend more on areas in the medial temporal lobes (Byrne et al., 2007). Allocentric representations support our long-term representations of the layout of environments that endure when we are no longer in or oriented to the environment and are less precise than online egocentric representations (Waller & Hodgson, 2006). They are often referred to as cognitive maps, so it is important to identify the ways in which they are unlike printed maps. For example, cognitive maps (especially maps of large-scale spaces that cannot be apprehended in a single view) encode locations and distances categorically and hierarchically (Friedman, Brown, & McGaffey, 2002; Hirtle & Jonides, 1985; Stevens & Coupe, 1978), distort distances (Holyoak & Mah, 1982; Sadalla, Burroughs, & Staplin, 1980), and encode the spatial relations between features as more aligned than they are in reality (Tversky, 1981).

Our cognitive maps differ depending on how they are learned. When we learn the layout of an environment from a map, the orientation of the map (usually North is up) defines a preferred orientation of our cognitive map in memory (Levine, Marchon, & Hanley, 1984; Richardson, Montello, & Hegarty, 1999). Preferred orientations are inferred when people are better able to perform pointing tasks (known as judgments of relative directions) from some imagined orientations in the environment than

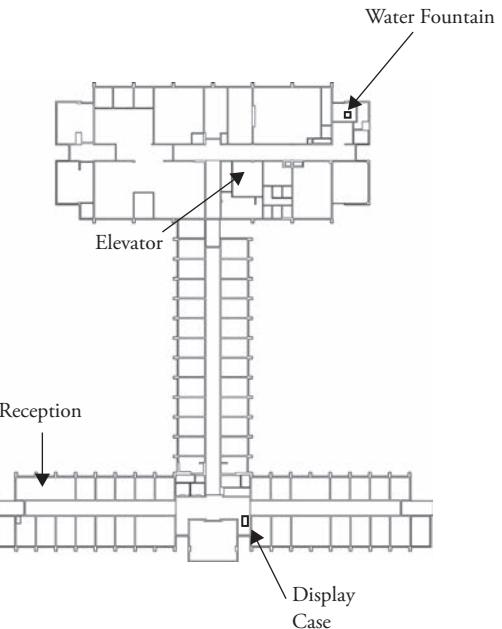

Fig. 31.4 Map of the corridors of a building with North up orientation.

from other imagined orientations. For example, if you learn the layout of a building from the map in Figure 31.4, it is more difficult to point to objects if you imagine yourself at the elevator facing the display case than if you imagine yourself at the display case facing the elevator.

Even when people learn the layout of an environment by direct experience, their enduring representations of the environment can have one or more preferred orientations in memory (e.g., Mou & McNamara, 2002; Shelton & McNamara, 2001). On the basis of extensive studies showing that judgments of relative direction are easier from some imagined orientations in an environment than others, McNamara and colleagues have proposed that object locations in an environment are represented with respect to spatial reference frames with an intrinsic axis. This intrinsic axis can be defined by the shape of the environment (e.g., the axis defined by the longer walls of a rectangular room), a more local reference system (e.g., a mat on the floor, Shelton & McNamara, 2001), or by the configuration of objects themselves, such as an axis of symmetry in the layout of a group of objects (Mou & McNamara, 2002). In the absence of these cues, the orientation from which one has experienced the environment typically defines the axis of the reference frame (Diwadkar & McNamara, 1997). Effects of experience in the environment can also

interact with aspects of the environment (Shelton & McNamara, 1997).

Processes in Orientation and Navigation

REMAINING ORIENTED TO AN ENVIRONMENT

When people are oriented to an environment, their actual facing direction in the environment strongly determines the preferred direction of their online representations. Ability to imagine a perspective other than your current orientation in the environment is effortful and related to the angular disparity between your actual direction and the direction to be imagined (Hintzman, O'Dell, & Arndt, 1981; Rieser, 1989). While perspective taking has been proposed to reflect a mental transformation process analogous to mental rotation (e.g., Easton & Sholl, 1995; Rieser, 1989), an alternative account suggests that the difficulty may reflect a conflict between one's actual directional relations to the objects in the environment and one's relation to those objects from the imagined perspective (e.g., May, 1996; Presson, 1987). Consistent with the interference account, when people are disoriented after viewing an environment (so that they do not know their facing direction), the effects of mismatch between their actual orientation and the orientation to be imaged are reduced (May, 1996; Waller, Montello, Richardson, & Hegarty, 2002). This account may also explain the fact that mental rotation ability and perspective-taking abilities are partially dissociated (Hegarty & Waller, 2004; Kozhevnikov & Hegarty 2001).

As we move about the world, internal and external self-motion cues allow us to keep track of the locations of external features with respect to the self in egocentric coordinates, a process known as spatial updating. These cues include optic flow, changes in the relative locations of objects as we move, as well as body-based self-motion cues (proprioception, motor efference copy, and the vestibular sense). Body-based cues are sufficient for spatial updating over short distances. For example, Rieser (1989) found that pointing from an imagined orientation in an environment was no more difficult than pointing from a studied view, as long as people physically turned to the imagined view, while blindfolded, after seeing the environment from the studied view (see also Presson & Montello, 1994; Rieser, 1989; Simons & Wang, 1998; Waller et al., 2002; Wang & Simons, 1999). In contrast, merely imagining moving from the studied to the imagined view, without actually moving, is not sufficient to

update one's orientation (Klatzky, Loomis, Beall, Chance, & Golledge, 1998). Body-based cues can also be hard to ignore. For example, Farrell and Robertson (1998) had people point to previously seen objects in an environment after being blindfolded and rotated in the environment and found that they had difficulty ignoring their body rotation to point from the original, viewed orientation. They suggested that updating is automatic. However, Waller et al. (2002) found that people could easily follow instructions to either imagine leaving the environment behind them when they rotated or to bring the environment with them, suggesting that updating is not automatic but instead can reflect cognitive awareness of how one's movement affects the task at hand.

While there is good evidence that remaining oriented to an environment involves updating egocentric representations, there has been controversy regarding whether people also update their orientation and location with respect to allocentric representations (Waller & Hodgson, 2006; Wang & Spelke, 2000). In studies on this topic, people first learn an array of objects and then point to the (no longer visible) objects before moving, after rotating in place, or after disorientation. It is argued that if each of the objects is updated with respect to an egocentric frame of reference, the configuration of objects should be distorted after movement, whereas if updating is with respect to an allocentric representation, the configuration of objects should remain intact in memory after movement. Wang and Spelke (2000) found that the configuration of objects (but not aspects of room geometry) was distorted in memory following disorientation, and they concluded that remaining oriented to the environment depends primarily on egocentric representations. Waller and Hodgson (2006) offered an alternative interpretation, that the increased disorientation in memory reflects a switch from more precise online representations to less precise offline representations. They showed that our offline representations of even very familiar environments (our bedrooms) were less precise than online representations of novel environments, and their research also suggested that the switch from online to offline representations could occur even without disorientation (after a rotation of 90 degrees or more). The relative dependence on egocentric versus allocentric representations can also depend on the geometric regularity of object layouts in an environment (Xiao, Mou, & McNamara, 2009).

REORIENTING AFTER DISORIENTATION

In everyday life, we have to reorient to the larger environment when we emerge from a building, such as a department store, through a different door than which we entered. More generally, while we can update our orientation and location in environments over short distances, error accumulates over large distances so that reorientation is often necessary.

There has been much research regarding the cues people use to reorient to an environment after disorientation. In classic research on this topic, Cheng (1986) and Gallistel (1990) found that rats used the general shape of environments (environmental geometry) but not distinctive landmarks to reorient. They placed rats in a rectangular enclosure including distinct odors and visual cues until they found food in one of the corners of the enclosure. Before they had eaten all the food, the rats were removed, disoriented, and placed in an identical enclosure, and it was observed where they searched for food. The surprising result was that the rats looked equally in the correct corner and the diagonally opposite corner (see Fig. 31.5), even though there were salient olfactory and visual cues that identified the correct corner. That is, they searched based on geometry alone and ignored featural cues.

Hermer and Spelke (1994) studied the same paradigm with children and found that young children (younger than 2 years) also ignored highly salient cues and reoriented to environments based on geometry alone. Older children who had acquired spatial language (especially the terms “left” and “right”) successfully combined geometric and featural cues. Moreover, when adults performed a verbal secondary task that prevented them from using language, they also reoriented based on geometry alone (Hermer-Vasquez, Spelke, & Katsnelson, 1999). On the basis of these results, they proposed that humans and animals share a “geometric module” that only processes environmental shape, but that language allows

humans to penetrate this module to combine geometric with featural information. However, recent research has questioned this account. For example, nonhuman species (who obviously do not have language) can use features in some circumstances, younger children do use features in larger environments than those tested by Hermer and Spelke, and nonverbal secondary tasks also impair adults’ performance (see Cheng & Newcombe, 2005; Twyman & Newcombe, 2010 for reviews). An alternative current account of reorientation is that it depends on an adaptive combination of cues (both geometric and featural), based on their salience, reliability, and familiarity (Cheng, Shettleworth, Huttenlocher, & Rieser, 2007), rather than a module that can only take geometry into account.

LEARNING SPATIAL LAYOUT

There has been much interest in how our representations of space develop with increasing experience in that space. One influential theory (Siegel & White, 1975) proposed that we construct qualitatively different types of representations at different stages in our familiarity with an environment; we initially construct landmark representations that allow us to recognize salient landmarks in the environment, later develop route representations that encode the relations between pairs of landmarks that one would encounter as one moves through an environment, and finally develop survey or configurational representations specifying the relations between locations in the environments, independent of the routes between them. Survey representations allow us to take novel shortcuts through the environment and to point directly or estimate straight-line distances to locations in the environment.

While distinguishing between landmark, route, and survey representations of large-scale space has been useful theoretically, this sequential theory by Siegel and White (1975) has been challenged

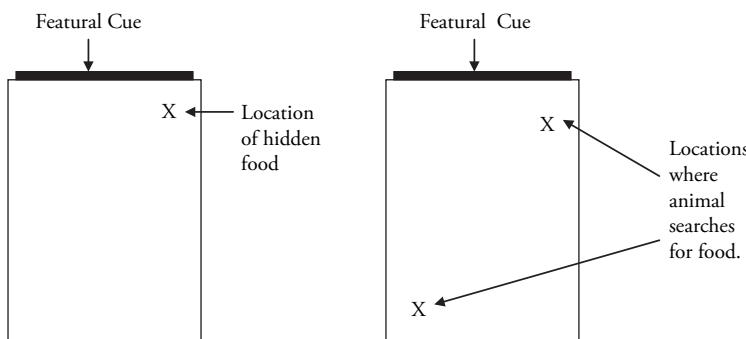

Fig. 31.5 Example of a trial from the experiments of Cheng (1986) showing the location at which food was hidden, and the locations in which the animal searched for food. Although there was a distinct cue that could discriminate the corner in which the food was hidden, the animal searched on the basis of environmental geometry alone (i.e., at a corner with a short side of the room on the left and the long side of the room on the right).

(Montello, 1993). Rather than progressing from landmark to route to survey representations in sequence, Montello reviews evidence that all three of these types of representation develop in parallel, but at different rates. Moreover, there are large individual differences in the rate at which these representations are constructed, and some people may never construct true survey representations. Ishikawa and Montello (2006) led participants on the same routes through a novel environment once a week for 10 weeks and measured their ability to estimate straight-line directions and distances between locations. Whereas some participants had almost perfect configural knowledge of the environment after one or two learning experiences, others performed at chance and did not improve over 10 learning trials.

These striking individual differences in environmental learning can be dissociated from individual differences in smaller scale tasks that involve simple object transformations (e.g., mental rotation). In a review of 12 studies, Hegarty and Waller (2005) found that the median correlation between small-scale spatial abilities and measures of learning the layout of new environments had correlations exceeding .3 only in two studies. Correlational studies are limited in that the correlation between two variables reflects variance specific to each of the tasks, as well as error variance. Using structural equation modeling to control for these sources of variance, Hegarty et al. (2006) demonstrated that object-based spatial abilities and the ability to learn the layout of an environment are partially dissociated. Object-based spatial ability was significantly more related to learning from media (video and virtual environments) than to learning from direct experience. Moreover, learning from direct experience in an environment was somewhat distinct from learning from media (see also Liben, Myers, & Christensen, 2010). It was concluded that object-based and environmental spatial abilities share the ability to encode spatial information from visual input, maintain this information in memory, and make inferences from this information, but learning from direct experience also involves the sensing and integration of self-motion cues.

STRATEGIES IN NAVIGATION AND WAYFINDING

While researchers have isolated different navigational cues in controlled experiments, in most everyday navigation and wayfinding situations multiple cues are available, including cues about the environmental geometry, salient features, and self-motion

cues. An interesting question raised in recent spatial cognition research is the degree to which people weigh and combine these different cues in navigation and wayfinding tasks. While these questions have been asked most prominently in the debate over the use of geometry versus landmarks for reorientation, discussed earlier, researchers have begun to study how people integrate these cues in other tasks such as spatial updating (Kelly, McNamara, Bodenheimer, Carr, & Rieser, 2009) and are beginning to identify the neural structures that encode and combine environmental geometry and landmark information (Doeller, King, & Burgess, 2008). Other researchers have examined how the integration of landmarks and self-motion cues are integrated. For example, both children and adults can use both landmarks and self-motion cues to place an object in its original position in an environment, but when these cues are put in conflict, only adults integrate the two types of cues (Nardini, Jones, Bedford, & Braddick, 2008). In another study, adults depended on landmarks to walk a shortcut in a virtual environment, but they fell back on coarse survey knowledge, constructed from self-motion perception, when landmarks were unreliable (Foo, Warren, Duchon, & Tarr, 2005).

Related research has revealed that different individuals can have preferences for route-based versus survey-based navigation strategies, and intriguingly these include qualitative differences in the environmental cues and strategies used by women and men. Women more often report navigating on the basis of local landmarks and familiar routes, whereas men report using cardinal directions, environmental geometry, and metric distances (Grön, Wunderlich, Spitzer, Tomczak, & Riepe, 2000; Lawton, 1994). While women do not differ from men in dependence on, or ability to use landmarks, they depend less on geometry when reorienting to an environment (Sandstrom, Kaufman, & Huettel, 1998) and also require more environmental cues to remain oriented to an environment (Kelly et al., 2009). Strategy choice can also depend on factors such as the demands of different navigation tasks and the information available to the navigator (Hölscher, Büchner, Meilinger, & Strube, 2009). An interesting question for future research is whether the best navigators are those who switch flexibly between different strategies, depending on what is optimal in a given situation.

In summary, orientation and navigation in large-scale space depend on both visual information about

the shape of the environment and the features of the objects therein, and information from other senses, notably those involved in perception of self-motion. Research in spatial cognition at the environmental scale has revealed the types of representations that people construct from the various sensory cues, how these representations are learned, and how they are processed to guide orientation, navigation, and wayfinding. Questions of current interest include discerning the relative roles of environmental geometry, salient visual features in the environment, and self-motion cues in different aspects of orientation and wayfinding, how these sources of information are weighted and combined in different situations and in using different navigation strategies, and the brain bases of orientation and navigation.

Using Space to Think

In addition to thinking about space, at the scale of objects and environments, visuospatial thinking includes situations in which we use spatial representations to think about other entities, both abstract and concrete. Using space to think, in this way, includes metaphorical uses of space in language, thought, and graphics.

Spatial Metaphors

In general, a metaphor occurs when a source domain, which is concrete or familiar, is used to reason about a target domain, which is abstract or unfamiliar. In their seminal work on this topic, Lakoff and Johnson (1980) proposed that metaphors result directly from the nature of the body and our experience grounded in everyday events, and that metaphors are fundamentally spatial (Johnson & Lakoff, 2002; Lakoff & Nunez, 2000; Wilson & Gibbs, 2007). For example, consider the metaphor that relates up with good and down with bad. It is common to associate vertical space in this way. Phrases such as “on the top of his game” express positive and desirable conditions, while phrases such as “down in the dumps” or “downtrodden” expresses negative or undesirable conditions. Notably, this division of space is consistent across cultures and languages, which has been proposed as evidence that it is physically rooted in our experience of standing erect with pride or slumping when depressed.

The relationship between abstract concepts and space also contributes to our ability to reason about the magnitude of numbers. When asked to compare two numbers, people are faster when responding with their left hand for lower numbers and

their right hand for higher numbers (Dehaene, Bossini, & Giraux, 1993). This is known as the SNARC effect (for Spatial-Numerical Association of Response Codes). It is independent of handedness, but it is influenced by direction of writing. For example, it is reversed for Iranian participants, who write from right to left. The SNARC effect suggests that we naturally map the abstract concept of number onto space, with the direction of mapping being influenced by culture.

In a similar manner, Boroditsky and colleagues (Boroditsky, 2000, 2001; Boroditsky & Ramscar, 2002) have explored the metaphorical relationship between time and space. Time is typically mapped onto the horizontal dimension of space. This metaphorical relationship between space and time can also be expressed differently, depending on whether the observer imagines himself or herself as moving through time, or whether time is imagined as moving toward the observer (Boroditsky & Ramscar, 2002; Gentner, Imai, & Boroditsky, 2002). For example, if you had a Wednesday meeting, which was moved forward 2 days, then the new meeting day might be Friday if you imagined yourself moving through time but Monday if you imagined time moving toward you. Adoption of one or the other structural metaphor for time is affected by valence, with negative events resulting in adoption of the metaphor of time moving toward a stationary observer and positive events resulting in adoption of the metaphor of the observer moving through time (Margolies & Crawford, 2008). Finally, valence can also affect right/left mappings of time to horizontal space. Right-hand dominant participants judge an item on the right to be more preferable than an item on the left and this pattern reverses for left-hand dominant participants (Casasanto, 2008, 2009). In essence, affect may have an influence on our metaphorical mapping of time to space, which may extend to how we subjectively perceive and reason about time.

Visual and Spatial Representations in Deductive Reasoning

There has been much controversy about the functionality of visual and spatial representations in deductive reasoning (see Evans, Chapter 8). Some researchers have claimed that reasoning problems are solved by constructing spatial mental models of the contents of the problems (e.g., Huttenlocher, 1968; Johnson-Laird, 1983; see Johnson-Laird, Chapter 9), whereas others have claimed that the

fundamental representations underlying reasoning are propositional (Clark, 1969; Rips, 1994). As with most controversies of this type, neither of these extreme characterizations is likely to account for all forms of reasoning (cf. Goel, 2007). However, there is now considerable evidence from verbal protocol studies (e.g., Egan & Grimes-Farrow, 1982), dual-task studies (Vandierendonck & De Vooght, 1997), individual-difference studies (e.g., Sternberg, 1980), and brain imaging studies (e.g., Goel & Dolan, 2001; Knauff, Fangmeier, Ruff, & Johnson-Laird, 2003) that spatial representations, in addition to verbal representations, are functional in deductive reasoning. It is therefore more informative to consider the circumstances under which spatial representations are used and the nature of the spatial representations that are functional in reasoning.

FORM OF REASONING

The strongest evidence for spatial representations in reasoning is during the solution of linear syllogisms (e.g., “John is smarter than Bob, Tom is dumber than Bob, John is smarter than Tom”). De Soto, London, and Handel (1965) first proposed that when solving these reasoning problems, people form spatial representations in which they imagine the objects in the problem (e.g., John, Bob, and Tom) in a linear array in order of the relation (in this case, smartness). Huttenlocher (1968) developed this theory and likened the mental processes of constructing and manipulating mental spatial representations to constructing and moving real objects. Although purely linguistic models could also account for the solution of linear syllogisms (Clark, 1969), further studies suggested that spatial representations are functional, if not essential in linear reasoning (Shaver, Pierson, & Lang, 1975), and individual difference studies suggested that most people were best fit by a model that assumed both verbal and spatial representations (Sternberg, 1980).

In contrast with linear reasoning, other forms of reasoning such as categorical syllogisms and conditionals may be less naturally dependent on spatial representations, although spatial representations can and are often used for these types of reasoning. For example, Euler’s circles offer a visuospatial representation that is effective for solving categorical syllogisms (Stenning & Oberlander, 1995), teaching people diagrammatic representations can improve deductive reasoning with double disjunctions (Bauer & Johnson-Laird, 1993), and conditional reasoning about spatial content depends on

spatial working memory (Duyck, Vandierendonck, & De Vooght, 2003). Mental models (Johnson-Laird, 1983) are also often assumed to be visuospatial in nature.

CONTENT BEING REASONED ABOUT

Research on the effects of content on reasoning has provided insights into the nature of the spatial representations in reasoning. Although initial theories suggested very abstract spatial representations (Huttenlocher, 1968), the representations underlying reasoning were often assumed to be visuospatial images, leading to the prediction that relations that are easier to visualize are also easier to reason about (e.g., Shaver et al., 1975). This prediction was not consistently supported. In contrast, Knauff and Johnson-Laird (2002) found that when problems contain highly visual content (e.g., the dog is cleaner than the bird), reasoning is actually less efficient than when the content is spatial (e.g., the dog is in front of the bird) or abstract (e.g., the dog is smarter than the bird). This is known as the visual impedance effect. The problem with earlier research on the spatial imagery theory is that it confounded “easy to visualize” with “easy to represent as a spatial array.” Knauff and colleagues have argued that when the relation in the premises is highly visual, the construction of an abstract spatial representation of the relation is impeded by irrelevant visual detail that automatically comes to mind. In contrast, both spatial relations and abstract relations are readily mapped onto abstract spatial representations without such interference. In support of this view, a brain imaging study showed that only problems with visual relations activated vision-related areas in occipital cortex, whereas reasoning with all relations (visual, spatial, and abstract) activated a bilateral parietal-frontal system suggestive of spatial representations (Knauff et al., 2003).

CHARACTERISTICS OF THE INDIVIDUAL

It is also likely that individual differences between people affect the degree to which they use visuospatial representations in reasoning and the nature of those representations (cf. Kozhevnikov, Hegarty, & Mayer, 2002). While most participants in Sternberg’s (1980) study were best fit by a model of linear reasoning that assumed both verbal and spatial representations, a minority had a better fit to a model using verbal representations alone or spatial representations alone. Egan and Grimes-Farrow (1982) found that people could be classified as “abstract

directional thinkers,” who constructed mental orderings of the terms in linear reasoning problems, or less successful “concrete properties thinkers,” who represented the terms as detailed mental images that included physical properties of the objects (roughness, darkness, etc.). Knauff and May (2006) found that congenitally blind individuals do not show the visual impedance effect, and they argued that because blind people have never experienced visual detail, they do not represent visual properties in transitive inferences like this. Finally, dyslexics are often characterized as highly visual thinkers and are more subject to the visual impedance effect than other students (Bacon, Handley, & Newstead, 2003).

In summary, there is evidence for spatial representations in deductive reasoning, especially for linear syllogisms and when the content is either spatial or easily mapped onto spatial representations. However, there are individual differences in the extent to which people rely on spatial representations in their reasoning and the representations that are most functional in reasoning are very schematic, without visual detail.

Thinking With Diagrams, Graphs, and Maps

People also use space to think when they use graphical displays, such as diagrams, maps, and graphs. These are visuospatial external representations that can represent objects, events, or more abstract information. Graphical displays can be categorized based on the relation between the representation and its referent and how space is used to convey meaning. The first category consists of iconic displays. In iconic displays, space on the page represents space in the world and the properties displayed (shape, color, etc) are also visible properties of the referent (e.g., a road map, a diagram of human heart). These types of displays are ancient (cave paintings are examples) and used by all cultures (Tversky, 2005).

Second, relational displays are metaphorical in that they represent entities that do not have spatial extent or visible properties (e.g., when an organization chart shows the hierarchy of positions in a business, or a graph shows the price of oil over time). In these displays, visual and spatial properties represent entities and properties that are not necessarily visible or distributed over space. Visuospatial variables, such as color, shape, and location are the *representing* dimensions of the display (Bertin, 1983). The *represented* dimensions can be any category or quantity. These

types of displays are a relatively recent invention. For example the invention of the graph is attributed to Playfair in the 18th century (Wainer, 2005).

Some visual displays, including statistical maps or geospatial displays, are hybrids of these two types in that they represent both visual information and nonvisual (but spatially distributed) information. For example, a politician might examine the pattern of states that voted Republican or Democrat in the last U.S. presidential election or a researcher might examine a functional magnetic resonance image (fMRI) of activity across the brain during a cognitive task. In these displays, there is a direct mapping between space in the representation and space in the referent. However, in this case nonvisual properties are “visualized,” that is, represented by visual variables, such as color, shape, and shading, so they are also partly metaphorical.

HOW GRAPHICAL DISPLAYS ENHANCE THINKING

Graphical displays can enhance visuospatial thinking in several ways. They store information externally, freeing up working memory for other aspects of thinking (Card et al., 1999; Scaife & Rogers, 1996). They can organize information by indexing it spatially, reducing search and facilitating integration of related information (Larkin & Simon, 1987; Wickens & Carswell, 1995). These displays can also allow the offloading of cognitive processes onto automatic perceptual processes (Scaife & Rogers, 1996), or visual routines (Ullman, 1984), that abstract task-relevant properties from the display, for example, when a line in a graph reveals a linear relationship between variables (Shah, Friedman, & Vekiri, 2005). When a display is interactive, people can offload internal mental computations on external manipulations of the display itself (Card et al., 1999; Kirsh, 1997). However, although graphical displays can enhance thinking in all of these ways, this does not mean that their use is easy or transparent. In the remainder of this section we review representative studies of what is sometimes called representational or metarepresentational competence (diSessa, 2004), that is, ability to produce appropriate graphical displays, choose the best display for a given task, understand graphical displays, and interact appropriately with these displays.

PRODUCING GRAPHICAL DISPLAYS

The graphical displays that people spontaneously produce often reflect and reveal spatial metaphors.

For example, Tversky, Kugelmass, and Winter (1991) asked children to place stickers on a page to represent spatial, temporal, quantitative, and preference dimensions. They might be asked to place stickers representing breakfast, lunch, and dinner or representing their least favorite food, a food they like, and their favorite food. Most children placed the stickers in a line while maintaining the ordinal relations between the items (e.g., placing a sticker for breakfast on the left, lunch in the middle, and dinner on the right), indicating that they naturally mapped more abstract relations to space. They mapped temporal dimensions to space at an earlier age than they mapped quantitative and preference dimensions, and their mappings were affected by writing order in their cultures (for example, in the breakfast-lunch-dinner example, Arabic children, who write right to left, typically placed the sticker for breakfast on the right, lunch in the middle, and dinner on the left). Tversky (2011) argues that there are natural mappings between graphic forms and their meanings and between spatial arrangements of these forms and their meanings. For example, lines are spontaneously used to represent connections, circles to indicate cyclic processes, the horizontal dimension is naturally mapped to time, and the vertical dimension is more naturally mapped to importance or other evaluative dimensions.

In the case of more iconic displays, educators and developmental psychologists have identified children's ability to create appropriate representations, for example, in graphing motion and mapping terrain (Azevedo, 2000; diSessa, 2004; Sherrin, 2000). However, these researchers also point to limitations in this natural competence. For example, children show a strong preference for realistic representations, even when less realistic representations are more effective. There are also individual differences in ability to produce the most effective representation for a problem, especially when this representation is less realistic. For example, Hegarty and Kozhevnikov (1999) found that when solving mathematical problems, the most successful students abstracted the essential information in the problem and represented it as a schematic diagram, whereas less successful students tried to imagine irrelevant visual aspects of the objects described in the problems.

CHOOSING GRAPHICAL DISPLAYS

Another aspect of metarepresentational competence is the ability to choose the best format of external representation for a given task. In research

on relational spatial displays (matrices, networks, and hierarchies), Novick and colleagues (Novick, 2001; Novick & Hurley, 2001) found a high degree of competence among college students to match the structure of a problem to a type of diagram. They argued that people have schemas that include applicability conditions for the different types of diagrams, and they found that college students were often able to articulate these conditions.

In contrast, with more iconic and spatial displays, people show less metarepresentational competence. Undergraduate students show a strong preference for more complex iconic displays that resemble their referents by adding animation, three-dimensional information, detail, and realism (Hegarty, Smallman, Stull, & Canham, 2009). However, in fact, these display enhancements do not always improve task performance and can even impede it (e.g., Khooshabeh & Hegarty, 2010; Tversky, Morrison, & Betrancourt, 2002; Zacks, Levy, Tversky, & Schiano, 1998). Similarly, U.S. Navy experts prefer realistic three-dimensional rendered icons of ships over less realistic, more abstract symbols in their tactical displays, but they perform better with icons that pare down realism to maximize discriminability (Smallman, St. John, Oonk, & Cowen, 2001). Finally, both expert meteorologists and naïve students choose to work with weather maps that display more variables and look more realistic, but they perform faster and more accurately with simpler displays (Hegarty et al., 2009). In summary, people prefer displays that simulate the real world with greater fidelity (Scaife & Rogers 1996; Smallman & Cook, 2011; Smallman & St. John, 2005), but they are often better served by simpler, more abstract displays.

UNDERSTANDING GRAPHICAL DISPLAYS

Models of graphics comprehension propose the following three component processes in understanding graphical displays. First, users must encode the visual features of the display (e.g., lines of different slopes in a line graph). Next, they must map these onto the conceptual relationships that they convey (e.g., an upwardly sloping line shows an increasing quantity). Finally, they need to relate these conceptual relationships to the referents of the graphs (e.g., an upwardly sloping line represents an increase in the value of some stock) (Bertin, 1983; Carpenter & Shah, 1998; Pinker, 1990). Understanding a graphic can also include making inferences from the information in the display, based on the individual's prior domain knowledge or other inference rules that can

operate on the internal representation (Trickett & Trafton, 2006). Thus, graphics comprehension involves interaction between bottom-up perceptual processes of encoding information and top-down processes of applying graph schemas (Pinker, 1990; Ratwani & Trafton, 2008) and domain knowledge.

The way in which information is displayed graphically can have powerful effects on how it is interpreted and processed, providing evidence for bottom-up influences of display design. People interpret the same data differently, depending on whether they are presented in pie charts or bar graphs (Cleveland & McGill, 1986; Simkin & Hastie, 1986), bar graphs or line graphs (Shah, Mayer, & Hegarty, 1999), and which variables are assigned to the x and y axes (Gattis & Holyoak, 1996; Peebles & Cheng, 2003;

Shah & Carpenter, 1995). Effects like these can often be traced to the Gestalt principles of perceptual organization, which determine which elements of displays are grouped and can be compatible or incompatible with the tasks to be carried out with a display. Line graphs facilitate comparisons for the variable plotted on the x axis (see Fig. 31.6a) because the lines group data points as a function of this variable, reflecting the Gestalt principle of good continuation (Shah & Friedman, 2011). In contrast, bar graphs facilitate comparisons between the variable shown in the legend because the bars comparing data points with respect to this variable are closer, reflecting the Gestalt principle of proximity (see Fig. 31.6b). Similarly, Novick and Catley (2007) found differences in comprehension of two types of common hierarchical diagrams

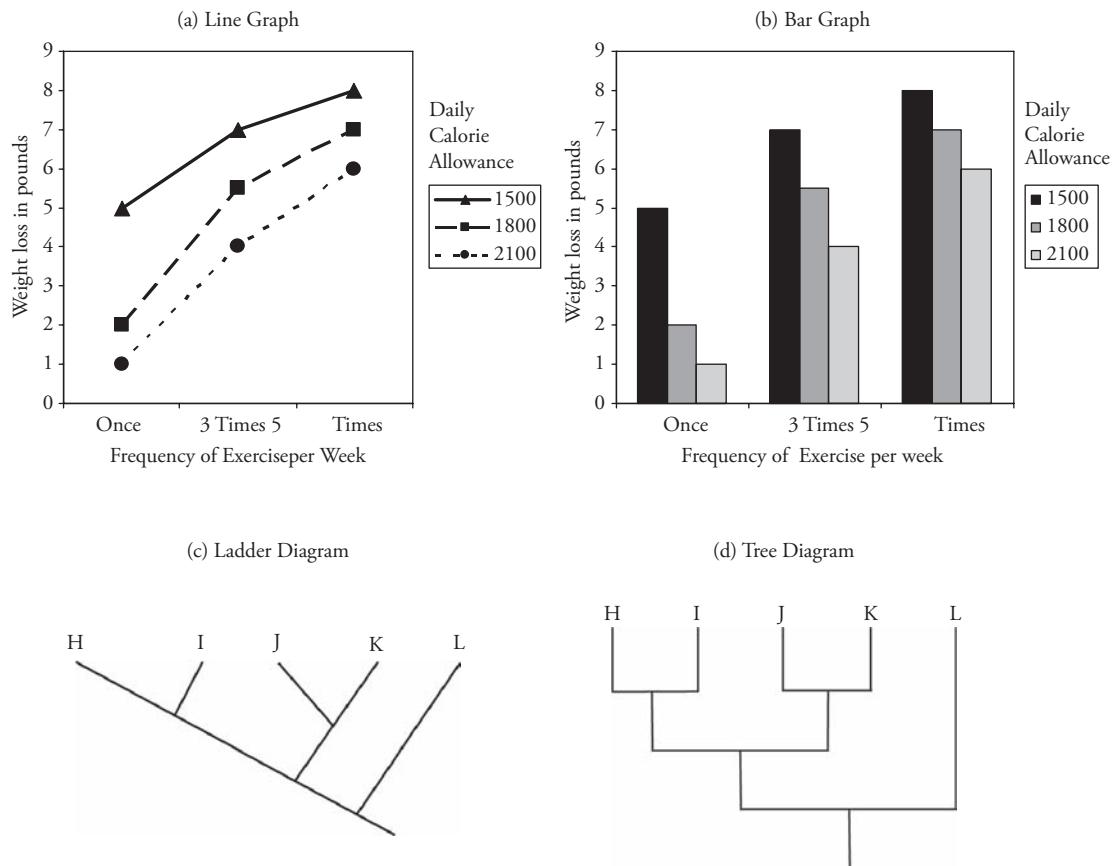

Fig. 31.6 Examples of graphics that show the same data but are processed differently. (a) and (b) are graphs of the same fictitious data showing weight loss as a function of frequency of exercise and daily calorie allowance. The line graph (a) facilitates comprehension of the effects of exercise, because the lines group data points as a function of this variable, whereas the bar graph (b) facilitates comprehension of the effects of calorie allowance because the bars comparing data points with respect to this variable are closer, reflecting the principle of proximity. (c) and (d) are examples of two types of common hierarchical diagrams (cladograms) used to display inheritance relationships in evolutionary biology. Novick and Catley (2007) found that comprehension of the ladder format (c) was more difficult than comprehension of the tree format (d), because the Gestalt principle of good continuation hindered the understanding of the hierarchical relationships in the ladder diagram.

(cladograms) in evolutionary biology, shown in Figure 31.6c and 31.6d. In the case of the diagram in Figure 31.6c, the Gestalt principle of good continuation hindered the understanding of the hierarchical relationships.

Comprehension of graphical displays is also influenced by knowledge. Experts and novices attend to different aspects of visual displays and extract different information from these displays. Experts in meteorology attend to thematically relevant aspects of displays regardless of their visual salience, whereas novices' attention is captured by the most salient features (Lowe, 1993, 1994, 1996). Experts in chess have a perceptual encoding advantage when looking at chess diagrams, such that their visual spans are larger (Reingold, Charness, Pomplun, & Stampe, 2001). Top-down effects on graphics comprehension can be separated into effects of knowledge of the graphic conventions (or graph schema) and knowledge of the domain (Shah et al., 2005; Shah & Friedman, 2011).

Finally, bottom-up effects of display design and top-down effects of knowledge can interact. Recent studies examined this interaction in a task involving making inferences from weather maps (Canham & Hegarty, 2010; Hegarty, Canham, & Fabrikant, 2010). Bottom-up effects of display design were investigated by manipulating the number of displayed variables on the maps, or the visual salience of task-relevant versus task-irrelevant information. Top-down effects of domain knowledge were investigated by examining performance and eye fixations before and after participants learned relevant meteorological principles. Map design and knowledge interacted such that salience had no effect on performance before participants learned the meteorological principles, but after learning, participants were more accurate if they viewed maps that made task-relevant information more visually salient.

INTERACTING WITH GRAPHICAL DISPLAYS

Graphical displays increasingly give the user the opportunity to choose the display he or she will use to perform a task, to add and subtract variables to graphs or maps, rotate, pan, and zoom displays. It is often assumed that this interactivity will enhance performance, by enabling people to offload internal mental computations on external manipulations of the graphic (Card et al., 1999). However, the decision to interact and choice of how to interact with a graphic also depend on knowledge of the affordances of that type of display, the problem solver's

metacognition about which transformations of displays are useful for the given problem, and the ability to make the appropriate transformation. This knowledge cannot always be assumed. In recent studies, users were given the opportunity to rotate visual displays, to perform a cross-section task, and rotating to a particular view improved performance, but many participants did not rotate the display to this optimal view (Keehner, Hegarty, Cohen, Khooshabeh, & Montello, 2008) and performed poorly. Moreover, interactivity can have other costs. For example, Yeh and Wickens (2001) found that the time and attention costs needed to decide to subtract irrelevant variables from a display outweighed the performance decrement due to visual clutter.

In summary, studies of metaphor in language and thought reveal that people naturally map abstract concepts such as time, number, and evaluative dimensions to space. Graphical displays capitalize on these natural mappings. However, this does not mean that the use of graphics is always easy. The use of spatial displays to represent both spatial and nonspatial entities is highly conventional, and the cognitive processes necessary to construct, comprehend, and use these displays are often complex and error prone. Current issues in research on this topic include the discernment of what aspects of representational competence are more and less intuitive, and how to best design graphical displays for optimal comprehension and use.

Future Directions

Our review of visuospatial cognition in this chapter has indicated that research on this topic has been dominated by many controversies and dichotomies. Is object recognition based on matching of two-dimensional visual templates or more schematic structural descriptions? Is the experience of imagery based on analog depictive representations or more abstract propositional representations? Is reorientation to an environment based on its visual features or its overall geometry? Each of these controversies reflects a distinction between more detailed, visual, often two-dimensional representations and more schematic, spatial, often three-dimensional representations. An important future direction, already evident in the research we have reviewed, will be a shift away from either-or thinking and toward understanding how different visual and spatial representations operate in different spatial thinking tasks, and how different representations and information sources are weighted and combined.

A related topic that will be important in future research is the role of strategies in visuospatial thinking. Spatial thinking tasks can often be accomplished in different ways. For example, you can find your way back to your car at the end of the day by following a well-learned route or by taking a shortcut based on a survey representation. People can solve chemistry and mechanics problems by mental simulation or by applying rules. More research is needed to examine the determinants of strategy choice in spatial thinking, which will probably include aspects of the situation and aspects of the individual (their expertise, native talents, etc.). A central question that this research will continue to address is the extent to which different methods of solving spatial problems are truly “strategic,” that is, under cognitive control, or determined by more hard-wired modular cognitive systems specialized for solving different spatial problems.

Although our review indicates that visuospatial thinking is pervasive and important in both everyday life and in many scientific disciplines, it is notable that visuospatial thinking is rarely explicitly taught. A recent National Research Council report (2006) claimed that spatial intelligence is “not just under-supported but underappreciated, undervalued, and therefore underinstructed” (p. 5) and called for a commitment to the development of spatial thinking across all areas of the school curriculum. There are important questions about the degree to which spatial thinking skills can be taught that are just beginning to be studied. For example, there is now evidence that mental rotation and aspects of spatial attention can be improved with practice (e.g., Kail, 1986; Wright, Thompson, Ganis, Newcombe, & Kosslyn, 2008) and even by experience playing video games (e.g., Feng, Spence, & Pratt, 2007; Green, Li, & Bavelier, 2010; Terlecki, Newcombe, & Little, 2008), that the effects of training can transfer to other spatial tasks (Green et al., 2010; Wright et al., 2008), and that the effects of training endure (Terlecki et al., 2008). But in training spatial thinking, what exactly should we instruct?

If we are to be most effective in fostering spatial thinking, we need to identify the basic components of this form of thinking so that training can be aimed at these fundamental components. To date, research on visuospatial thinking has been dominated by in-depth studies of a small number of paradigms such as mental rotation and reorientation in rectangular rooms. A final (or perhaps preliminary) goal we identify for future research on visuospatial cognition (or spatial

cognition more generally) is the development of a taxonomy of spatial thinking tasks that is grounded in an understanding of the different processes that make up visuospatial reasoning (see Wiener, Büchner, & Hölscher, 2009 for a preliminary taxonomy of wayfinding tasks). This will involve looking beyond the laboratory into the world to better characterize the spatial thinking challenges that people face in everyday life and in their professions, but also studying these under controlled conditions using virtual environment and brain imaging technologies as well as more traditional methods. With the new recognition of the importance of spatial thinking, this promises to be an important and exciting endeavor.

Acknowledgments

The preparation of this chapter was funded in part by grant DRL-1008650 from the National Science Foundation. We thank Rob Goldstone and Keith Holyoak for comments on an earlier version of the chapter.

Gesture in Thought

Susan Goldin-Meadow and Susan Wagner Cook

Abstract

The spontaneous gestures that speakers produce when they talk about a task reflect aspects of the speakers' knowledge about that task, aspects that are often not found in the speech that accompanies the gestures. But gesture can go beyond reflecting a speaker's current knowledge—it frequently presages the next steps the speaker will take in acquiring new knowledge, suggesting that gesture may play a role in cognitive change. To investigate this hypothesis, we explore the functions gesture serves with respect to both communication (the effects gesture has on listeners) and cognition (the effects gesture has on speakers themselves). We also explore the mechanisms that underlie the production of gesture, and we provide evidence that gesture has roots in speech, visuospatial thinking, and action. Gesturing is not merely hand waving, nor is it merely a window into the mind. It can affect how we think and reason and, as such, offers a useful tool to both learners and researchers.

Key Words: communication, embodied cognition, expert, learning, novice, speech, transitional knowledge, visuospatial thinking, working memory

Introduction

When people talk, they move their hands. These hand movements produced in conjunction with speech are called *gestures*. Like spoken language, gestures have the potential to reveal our thinking. But because gestures use a different representational format than speech does, they have the potential to reveal aspects of our thinking that are not evident in speech. Gesture thus offers a useful tool for learning about, and possibly changing, how we think.

We begin by situating gesture within the world of nonverbal behavior and highlighting why we think gesture, a nontraditional topic for a handbook on higher cognition, could contribute to our understanding of thinking and reasoning. We then take the first step in the argument that gesture plays a role in thinking by showing that gesture is not mere hand waving. It conveys substantive information

and, importantly, can reveal thoughts not found in the speech it accompanies. Gesture thus offers a unique window into the mind of the speaker. We then provide evidence that a speaker's spontaneous gestures often presage the next steps in the speaker's thinking and learning. Finally, we explore the purpose gesture serves (the functions of gesture) and the processes underlying its production (the mechanisms of gesture). We end with thoughts about how the study of gesture can continue to contribute to our understanding of the mind.

What Is Gesture?

In 1969, Ekman and Friesen outlined five categories of nonverbal behaviors produced during communication, thus framing the field of nonverbal communication. These behaviors vary according to where they are produced, how they relate to speech, and whether they are under conscious control.

Two behaviors—*emblems* and *illustrators*—are what people typically mean when they use the term *gesture*. Emblems are conventionalized movements of the hand that have word- or phrase-like meanings and can, in fact, substitute for words. Take, for example, the OK emblem (thumb and index finger touch and form a circle) or the thumbs-up emblem. Emblems share many properties with spoken words and with the signs in conventional sign languages of the deaf: They are consciously produced with the intent to communicate; they encode information arbitrarily; and they adhere to standards of well-formedness. Just as one can mispronounce a word or sign, it is possible to produce the wrong form of an emblem (imagine producing the OK emblem with the thumb and fourth finger—it just doesn't work). Because they are codified, emblems can stand on their own and, in fact, are often produced without speech.

In contrast, illustrators depend on speech for their meaning. Because they are always produced with speech, they take on the intentionality of speech. However, illustrators rarely come under conscious control, and they do not have a right or wrong form. Take, for example, a speaker who says that she ran upstairs while gesturing her trajectory with her hands; she can carve out her path using a pointing hand, an open palm, or any other hand shape. In general, illustrators convey information holistically and imaginatively and thus differ from speech, which conveys information componentially and categorically (Goldin-Meadow, 2003; McNeill, 1992). As a result, illustrators have the potential to reveal aspects of thinking not evident in speech. It is because illustrators are produced as part of an intentional communicative act, but are constructed at the moment of speaking, that they are of interest to us. They participate in communication, yet they are not part of a codified system.

We focus in this chapter on illustrators, called *gesticulation* by Kendon (1980) and plain old *gesture* by McNeill (1992), the term we use here. Thus, for the most part, we ignore emblems, as well as the three remaining nonverbal behaviors identified by Ekman and Friesen (1969): *Affect displays*, whose primary site is the face, convey the speaker's emotions, or at least those emotions that the speaker does not wish to mask (Ekman, Friesen, & Ellsworth, 1972). *Regulators*, which typically involve head movements or slight changes in body position, maintain the give and take between speaker and listener and help pace the exchange. *Self-adaptors*, which are fragments or reductions of previously learned adaptive hand movements,

are maintained by habit; for example, smoothing the hair, pushing glasses up the nose even when they are perfectly positioned, holding or rubbing the chin.

Gestures can mark the tempo of speech (beat gestures), point out referents of speech (deictic gestures), or exploit imagery to elaborate the contents of speech (iconic or metaphoric gestures). One question that is ripe for future research is whether these different types of gestures serve different functions and are served by different mechanisms. There is, in fact, evidence that beats and iconic/metaphoric gestures respond differently to the presence or absence of a listener (Alibali, Heath, & Myers, 2001), and that beat gestures are affected less by variation in the conceptual difficulty of speech than iconic or metaphoric gestures (Kita & Davies, 2009). Further research is needed to verify and explain these patterns. For now, we focus on deictic, iconic, and metaphoric gestures, as these are the gestures that have the potential to tell us the most about what a speaker is thinking.

Gesture Is Not Mindless Hand Waving and Often Reveals Thoughts Not Found in Speech

Gestures are interesting because they appear to provide a unique window onto thinking in that they reveal reliable information about a speaker's thoughts not evident in other behaviors. Accordingly, gesture can be a useful tool for exploring thinking and reasoning. As an example, gesture can reveal information about a speaker's prior motor experience that is not expressed in the accompanying speech. Cook and Tanenhaus (2009) asked adults to explain their solutions to the Tower of Hanoi problem after either solving the problem on the computer or solving it with real disks. The problem-solvers' verbal explanations were identical across the two groups (naïve observers could not distinguish the explanations produced by adults who had solved the problem on the computer from those produced by adults who had solved the problem using real disks). But their gestures differed. Adults who had solved the problem with real disks traced the trajectory of the disk with their hands (they mimed moving the disk up and over each peg). In contrast, adults who had solved the problem on the computer moved their hands laterally, mimicking the way the disks are moved on the screen (i.e., they do not have to be taken off the pegs before they are moved). The adults thus provided reliable cues about the problem-solving experiences they had had, cues that were not evident in their speech (Cook & Tanenhaus, 2009).

Gesture is not limited to displaying motor information and has been shown to reveal conceptual knowledge as well. Consider a child asked to participate in a series of Piagetian conservations tasks—the experimenter pours water from a tall, thin glass into a short, wide dish and asks the child whether the amount of water is still the same after the pouring. To succeed on this task and understand conservation of quantity, children need to integrate information across multiple dimensions—the height of the water in the container and its width. Nonconserving children focus on only one dimension, height or width, but not both. However, at times, a child will focus on one dimension in speech but provide evidence that he understands something about the importance of the second dimension in gesture. The child says that the amount of water is “different because this one is taller than that one,” thus focusing on the height of the water in speech. At the same time, he places a narrow C-shaped hand near the tall thin container, followed by a wider C-shaped hand near the short wide container, thus focusing on width in gesture—he displays knowledge of the second dimension *only* in his hands (Church & Goldin-Meadow, 1986). Note that children need to appreciate the compensatory relation between height and width in order to understand conservation of liquid quantity. Although this child appears to be firmly convinced that pouring the water alters its quantity, his hands reveal the first inkling that he may be ready to change his mind.

As a second example, gesture reveals knowledge that is relevant to understanding mathematical equivalence but is not evident in speech. The child is asked to solve problems like $3 + 4 + 6 = \underline{\quad} + 6$. To solve these problems correctly, children need to consider the relation between the two sides of the equation rather than simply adding up all of the numbers on the left side of the equation, or adding up all of the numbers in the problem (two common errors that children make when solving problems of this type). As in the conservation example, children sometimes produce gestures that reflect problem representations not expressed in the accompanying speech. For example, on the $3 + 4 + 6 = \underline{\quad} + 6$ problem, a child puts 19, an incorrect answer, in the blank and says, “I added the three, the four, the six, and the six to get nineteen” (an add-all-numbers strategy). At the same time, the child sweeps her left hand under the left side of the equation and then produces the same sweeping motion under the right side of the equation (an equalizer strategy), thus

displaying an awareness that the equation has two sides that should be treated alike (Alibali & Goldin-Meadow, 1993; Perry, Church, & Goldin-Meadow, 1988). Here again, the child displays an incorrect understanding of the problem in speech, but her hands reveal the first inkling that she may be ready to change her mind.

Gesture reveals aspects of children’s early cognitive development at a variety of ages and with respect to a variety of tasks. For example, toddlers reveal an understanding of one-to-one correspondence in the gestures they use in early counting before they display the same level of understanding in speech, and successful counting is associated with these gestural behaviors (Graham, 1999). Preschoolers (particularly boys) reveal an ability to mentally rotate shapes in their gestures not evident in their speech, and children whose gestures portrayed the spatial transformations were particularly successful at solving the mental transformation problems (Ehrlich, Levine, & Goldin-Meadow, 2006). Finally, early elementary school children solving balance problems reveal an understanding of the problems in their gestures that is not found in their speech (Pine, Lufkin, Kirk, & Messer, 2007), as do sixth grade children learning about plate tectonics (Singer, Radinsky, & Goldman, 2008) and preschool children learning to solve simple problems involving gears (Boncoddo, Dixon, & Kelley, 2010). Gesture can thus be used to make reliable inferences about children’s thinking across development.

Adults also reveal knowledge in their gestures that they do not display in their speech. For example, Alibali and colleagues (1999) asked adults first to describe algebra word problems about constant change, and then to indicate how they would go about solving the problems. The problems could be solved using either a discrete or continuous problem-solving strategy. Adults would often express one type of strategy in speech (e.g., continuous) while at the same time expressing the other type of strategy in gesture (discrete). Interestingly, speech and gesture taken together provided a more accurate picture of the strategy the adults planned to use to solve the problem than speech alone. Along the same lines, Garber and Goldin-Meadow (2002) found that speech and gesture taken together provided insight into the moments when adults (and children) were considering alternative routes in solving the Tower of Hanoi problem, moments that were not detectable from speech alone.

Finally, we see the same phenomenon in children at the early stages of language learning. For example,

when children begin to express causal relationships in speech, 3-year-olds use gesture to reinforce the goal of an action and 5-year-olds use gesture to add information about the instrument or direction of the action, information that is often not found in the accompanying speech; for example, producing an iconic *throw* gesture that adds information about the instrument to the utterance, “he broke the window” (Göksun, Hirsh-Pasek, & Golinkoff, 2010). As another example, when children begin to describe motion events in speech (e.g., “it went under there”), gesture is often used to reinforce or add information about manner, path, source, and endpoint. The type of information children choose to convey in gesture reflects not only their understanding of the event but also the linguistic framing of the particular language they are learning. For example, English allows speakers to combine manner and path within a single clause (“he rolls down”), and the gestures English speakers produce parallel this arrangement (the hand rolls as it moves down); in contrast, Turkish allows speakers to separate manner and path into separate clauses (the analog in English would be “he goes down by rolling”), and the gestures Turkish speakers produce reflect this structure (the hand rolls in place, followed by the hand moving down) (Özyürek, Kita, Allen, Furman, & Brown, 2005; Özyürek & Özçalışkan, 2000). Cross-linguistic studies of gesture can thus provide insight into how children come to describe events in the manner typical of their language.

Gestures Presage Next Steps in Thinking and Learning

Gestures not only reveal a person’s thinking at the time that they are produced, but they also forecast subsequent changes in thinking. Gesture has been found to reliably predict future thinking across a wide variety of domains. In fact, the data suggest that gesture is often a more useful predictor of subsequent thinking than the concurrent speech. We begin by examining gesture’s ability to foreshadow changes in child language learning.

Learning Language

Children’s early gestures have been shown to foreshadow their subsequent vocabulary development (Bavin et al., 2008; Goodwyn & Acredolo, 1993; Rowe & Goldin-Meadow, 2008, 2009; Rowe, Özçalışkan, & Goldin-Meadow, 2008). For example, a child’s early deictic gestures reliably predict which nouns are likely to enter that child’s

spoken vocabulary in the next 3 months (Iverson & Goldin-Meadow, 2005).

Early gesture not only predicts the particular words children are likely to learn but also when and how those words are combined with one another. A child’s early single-word utterances are often accompanied by gesture, and the relation between these early gestures and the speech they accompany reliably predicts when the child will produce her first two-word utterance. Children whose gestures overlap in meaning with the accompanying speech (e.g., pointing at a cup while saying “cup”) are likely to remain in the single-word stage for many months. In contrast, children whose gestures convey a different meaning from the accompanying speech (e.g., pointing at a cup while saying “mine”) are likely to begin combining words into two-word combinations within the next few months (Goldin-Meadow & Butcher, 2003; Iverson & Goldin-Meadow, 2005). In fact, the particular constructions expressed in gesture + speech combinations can be used to predict the emergence of the same constructions in speech later in development. For example, a child who conveys an action predicate plus an object argument in speech and gesture (e.g., “open” combined with a point at a box) is likely to produce an action predicate + object argument construction entirely in speech (“open box”) several months later (Özçalışkan & Goldin-Meadow, 2005).

Gesture continues to forecast children’s verbal milestones beyond the transition from one-word to two-word speech. For example, children produce their first complex sentence containing two predicates in gesture and speech (e.g., “I like it,” said while producing an *eat* gesture) several months before producing their first complex sentence entirely in speech (“I like eating it;” Özçalışkan & Goldin-Meadow, 2005). Interestingly, although children rely on gesture to produce the first instance of a construction (e.g., a predicate plus one argument, “give” + point at cookie), once the construction is established in their repertoire, children are no more likely to use gesture to flesh out the construction than they are to use speech. For example, they are just as likely to produce their first predicate plus three arguments entirely in speech (“*you see my butterfly on my wall*”) as they are to produce their first predicate plus three arguments in gesture and speech (“*Daddy clean all the bird poopie*” + point at *table*) (Özçalışkan & Goldin-Meadow, 2009). Gesture thus acts as a harbinger of linguistic steps only when those steps involve new constructions, not when the steps merely flesh out existing constructions.

As these findings suggest, gesture is not a global index of subsequent linguistic change but rather an indication of specific changes. Rowe and Goldin-Meadow (2009) observed 52 children interacting with their caregivers at home and found that gesture use at 18 months *selectively* predicted lexical versus syntactic skills at 42 months, even with early child speech controlled. Specifically, the number of different meanings children conveyed in gesture at 18 months predicted the size of their spoken vocabularies at 42 months, but the number of gesture + speech combinations did not. In contrast, the number of gesture + speech combinations, particularly those conveying sentence-like ideas, produced at 18 months predicted sentence complexity at 42 months, but meanings conveyed in gesture did not. Particular milestones in vocabulary and sentence complexity at age 3 1/2 years can thus be predicted from the way children moved their hands 2 years earlier.

Importantly, not only does gesture predict language development in typically developing children, but it also predicts subsequent language development in atypical populations. For example, some children who are late talkers will “catch up” to their typically developing peers, whereas others will continue to have persistent delays in language production. The interesting result is that early gesture can predict which children will catch up and which children will not (Thal, Tobias, & Morrison, 1991; Thal & Tobias, 1992); the children who caught up performed well on two gesture tasks: They could imitate object-related gestures produced by the experimenter (e.g., making a toy airplane fly), and they could reproduce a series of familiar, scripted actions modeled by an experimenter (e.g., feeding a teddy bear by putting him in a highchair, putting on his bib, feeding him an apple, and wiping his mouth). Gesture can also predict which children with early unilateral focal brain injury are likely to remain delayed with respect to vocabulary development, and which children are likely to move into the normal range. Children with brain injury who produced a repertoire of gestures at 18 months comparable to the repertoire of gestures produced by typically developing 18-month-old children were subsequently within the normal range of spoken vocabulary development at 22, 26, and 30 months. In contrast, children with brain injury whose gesture production at 18 months was outside of the typical range continued to show delays in vocabulary development at 22, 26, and 30 months (Sauer, Levine, & Goldin-Meadow, 2010). As a final example, early gesture

appears to be a more robust predictor of subsequent language development in children with autism than other social communication factors (Luyster, Kedlec, Carter, & Tager-Flusberg, 2008; see also Smith, Mirenda, & Zaidman-Zait, 2007). Gesture is thus an early marker that can be used to determine whether children whose language-learning trajectory has the potential to go astray will, in fact, experience delay. In this sense, gesture is a promising tool for diagnosing persistent delay.

Learning Other Cognitive Tasks

Children enter language learning hands first. But they continue to gesture even after having mastered the rudiments of language. At that point, children’s gestures begin to forecast changes in their thinking in other areas of cognitive development. One important experimental difference between the studies of gesture in learning language versus learning other cognitive tasks is that the language studies are all longitudinal observations of children in naturalistic settings. We see variability in the gestures children spontaneously produce at an early time point, and we use that variability to predict the onset of linguistic constructions at a later time point. We assume that the early gesture producers are ready to learn these linguistic constructions and need only more time or more input to do so.

In contrast, the studies of children learning other cognitive tasks tend to be short-term experimental manipulations. We again see variability in the gestures children spontaneously produce, this time with respect to a particular task, say, conservation of liquid quantity. But rather than wait for the children to experience additional input, we give the children instruction in the task and observe which children profit from that instruction. Recall the child described earlier who talked about the height of the water in speech but indicated its width in gesture. Although this child says that the amount of water is different when it is poured from one container to another (i.e., he is a nonconserver), his gestures indicate that he knows more about the task than his words indicate. And, indeed, when given instruction in conservation, this child is likely to make progress on the task—more likely than a child who focuses on the height of the water in both speech and gesture (Church & Goldin-Meadow, 1986).

As another example, consider the child described earlier who was asked how she arrived at her incorrect answer to a mathematical equivalence problem and produced an add-all-numbers strategy in speech while

at the same time producing an equalizer strategy in gesture. Here again, the child's gestures indicate that she knows more about mathematical equivalence than her words indicate. When given instruction in the problem, the child is likely to profit from that instruction and learn how to solve problems of this type correctly—more likely than a child who gives an add-all-numbers strategy in both speech and gesture (Perry, Church, & Goldin-Meadow, 1988). Moreover, when children's responses are charted during the course of instruction, we can see a child systematically progress through three periods characterized by the relation between gesture and speech—the child produces (1) the same strategy in both speech and gesture and that strategy is incorrect (e.g., add-all-numbers); (2) two different strategies, one in speech (e.g., add-all-numbers) and a different one in gesture (e.g., equalizer); (3) the same strategy in both speech and gesture but now the strategy is correct (e.g., equalizer) (Alibali & Goldin-Meadow, 1993). If, as in this case, only one of the modalities conveys a correct strategy, that correct strategy is often found in gesture rather than speech. Gesture, when taken in relation to speech, signals that the child is ready to take the next step in learning about mathematical equivalence. Interestingly, when a child fails to pass through step (2) and goes directly from step (1) to step (3), the child's understanding of mathematical equivalence is relatively fragile; in particular, the child is unable to generalize the knowledge gained during instruction and does not retain the knowledge on a follow-up test (Alibali & Goldin-Meadow, 1993).

We see this phenomenon on a variety of tasks and ages. For example, as described earlier, elementary school children asked to reason about balance often express new ideas about the task in gesture before expressing these same ideas in speech (Pine et al., 2007). When given instruction in the task, these children are the ones most likely to benefit from that instruction (Pine, Lufkin, & Messer, 2004). A similar effect has been found in adult learners asked to predict which way the last gear in a configuration of gears will turn (Perry & Elder, 1997) or asked to draw the stereoisomer of a molecule (Larson et al., 2010). In both cases, adults who display task-relevant information in their gestures not found in their speech are particularly likely to make progress on the task after getting instruction in the task.

It is clear that gesture offers a window onto thinking, and that the picture provided by gesture is often different from the view provided by speech. But why does gesture offer this privileged view? We

explore first the functions gesture serves and then the mechanisms underlying its production to better understand why and how gesture precedes and predicts our thinking and reasoning.

The Functions Gesture Serves: What Does Gesture Do? *Communication: The Impact of Gesture on the Listener*

We now know that speakers' gestures reveal their thoughts. Accordingly, one function that gesture could serve is to convey those thoughts to listeners. For gesture to serve this function, listeners must be able to extract information from the gestures they see. And, indeed, there is considerable evidence that listeners can use gesture as a source of information about the speaker's thinking (e.g., Graham & Argyle, 1975; McNeil, Alibali, & Evans, 2000).

The ability of listeners to glean information from a speaker's gestures can be seen most clearly when the gestures convey information that cannot be found anywhere in the speaker's words. Take, for example, the Cook and Tanenhaus (2009) Tower of Hanoi study described earlier in which speakers conveyed information about the trajectory a disk followed as it was moved from one peg to another—either an arced trajectory that went up and over the peg, or a lateral trajectory that ignored the peg. This information was *not* represented in the speakers' words. Listeners who saw the arced gestures were more likely to move the disk up and over the peg when they were later asked to solve the Tower of Hanoi problem on the computer (where it is not necessary to arc the disks to move them) than listeners who saw the lateral gestures (Cook & Tanenhaus, 2009). The listeners had not only read the action information off of the speakers' gestures, but that information had had an effect on their own subsequent actions.

Adults can also glean information from child speakers. When adult listeners are asked to describe the responses child speakers give on a conservation task, the adults frequently describe information that the children expressed *only* in gesture and not in speech (Goldin-Meadow & Momeni Sandhofer, 1999), making it clear that listeners can glean substantive information from speakers' gestures.

Perhaps the clearest example of this phenomenon is when the listener translates the information conveyed in the speaker's gestures into speech. Take, for example, a listener retelling a story in which the speaker said, "She whacks him one," while producing a punching gesture. The listener subsequently

redescribed this event as “She punches Sylvester out” (Cassell, McNeill, & McCullough, 1999); she had not only seen and interpreted the speaker’s punching gesture but also integrated the information into her speech (see also Goldin-Meadow, Kim, & Singer, 1999; Goldin-Meadow & Singer, 2003). Similarly, mothers of young language-learning children frequently respond to their children’s early gestures by translating them into speech (e.g., saying, “Yes, the bird is napping,” in response to a child’s point at a bird produced while saying “nap;” Goldin-Meadow, Goodrich, Sauer, & Iverson, 2007).

Not surprisingly, listeners increase their reliance on the speaker’s gestures in situations where speech is difficult to understand; for example, when there is noise in the speech signal (Holle, Obleser, Rueschemeyer, & Gunter, 2010; Rogers, 1978; Thompson & Massaro, 1986, 1994). Listeners are also particularly influenced by gesture when the spoken message is relatively complex (McNeil, Alibali, & Evans, 2000).

Gesture can even affect the information listeners glean from the accompanying speech. Listeners are faster to identify a speaker’s referent when speech is accompanied by gesture than when it is not (Silverman, Bennetto, Campana, & Tanenhaus, 2010). When processing speech that is accompanied by gesture conveying the same information, listeners are *more* likely to glean the message from speech than when processing speech accompanied by no gesture (Beattie & Shovelton, 1999, 2002; Graham & Argyle, 1975; McNeil et al., 2000; Thompson & Massaro, 1994). Conversely, when processing speech that is accompanied by gesture conveying different information, listeners are *less* likely to glean the message from speech than when processing speech accompanied by no gesture (Goldin-Meadow & Momeni Sandhofer, 1999; Kelly & Church, 1998; McNeil et al., 2000). In addition, more incongruent gestures lead to greater processing difficulty than congruent gestures (Kelly, Özyürek, & Maris, 2010). The effect that gesture has on listeners’ processing is thus linked to the meaning relation between gesture and speech. Moreover, listeners cannot ignore gesture even when given explicit instructions to do so (Kelly, Özyürek, & Maris, 2010; Langton, O’Malley, & Bruce, 1996), suggesting that the integration of gesture and speech is automatic.

Like adults, children are able to extract information from a speaker’s gestures, even when the information is not conveyed in the accompanying speech

(Kelly & Church, 1997). Very young children can use gesture as a source of information to support word learning (Booth, McGregor, & Rohlfing, 2008; McGregor, Rohlfing, Bean, & Marschner, 2008). By age 3 years, children are able to integrate information across speech and gesture (Kelly, 2001; Morford & Goldin-Meadow, 1992; Thompson & Massaro, 1986). However, the influence that gesture has on how speech is interpreted does appear to increase throughout childhood (Thompson & Massaro, 1986, 1994).

The fact that gesture can communicate information to listeners suggests that gesture might be particularly helpful in teaching and learning situations. Indeed, child listeners have been shown to learn more from a lesson that contains gesture than from a lesson that does not contain gesture (Church, Ayman-Nolley, & Mahootian, 2004; Valenzano, Alibali, & Klatzky, 2003), even when the gestures are not directed at objects in the immediate environment (Ping & Goldin-Meadow, 2008). Interestingly, even though communication often suffers when speakers produce gestures that convey different information from their speech (Goldin-Meadow & Momeni Sandhofer, 1999; Kelly & Church, 1998; McNeil et al., 2000), children learning mathematical equivalence seem to benefit most from instruction that contains one correct strategy in speech and a different correct strategy in gesture (Singer & Goldin-Meadow, 2005); that is, from instruction in which gesture conveys different information from speech. One possibility is that, in these instances, the additional information in gesture makes it more likely that one of the representations in the instruction matches the child’s next developmental state and, in this way, facilitates learning.

The process by which gesture affects the listener is currently being explored using a variety of brain imaging paradigms. Using functional magnetic resonance imaging (fMRI), researchers have found that gesture activates areas associated with language processing, including Broca’s area (Skipper, Goldin-Meadow, Nusbaum, & Small, 2007; Willems, Özyürek, & Hagoort, 2007). Gesture also appears to affect how processing is organized by influencing the connectivity among the relevant brain regions (Skipper, Goldin-Meadow, Nusbaum, & Small, 2007).

Using electroencephalography (EEG), a number of researchers have demonstrated that the relation between gesture and speech can modulate brain activity. Gestures that are semantically anomalous with respect to the accompanying speech are

associated with a more negative N400 waveform (Bernardis, Salillas, & Caramelli, 2008; Holle & Gunter, 2007; Kelly, Kravitz, & Hopkins, 2004; Özyürek Willems, Kita, & Hagoort, 2007; Wu & Coulson, 2005, 2007); the N400 is known to be sensitive to incongruent semantic information (Kutas & Hillyard, 1984). For example, gestures conveying information that is truly incongruent with the information conveyed in speech (gesturing *short* while saying “tall”) produce a large negativity at 400 ms (Kelly et al., 2004). Interestingly, gestures conveying information that is different from, but complementary to, information conveyed in speech (gesturing *thin* while saying “tall” to describe a tall, thin container) are processed no differently at this stage from gestures that convey the same information as speech (gesturing *tall* while saying “tall;” Kelly et al., 2004). Neither one produces a large negativity at 400 ms; that is, neither one is recognized as a semantic anomaly. It is important to note, however, that at early stages of sensory/phonological processing (P1-N1 and P2), speech accompanied by gestures conveying different but complementary information (e.g., gesturing *thin* while saying “tall”) is processed differently from speech accompanied by gestures conveying the same information (gesturing *tall* while saying “tall”). Thus, complementary differences between the modalities (i.e., the information conveyed in gesture is different from, but has the potential to be integrated with, the information conveyed in speech) are noted at early stages of processing, but not at later, higher level stages.

Gestures can affect the message listeners glean from speakers. Nonetheless, it is not clear that speakers *intend* their gestures to be communicative. Some gestures are meant to be communicative; for example, gestures that are referred to explicitly in the accompanying speech (“this one,” accompanied by a pointing gesture). However, it is not clear whether gestures that are not explicitly referenced in speech are intended to be communicative. One way to explore this issue is to vary whether speakers and listeners have visual access to one another. The question is whether speakers will gesture even when their listeners cannot see them and thus cannot acquire any information from those gestures. The answer is that speakers gesture less frequently when their listeners do not have visual access to gesture, particularly iconic gestures (Alibali et al., 2001; Cohen, 1977; Emmorey & Casey, 2001). However, speakers do not stop gesturing completely when their listeners cannot see them (Alibali et al., 2001;

Bavelas, Chovil, Lawrie, & Wade, 1992; Bavelas, Gerwing, Sutton, & Prevost, 2008; Cohen, 1977; Cohen & Harrison, 1973; Emmorey & Casey, 2001; Krauss, Dushay, Chen, & Rauscher, 1995; Rimé, 1982), suggesting that gesture may be produced for the benefit of the speaker as well as the listener. The next section explores the functions gesture can serve for the speaker.

Cognition: The Impact of Gesture on the Speaker

FACILITATING LEXICAL ACCESS

Gestures have long been argued to help speakers “find” words, that is, to facilitate lexical access (Rauscher, Krauss, & Chen, 1996). Consistent with this hypothesis, speakers are more likely to gesture when they are producing unrehearsed speech (Chawla & Krauss, 1994), when they are about to produce less predictable words (Beattie & Shovelton, 2000), and when lexical access is made more difficult (Rauscher, Krauss, & Chen, 1996). Temporally, gestures precede less familiar words to a greater degree than they precede more familiar words (Morrel-Samuels & Krauss, 1992). And brain-damaged patients with difficulties in lexical access (that is, patients with aphasia) gesture at a higher rate than patients with visuospatial deficits (Hadar, Burstein, Krauss, & Soroker, 1998). These findings suggest that gesture is associated with difficulties in lexical access. More direct evidence that gesture plays a role in lexical access comes from reports that speakers are more successful at resolving tip-of-the-tongue states when they are permitted to gesture than when they are not, for both adult (Frick-Horbury & Guttentag, 1998) and child (Pine, Bird, & Kirk, 2007) speakers (but see Beattie & Coughlan, 1999).

REDUCING DEMANDS ON CONCEPTUALIZATION

Speakers gesture more on problems that are conceptually difficult, even when lexical demands are equated (Alibali, Kita, & Young, 2000; Hostetter, Alibali, & Kita, 2007; Kita & Davies, 2009; Melinger & Kita, 2007). As an example, when adult speakers are asked to describe dot patterns, they gesture more when talking about patterns that do not have lines connecting the dots (patterns that are more difficult to conceptualize) than patterns that do have lines (Hostetter et al., 2007). As a second example, children who are asked to solve Piagetian conservation problems (problems that require conceptualization) gesture more than when they are

simply asked to describe the materials used in the conservation problems (Alibali et al., 2000).

Gesture may be particularly effective in reducing conceptual demands in visuospatial tasks, as gesture is a natural format for capturing spatial information. Gesture has, in fact, been found to facilitate visuospatial processing in speakers, either by maintaining visuospatial information in memory (Morsella & Krauss, 2004; Wesp, Hesse, Keutmann, & Wheaton, 2001) or by facilitating packaging of visuospatial information for spoken language (Kita, 2000). Gesture can also facilitate transformation of spatial information in memory; when performing mental rotation tasks, adults are particularly successful if they produce gestures (Chu & Kita, 2008; Schwartz & Black, 1999) or hand movements (Wexler, Kosslyn, & Berthoz, 1998; Wohlschlager & Wohlschlager, 1998) consistent with the actual rotation that is to be performed, or consistent with the movement that would activate the rotation (e.g., a pulling gesture that mimics pulling a string from a spool to make the spool turn; Schwartz & Holton, 2000).

Although these findings are consistent with the idea that gesturing reduces demands on conceptualization, the relevant studies manipulated conceptualization difficulty and observed the effects of the manipulation on gesturing, finding that conceptualization difficulty and gesturing go hand in hand. But to be certain that gesturing plays a role in reducing conceptualization demands (as opposed to merely reflecting those demands), future work will need to manipulate gesture and demonstrate that the manipulation reduces the demands on conceptualization.

REDUCING DEMANDS ON WORKING MEMORY

Gesturing has been shown to reduce demand on speakers' working memory. When asked to remember an unrelated list of items while explaining how they solved a math problem, speakers are able to maintain more items in verbal working memory (and thus recall more items) when they gesture during the explanation than when they do not gesture. This effect has been found in both children and adults (Goldin-Meadow, Nusbaum, Kelly, & Wagner, 2001). Interestingly, the effect has also been found for items in visual working memory (i.e., speakers maintain more items in visual working memory when they gesture during their explanations than when they do not gesture; Wagner, Nusbaum, & Goldin-Meadow, 2004), suggesting that gesturing lightens the load on working memory whether the

stored items are visual or verbal. In addition, gesturing reduces demand on working memory even when the gestures are not directed at visually present objects (Ping & Goldin-Meadow, 2010), suggesting that gesturing confers its benefits by more than simply tying abstract speech to objects directly visible in the environment.

Importantly, it is not just moving the hands that reduces demand on working memory—it is the fact that the moving hands convey meaning. Producing gestures that convey different information from speech reduces demand on working memory *less* than producing gestures that convey the same information in speakers who are experts on the task (Wagner et al., 2004). Interestingly, we find the opposite effect in speakers who are novices—producing gestures that convey different information from speech reduces demand on working memory *more* than producing gestures that convey the same information as speech (Ping & Goldin-Meadow, 2010). In both cases, however, it is the meaning relation that gesture holds to speech that determines, at least in part, the extent to which the load on working memory is reduced.

LINKING INTERNAL REPRESENTATIONS TO THE WORLD

Gesturing may help link the speaker's internal representations to the physical and communicative environment. Deictic gestures, in particular, may facilitate speakers' use of the surrounding space (Ballard, Hayhoe, Pook, & Rao, 1997). For example, for children learning to count, gesture seems to be important in coordinating number words with objects and in keeping track of which objects have already been counted (Saxe & Kaplan, 1981). Alibali and DiRusso (1999) explored gesture's role in children's counting by comparing three conditions: the child gestured while counting, the child was restricted from gesturing while counting, and the child watched a puppet gesture while the child counted. They found that children were most accurate when their counting was accompanied by gesture, theirs or the puppet's. But they were least likely to make errors coordinating number words and objects when the children themselves produced the gestures.

However, as mentioned earlier, gestures do not have to be directed at visible objects in order for speakers to benefit from gesturing. Ping and Goldin-Meadow (2010) measured demand on working memory in children asked to remember

an unrelated list of items while explaining their responses to a conservation task. Children were told to gesture on half the trials and not to gesture on the other half. One group gave their explanations with the task objects present; the other group gave their explanations with the task objects out of view. Children remembered more items, reflecting a reduced demand on working memory, when they gestured during their explanations than when they did not gesture, even when the objects were not visible. Gesturing does not need to be tied to the physical environment in order to be effective. Indeed, over the course of learning a task, gestures can become more and more removed from the immediate physical environment, eventually becoming internalized (Chu & Kita, 2008).

ACTIVATING OLD KNOWLEDGE AND BRINGING IN NEW KNOWLEDGE

Gesturing can activate knowledge that the speaker has but does not express. Broaders, Cook, Mitchell, and Goldin-Meadow (2007) asked children to explain how they solved six mathematical equivalence problems with no instructions about what to do with their hands. They then asked the children to solve a second set of comparable problems and divided the children into three groups: Some were told to move their hands as they explained their solutions to this second set of problems; some were told not to move their hands; and some were given no instructions about their hands. Children who were told to gesture on the second set of problems added strategies to their repertoires that they had not previously produced; children who were told not to gesture and children given no instructions at all did not. Most of the added strategies were produced in gesture and not in speech and, surprisingly, most were correct. In addition, when later given instruction in mathematical equivalence, it was the children who had been told to gesture, and who had added strategies to their repertoires, who subsequently profited from the instruction and learned how to solve the math problems. Being told to gesture thus encouraged children to express ideas that they had previously not expressed, which, in turn, led to learning.

But can gesture, on its own, create new ideas? To determine whether gesture can create new ideas, we need to teach speakers to move their hands in particular ways. If speakers can extract meaning from their hand movements, they should be sensitive to the particular movements they are taught to produce

and learn accordingly. Alternatively, all that may matter is that speakers move their hands. If so, they should learn regardless of which movements they produce. To investigate these alternatives, Goldin-Meadow, Cook, and Mitchell (2009) manipulated gesturing during a math lesson. They found that children required to produce *correct* gestures learned more than children required to produce *partially correct* gestures, who learned more than children required to produce *no* gestures. This effect was mediated by whether, after the lesson, the children added information to their spoken repertoire that they had conveyed only in their gestures during the lesson (and that the teacher had not conveyed at all). The findings suggest that gesture is involved not only in processing old ideas but also in creating new ones. We may be able to lay the foundations for new knowledge simply by telling learners how to move their hands (see Cook, Mitchell & Goldin-Meadow, 2008 for related findings) or by moving our hands ourselves (children who see their teachers gesture a concept are likely to gesture themselves and, in turn, are likely to learn the concept; Cook & Goldin-Meadow, 2006).

The Mechanism Underlying Gesture Production: Where Does Gesture Come From?

Gesture is not simply mindless hand waving. It offers a window onto speakers' thinking, affording access to information not available in the speakers' other behaviors. But gesture does more than simply externalize speakers' thinking. When speakers gesture, those gestures have an impact not only on their listeners but also on their own cognition. We next explore the mechanism that underlies gesture production.

Roots in Speech

Gestures are produced in conjunction with speech. One mechanism that could underlie the production of gesture is speech production; that is, the processes supporting speech production may naturally lead to gesture production.

It is clear that gesture and speech are inexorably linked. Congenitally blind speakers, who have never seen another person gesture, produce gestures when they speak, even when speaking to blind listeners (Iverson & Goldin-Meadow, 1997, 1998). Prior to speaking, children produce rhythmic hand movements in conjunction with their vocal babbling (Masataka, 2001). Although gestures are sometimes

produced without accompanying speech, the vast majority of gestures are produced while speaking (McNeill, 1992), suggesting that speech and gesture production may share a single mechanism. Moreover, even when speakers do not produce overt gestures, recalling concrete and spatial words from definitions is associated with changes in muscle potentials in the arms (Morsella & Krauss, 2005). More generally, speaking is associated with increases in corticospi-
nal excitability of hand motor areas (Meister et al., 2003; Seyal, Mull, Bhullar, Ahmad, & Gage, 1999; Tokimura, Tokimura, Oliviero, Asakura, & Rothwell, 1996). Listening to speech has also been associated with activity in the hand motor cortex (Flöel, Ellger, Breitenstein, & Knecht, 2003). Production of speech and production of hand movements are thus tightly linked to one another, at both the behavioral and the neural level.

Gesture is linked to spoken language at every level of analysis, including the phonological level, lexical level, syntactic level, prosodic level, and conceptual level (as discussed earlier in the section on “The Functions Gesture Serves”). At the phonological level, producing hand gestures influences the voice spectra of the accompanying speech for deictic gestures (Chieffi, Secchi, & Gentilucci, 2009), emblem gestures (Barbieri, Buonocore, Dalla Volta, & Gentilucci, 2009; Bernardis & Gentilucci, 2006), and beat gestures (Krahmer & Swerts, 2007). When phonological production breaks down, as in stuttering or aphasia, gesture production stops as well (Mayberry & Jacques, 2000; McNeill, Levy, & Pedelty, 1990). There are phonological costs to producing gestures with speech—producing words and deictic gestures together leads to long initiation times for the accompanying speech, relative to producing speech alone (Feyereisen, 1997; Levelt, Richardson, & Laheij, 1985). Viewing gesture also affects voicing in listeners’ vocal responses to audio-visual stimuli (Bernardis & Gentilucci, 2006).

At the lexical level, as discussed earlier, gesturing increases when the speaker is searching for a word. More generally, gestures both reflect, and compensate for, gaps in a speaker’s verbal lexicon. Gestures can package information in the same way that information is packaged in the lexicon of the speaker’s language. For example, when speakers of English, Japanese, and Turkish are asked to describe a scene in which an animated figure swings on a rope, English speakers overwhelmingly use the verb “swing” along with an arced gesture (Kita & Özyürek, 2003). In contrast, speakers of Japanese

and Turkish, languages that do not have single verbs that express an arced trajectory, use generic motion verbs along with the comparable gesture; that is, a straight gesture (Kita & Özyürek, 2003). But gesture can also compensate for gaps in the speaker’s lexicon by conveying information that is not encoded in the accompanying speech. For example, complex shapes that are difficult to describe in speech can be conveyed in gesture (Emmorey & Casey, 2001).

At the syntactic level, as described earlier, gestures are influenced by the structural properties of the accompanying speech. For example, English expresses manner and path within the same clause, whereas Turkish expresses the two in separate clauses. The gestures that accompany manner and path constructions in these two languages display a parallel structure—English speakers produce a single gesture combining manner and path (a rolling movement produced while moving the hand forward), whereas Turkish speakers produce two separate gestures (a rolling movement produced in place, followed by a moving forward movement) (Kita & Özyürek, 2003; Kita et al., 2007). Gesture production also reflects the amount of information encoded in a syntactic structure. Speakers gesture more when producing an unexpected (and, in this sense, more informative) syntactic structure than when producing an expected structure (Cook, Jaeger, & Tanenhaus, 2009).

At the prosodic level, the movement phase of a speaker’s gesture co-occurs with the point of peak prosodic emphasis in the accompanying clause in speech (Kendon, 1980; McClave, 1998). And listeners make inferences about the perceived prominence of words in an utterance from the speaker’s gestures (Krahmer & Swerts, 2007).

Gestures have also been linked to the conceptualization process involved in speaking, that is, the process by which speakers determine which information to linguistically encode in an utterance. Support for this hypothesis comes from studies showing that difficulty, or greater ambiguity about what to say, is associated with increases in gesture production (Alibali et al., 2000; Hostetter, Alibali, & Kita, 2007; Kita & Davies, 2009; Melinger & Kita, 2007). However, not all studies find that increases in conceptualization difficulty are associated with increases in gesture rate (Sassenberg & van der Meer, 2010).

An explanation on the evolutionary timespan for the close relationship between gesture and speech is that spoken language may have evolved from

more primitive gestural communication systems (Corballis, 1992; Fitch, 2000; Holden, 2004). If so, modern-day gestures that are produced in conjunction with speech may represent vestigial activity of a prior system for communication. Gesture may continue to contribute functionally to spoken communication, as the findings in the previous section suggest, or may simply reflect the underlying organization of the system without being functionally involved in spoken language production.

Roots in Visuospatial Thinking

Gestures could also emerge from visuospatial thinking. Consistent with this hypothesis, speakers are likely to gesture when talking about things that are spatial or imageable (Alibali et al., 2001; Beattie & Shovelton, 2002; Krauss, 1998; Lavergne & Kimura, 1987; Rauscher et al., 1996; Sousa-Poza, Rohrberg, & Mercure, 1979) and when conveying information that has been acquired visually (as opposed to verbally, Hostetter & Hopkins, 2002). In addition, when speakers are restricted from gesturing, the spatial (Graham & Heywood, 1975) and/or imagistic (Rime, Schiaratura, Hupet, & Ghysselinckx, 1984) content of the accompanying speech changes. Finally, brain-damaged patients with visuospatial deficits gesture less than comparable patients with lexical access deficits (Hadar et al., 1998).

In a striking example of the link between visuospatial representation and gesture production, Haviland (1993) described how a speaker of Guugu Yimithirr, an Australian language that uses an absolute rather than a relative reference frame to represent direction, adjusted his gesture production across two tellings of the same story so that his gestures were true to the actual spatial layout of the original event (i.e., his gestures were also absolute rather than relative). The speaker, describing how a boat overturned many years ago, produced a rolling motion away from his body when facing west since the boat had actually rolled from east to west. However, when telling the story on another occasion, he happened to be facing north rather than west. In this retelling, he produced the same rolling-over gesture, but this time his hands rolled from right to left rather than away from his body. The gesture was accurate with respect to the actual event (an east-to-west roll). Importantly, the speaker did not refer to the absolute spatial context of the original event in his speech.

Gestures are particularly likely to represent visuospatial thinking that involves transformations.

For example, gestures frequently represent orientations and rotations of block locations (Emmorey & Casey, 2001), spatial transformations (Trafton et al., 2006), and component motions of entities in physics problems (Hegarty, Mayer, Kriz, & Keehner, 2005; see Hegarty & Stull, Chapter 31).

In addition to representing spatial information directly, gestures may also reflect metaphoric use of visuospatial representations. Speakers use a wide variety of spatial metaphors when representing nonspatial concepts, including time (Alverson, 1994; Clark, 1973), mathematics (Lakoff & Nunéz, 2000), and emotions (Lakoff & Johnson, 1999). Moreover, these metaphoric representations are not simply linguistic conventions but can have an effect on information processing. For example, people's judgments about the meaning of a temporal expression like "the meeting has been moved forward 2 days" depends on how they envision themselves moving through space (Boroditsky & Ramscar, 2002). Gestures that are produced when talking about time are consistent with the underlying metaphoric mapping between space and time in the speaker's language (e.g., English speakers gesture in front of themselves when talking about the future, whereas speakers of Aymara gesture to their backs; Núñez & Sweetser, 2006). Producing appropriate hand movements can also facilitate comprehension of metaphoric expressions like "push the argument" (Wilson & Gibbs, 2007). Thus, gestures may reflect and engage visuospatial thinking when it is used metaphorically as well as when it is used literally.

Roots in Action

Hostetter and Alibali (2008) have proposed that gestures emerge from perceptual and motor simulations underlying the speaker's thoughts (see also Rimè & Schiaratura, 1991). This proposal is based on recent theories claiming that linguistic meaning is grounded in perceptual and action experiences (Barsalou, 1999; Glenberg & Kaschak, 2002; Richardson, Spivey, Barsalou, & McRae, 2003; Zwaan, Stanfield, & Yaxley, 2002). If so, gesture could be a natural outgrowth of the perceptual-motor experiences that underlie language. Under this view, the richer the simulations of the experiences, the more speech will be accompanied by gesture.

Support for the hypothesis that gestures emerge out of motor processes comes from a study conducted by Feyereisen and Havard (1999) who explored whether certain types of imagery, including motor imagery, are likely to lead to gesture. Speakers

were asked to describe motor activities (e.g., changing a tire, wrapping a present), visual scenes (e.g., rooms, landscapes), or abstract topics (e.g., women in politics, the death penalty). Motor imagery frequently resulted in iconic gestures, whereas abstract topics led to beat gestures. However, the weakness of the study is that topic and type of imagery were confounded. The action words generated to describe the topic, rather than motor imagery, might therefore have led to the frequent iconic gestures.

The study conducted by Cook and Tanenhaus (2009) that was described in an earlier section also explored the relation between motor imagery and gesture. In this study, speakers who performed the Tower of Hanoi task with real disks gestured differently from speakers who performed the task on the computer, even though their verbal descriptions were identical. The speakers who solved the problem with real disks produced gestures that simulated the actions they used to move the disks (i.e., they lifted the disk up and over the peg), suggesting that gestures can reflect motor representations. As another example, speakers gesture more when describing dot patterns that they constructed with wooden pieces than dot patterns that they viewed on a computer screen (Hostetter & Alibali, 2010).

But gestures do not merely reflect the action simulations that underlie the speaker's thinking; they can also influence which action components become part of the speaker's mental representation. Beilock and Goldin-Meadow (2010) asked adults to first solve the Tower of Hanoi problem with real, weighted disks (TOH1). The smallest disk in the tower was the lightest and could be lifted with one hand; the biggest was so heavy that it required two hands. The adults were then asked to explain how they solved the problem, gesturing while doing so. After the explanation, they solved the problem a second time (TOH2). For some problem solvers (*No-Switch Group*), the disks in TOH2 were identical to TOH1, and they, not surprisingly, improved on the task (they solved TOH2 in fewer moves and in less time than TOH1). For others (*Switch Group*), the disk weights in TOH2 were reversed—the smallest disk was now the heaviest and could no longer be lifted with one hand. This group did not improve and, in fact, took more moves and more time to solve the problem on TOH2 than TOH1. Importantly, however, the performance on the *Switch group* on TOH2 could be traced back to the gestures they produced during the explanation task: The more they used one-handed gestures when talking about

moving the smallest disk during the explanation, the worse they did on TOH2 (remember that the smallest disk on TOH2 in the *Switch group* could no longer be lifted with one hand). There was no relation between the type of gesture used during the explanation and performance on TOH2 in the *No-Switch group* simply because the smallest disk on TOH2 could be lifted using either one or two hands.

Beilock and Goldin-Meadow (2010) suggested that the one-handed gestures speakers produced during the explanation task helped to consolidate a representation of the smallest disk as "light." This representation was incompatible with the action that had to be performed on TOH2 in the *Switch group* but not in the *No-Switch group*. If gesturing is responsible for the decrement in performance in the *Switch group*, removing gesturing should eliminate the decrement—which is precisely what happened. In a second experiment that eliminated the explanation phase and thus eliminated gesturing entirely, the *Switch group* displayed no decrement in performance and, in fact, improved as much as the *No-Switch group* (Beilock & Goldin-Meadow, 2010). Thus, the switch in disks led to difficulties on TOH2 only when the adults gestured in between the two problem-solving attempts, and only when those gestures conveyed information that was incompatible with the speaker's next moves.

Note that disk weight is not a relevant factor in solving the Tower of Hanoi problem. Thus, when the speakers explained how they solved TOH1, they never talked about the weight of the disks or the number of hands they used to move the disks. However, it is difficult not to represent disk weight when gesturing—using a one-handed versus a two-handed gesture implicitly captures the weight of the disk, and this gesture choice had a clear effect on TOH2 performance. Moreover, the number of hands that the *Switch group* actually used when acting on the smallest disk in TOH1 did not predict performance on TOH2; only the number of one-handed gestures predicted performance. The findings suggest that gesture is adding action information to the speakers' mental representation of the task, rather than merely reflecting their previous actions. Gesturing about an action can thus solidify in mental representation the particular components of the action reflected in the gesture.

Conclusions and Future Directions

We know that the gestures speakers spontaneously produce along with their talk reflect their thoughts,

and that those thoughts are often not expressed in the talk itself. Moreover, evidence is mounting that gesture not only reflects thought but also plays a role in changing thought. The next frontier is to figure out *how* gesture influences thinking.

We have seen that gesture serves a range of functions for both listeners (communicative functions) and speakers (cognitive functions). One question for future research is how these functions work together. For example, gesturing reduces demands on the speaker's working memory, and it can also introduce new information into the speaker's mental representations. Are these two functions synergistic? Recall that producing gestures that convey different information from speech is particularly effective in lightening demands on the novice's working memory. Moreover, seeing gestures that convey different information from speech is highly effective in teaching the novice new information. The parallel hints at a potential relation between the two functions and warrants additional study.

Another important question is whether the processes that are responsible for the effect gesture has on learning are unique to gesture. Gesture may be special only in the sense that it makes efficient use of ordinary learning processes; for example, cues may be more distinctive when presented in two modalities than in one, and speech and gesture may simply be an effective way of presenting information multimodally. On the other hand, it is possible that traditional principles of learning and memory (e.g., distinctiveness, elaboration, cue validity, cue salience, etc.) will, in the end, not be adequate to account for the impact that gesture has on learning; in this event, it will be necessary to search for processes that are specific to gesture.

We have also seen that gesture is served by a range of mechanisms and has roots in speech, visuospatial thinking, and action. Again, the question is how these processes work together. If current theories are correct that speech has an action base (Barsalou, 1999; Glenberg & Kaschak, 2002; Richardson et al., 2003; Zwaan et al., 2002), gesture may be a natural reflection of this foundation. We can then ask whether action holds a privileged position not only in gesture production but also in gesture's effect on thinking. For example, do gestures that closely resemble action (e.g., simulating the movement of the hands as they lift the disks in the Tower of Hanoi task) have a more powerful effect on the mental representations of the speaker than gestures that incorporate some, but not all, aspects of the

action (e.g., tracing the trajectory of the disks as they are lifted, but including no information about how the hand was shaped as it moved the disk) or than gestures that are only abstractly related to action (i.e., metaphoric gestures)?

Another question for future research is whether gesture and action affect mental representations in the same way. Although gesturing is based in action, it is not a literal replay of the movements involved in action. Thus, it is conceivable that gesture could have a different impact on thought than action itself. Arguably, gesture should have less impact than action, precisely because gesture is "less" than action; that is, it is only a representation, not a literal recreation, of action. Alternatively, this "once-removed-from-action" aspect of gesture could have a more, not less, powerful impact on thought (see, for example, Goldin-Meadow & Beilock, 2010).

Finally, we can ask whether visuospatial thinking is privileged with respect to gesture. Gesture is an ideal medium for capturing spatial information, which leads to an important question about the mechanism that underlies gesture. Do domains that are inherently spatial (e.g., reasoning about the configuration of objects, as in organic chemistry) lend themselves to gesture more than nonspatial domains (e.g., reasoning about moral dilemmas)? Gesture's affinity with space also leads to questions about gesture's function. Does gesture affect cognitive processes more in spatial domains than in nonspatial domains? Is gesture effective in changing thinking because it can "spatialize" any domain (e.g., producing spatial gestures along with a description of a moral dilemma introduces spatial elements into the problem space and, in this way, allows spatial mechanisms to be brought to bear on the problem)?

The hope is that future work will allow us to build a model of exactly how speech and gesture emerge, both over ontogeny and in the moment during processing. In development, there is considerable evidence that early thoughts are often expressed in gesture prior to being expressed in speech, and that expressing those thoughts in gesture facilitates expressing them in speech. However, it is less clear whether gesture and speech have a similar relation during processing in the moment. Gestures often onset before the words they represent during production (McNeill, 1992) and, in fact, there is a precise relation in the timing of gesture to word—the more familiar the word, the smaller the gap between onset of gesture and onset of word (Morrel-Samuels & Krauss, 1992). But this timing relation need not reflect

the process by which thoughts are translated into gesture and speech. It is possible that some thoughts can be accessed by gesture before being accessed by speech (thoughts that are less amenable to speech and perhaps privileged in gesture). It is also possible that some thoughts are accessed by gesture only after they have been packaged into a spoken representation, although the results we have reviewed here demonstrating a direct link between gesture and thinking may make this second possibility less plausible.

In sum, the spontaneous gestures we produce when we talk are not mindless hand waving. They not only reflect our thoughts, but they also have the potential to change the thoughts of others (our listeners) and even to change our own thoughts (as speakers). Gesture thus offers a tool that allows both learners and researchers to make new discoveries about the mind.

Impact of Aging on Thinking

Shannon McGillivray, Michael C. Friedman, and Alan D. Castel

Abstract

This chapter discusses the impact of aging on judgment and decision making, problem solving, reasoning, induction, memory, and metacognition, as well as the influence of expertise, training, and wisdom. In addition, the chapter presents theories of cognitive aging and addresses the ways in which changing goals (such as emotional goals) in old age can alter the processes and outcomes associated with cognitive operations. There is a wealth of research documenting age-related cognitive declines and impairments in areas such as decision making, reasoning, problem solving, category learning, and memory. However, in addition to addressing the potential difficulties older adults may experience when performing demanding cognitive operations, this chapter also examines certain situations and variables that have been shown to lessen or ameliorate age-related differences in performance. Lastly, the impact of training, expertise, and wisdom are discussed as they relate to successful cognitive aging.

Key Words: aging, cognitive aging, decision making, memory, metacognition, problem solving, reasoning, inductive learning, training, expertise, wisdom

As an increasingly large proportion of the population falls into the category of “senior citizen,” it is vital to understand and explore how aging impacts cognitive functioning. Even during normal, non-pathological aging (which is the exclusive focus of this chapter) there is a large amount of evidence that older adulthood is associated with a decline in certain cognitive abilities, some of which are summarized in Figure 33.1 (McCabe et al., 2010; see also Craik & Salthouse, 2008). As Figure 33.1 illustrates, there are substantial declines in working memory capacity, episodic memory, executive functioning, as well as the speed at which information is processed. However, as Figure 33.1 also shows, aging does not negatively impact all functions to the same degree, if at all; and there is growing evidence that potential age-related deficits are moderated by other important factors such as goals, motivation, and prior knowledge (e.g., Zacks & Hasher, 2006). The

current chapter will first discuss some of the major theories regarding age-related cognitive changes, as well as theories that address important changes during life-span development, more generally. This chapter will then review some classic as well as more recent findings within the areas of judgment and decision making, problem solving, reasoning, inductive learning, memory, and metacognition in older adults. In addition, the roles of emotion, expertise, training, and wisdom will be discussed as they relate to various aspects of cognition.

Cognitive Aging Theories

A number of theories have been proposed to explain why cognitive capabilities are so susceptible to the effects of aging. These theories focus on possible mechanisms driving age-related changes, and they highlight situations in which older adults are more or less likely to experience difficulties.

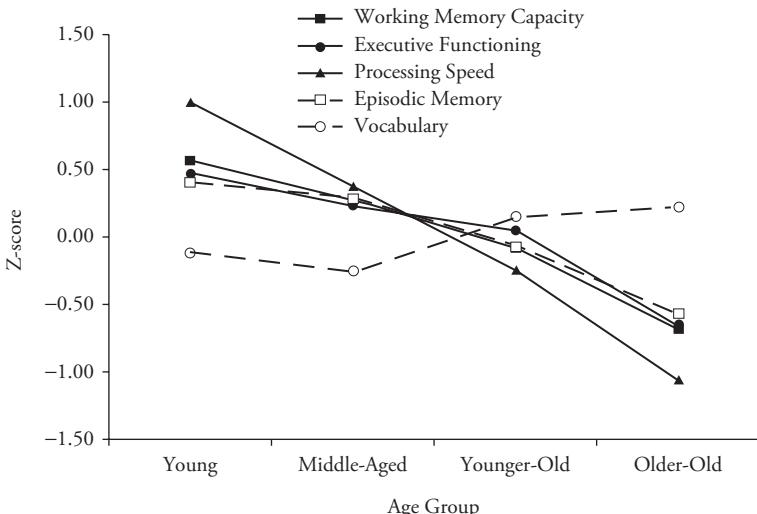

Fig. 33.1 Age-related differences in performance within various cognitive domains. The figure shows that aging is associated with declines in working memory capacity, executive functioning, processing speed, episodic memory, but an increase in vocabulary knowledge. (From McCabe, Roediger, McDaniel, Balota, & Hambrick, 2010. Copyright © 2010 by the American Psychological Association. Reproduced with permission.)

Although certainly not an exhaustive review of existing theories, this section discusses those that have received wide support within the cognitive aging literature: the general slowing theory, the reduced resources theory, the inhibition deficit theory, prefrontal theories, as well as the selective optimization with compensation theory and the socioemotional selectivity theory (both of which are more general theories of life-span development).

General Slowing Theory

The general slowing theory posits that a reduction in the speed with which cognitive processes operate occurs during aging (see Fig. 33.1, which shows a steep decline in processing speed), and this reduction in processing speed accounts for the majority of age-related variance on a variety of cognitive tasks (Henninger, Madden, & Huettel, 2010; Salthouse, 2000). For example, there is evidence that measures of speed share upward of 50%–75% of the age-related variance on numerous cognitive tasks (Salthouse, 1996). Salthouse (1996) suggests that there are two mechanisms responsible for the relationship between speed and cognition: limited time and simultaneity. Limited time plays an important role in that the time needed to perform later cognitive operations can become restricted when large portions of available time are taxed with earlier operations. Simultaneity refers to the idea that outputs of earlier cognitive processes may be

lost by the time that later processing is completed (as can occur when there are multiple demands on working memory), thus potentially creating situations in which relevant information is no longer available when it is actually needed.

Reduced Resources Theory

The reduced resource theory is similar to the general slowing theory, in that they both assert that a general change in specific cognitive abilities can account for large age-related changes in cognition. However, rather than positing a reduction in speed of processing, the reduced resources theory proposes that aging reduces the availability and/or the ability to successfully allocate attentional resources necessary for efficient performance on cognitive tasks (Craik & Byrd, 1982). For example, when older adults are placed under divided attention (which reduces the amount of attention available for other tasks), there is a larger detrimental impact on performance compared with younger adults also under divided attention (Anderson, Craik, & Naveh-Benjamin, 1998; Park, Smith, Dudley, & Lafronza, 1989). The reduction in available attentional resources can make it difficult for older adults to engage in more cognitively demanding operations, such as elaborative encoding during memory operations, which is considered necessary for effective consolidation and retrieval of to-be-remembered information (Craik & Salthouse, 2008).

Inhibition Deficit Theory

While there is evidence for age-related general cognitive slowing and a reduction in resources such as attention (which limit the amount of information one can process), other theories have proposed that older adults' troubles stem from the processing of too much (irrelevant) information. Hasher and colleagues (Darowski, Helder, Zacks, Hasher, & Hambrick, 2008; Hasher & Zacks, 1988; Lustig, Hasher, & Zacks, 2007) have suggested that older adults may suffer disproportionately from deficits in inhibitory processes (inhibition deficit theory), and this, in turn, can lead to poorer performance on cognitive tasks. An efficient system requires control and inhibition of irrelevant information in order to function properly, and thus it requires working memory and attention. Older adults in particular may have difficulty suppressing inappropriate or irrelevant responses, controlling the focus of attention, and keeping irrelevant information out of working memory and the focus of attention. As Figure 33.2 depicts, inefficient inhibition, therefore, can lead to information unrelated to the "goal path" entering working memory, resulting in a disruption of task operations. These non-goal path thoughts can involve irrelevant environmental details, personal memories and concerns, and interpretations that are inconsistent with current goals. Furthermore, decreased inhibitory functions can reduce the ability to switch attention from one target to another, and it can lead to misinterpretation of information, inappropriate responses, and also forgetting.

Prefrontal Theories

From a more neurological perspective, there is evidence that the prefrontal regions of the brain, which are responsible for many higher order cognitive operations (see Morrison & Knowlton, Chapter 6), are particularly susceptible to age-associated atrophic

changes (Cabeza, 2001; Raz et al., 1997). Such specific, age-related changes in the prefrontal cortex likely contribute to cognitive decline in older adults (West, 1996). In particular, performance on tasks reliant on dorsolateral prefrontal function (e.g., executive functioning and working memory) seem to be the most negatively affected during the normal aging process, whereas tasks associated with ventromedial prefrontal areas (e.g., social behavior regulation and emotion) are less affected (MacPherson, Phillips, & Della Sala, 2002). Furthermore, it has been suggested that it is the compromised integrity of not only the dorsolateral prefrontal regions but the dopamine projections to the prefrontal cortex that contribute to age-related cognitive declines (Braver & Barch, 2002). For example, there is evidence that dopamine and dorsolateral dysfunction contribute largely to older adults' deficits on tasks in which cognitive control is necessary, such as efficient inhibitory control, working memory, and attention (Braver & Barch, 2002).

Selective Optimization With Compensation Theory

In addition to theories that focus on the mechanisms driving declines in cognitive function during aging, there are also theories that explore the contributing factors to successful cognitive aging. Selective optimization with compensation (SOC; Baltes & Baltes, 1990) asserts that successful aging is related to a focused and goal-directed investment of limited resources into areas that yield optimal returns. Thus, older adults can selectively choose certain options in order to maximize performance based on their goals, compensating for impairments by optimizing performance in these specific, goal-related domains (see also Riediger, Li, & Lindenberger, 2006, for the adaptive nature of SOC). As the SOC theory suggests, older adults are able to successfully allocate limited resources when appropriate motivation (such

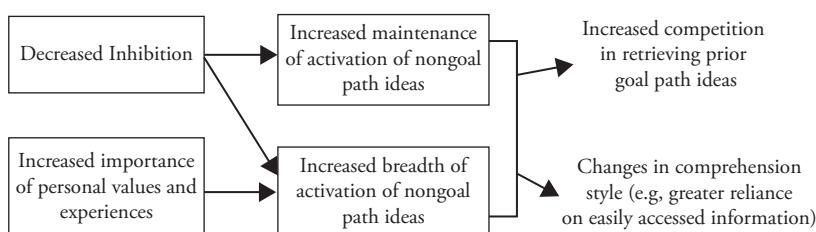

Fig. 33.2 Theoretical framework depicting the consequences of reduced inhibitory control as well as changing goals. (Adapted from *Psychology of Learning and Motivation*, Vol. 22, Hasher & Zacks, "Working Memory, Comprehension, and Aging: A Review and a New View," p. 213, Copyright 1988, with permission from Elsevier.)

as personal relevance and accountability) is present, enhancing performance (Germain & Hess, 2007; Hess, Rosenberg, & Waters, 2001). Furthermore, Heckhausen (1999; Heckhausen & Schulz, 1995) suggests that individuals have to take on the regulation of losses in aging-related resource in order to function efficiently, and if successful, such regulation can aid efficient cognitive function.

Socioemotional Selectivity Theory

Lastly, although not a theory of cognitive aging per se, the socioemotional selectivity theory (SST; Carstensen, 1992; 1995) highlights the importance of changing goals and motivations during aging. The SST asserts that people have some sort of awareness of the time left in life, and when time is seen as open ended (as it may be for young, healthy adults), goals and motivations are focused on acquiring information, experiencing novelty, and expanding one's knowledge. When time is seen as more limited (as may be the case for older adults), motivation and goals focus more on monitoring the environment in order to optimize emotional meaningfulness and emotional functioning. Depictions of the trajectories of these changing motivations are displayed in Figure 33.3, which show that in middle-to-older adulthood social motives shift from being more knowledge driven to more emotionally driven. Evidence supporting this theory has shown that older adults are better than younger adults at regulating emotions (Carstensen, Pasupathi, Mayr, & Nesselroade, 2000), prefer to spend time with more emotionally meaningful (compared to novel) social partners (Fredrickson & Carstensen, 1990), and are more likely to remember information emphasizing emotional relative to novelty-seeking information (Fung, Carstensen, & Lutz, 1999). Thus, while this framework is not a specific theory of cognitive aging, it has implications for the approach that older adults may take toward decision making, problem solving,

remembering information, and achieving emotional goals.

Summary

The purpose of this brief and selective review of theories regarding cognitive aging was to bring to the fore some of the possible mechanisms driving age-related changes in cognition. As was discussed, older adults may experience difficulties on cognitive tasks due to decreases in the speed (and thus efficiency) with which cognitive processes operate, decreases in the availability of attentional resources and/or in the ability to effectively allocate attention, and decreased ability to successfully inhibit irrelevant and intrusive competing information. Furthermore, age-related cerebral atrophy occurs at disproportionately higher rates within regions of the frontal lobe, an area that is largely responsible for many of the higher order cognitive operations. At the same time, life-span theories of aging suggest that older adults may approach tasks and situations in a qualitatively different manner than younger adults (e.g., older adults may have different goals) and, at times, can selectively allocate resources in order to compensate for deficiencies in cognitive abilities. It is important to consider these theories, and other potential frameworks, as we now review and discuss the effects of age within specific areas of cognition.

Judgment and Decision Making

As individuals age they are faced with a number of life changes and often need to make important decisions involving aspects such as medical care and retirement, in addition to the everyday decisions faced by most individuals. Thus, an understanding of judgment and decision-making abilities in older adults is of paramount importance. Research has suggested that the decision-making ability of older adults in everyday life may be compromised

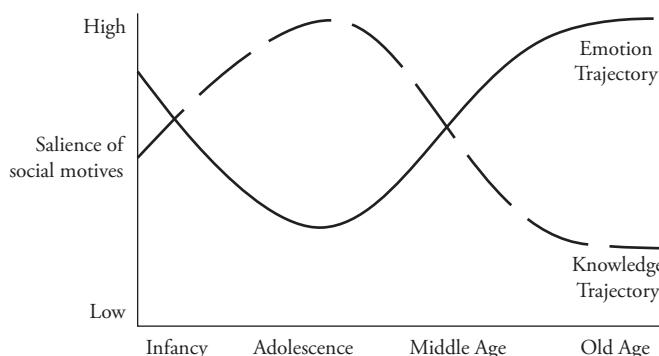

Fig. 33.3 Idealized depiction of changes in two social motives across the life span as predicted by the socioemotional selectivity theory. (Adapted from Carstensen, Gross, & Fung. Copyright 1997 by Springer Publishing Company Inc. Reproduced with permission of Springer Publishing Company, Inc.)

relative to younger and middle-aged adults (Peters, Finucane, MacGregor, & Slovic, 2000; Thornton & Dumke, 2005). In particular, older adults may make more comprehension errors and display less consistency in their preferences (Finucane et al., 2002), and they may exhibit poorer decision-making abilities when the task requires more cognitively demanding strategies (Mata, von Helversen, & Rieskamp, 2010). Furthermore, a decline in more controlled, deliberative processing and an increased reliance on more automatic, heuristic processing may lead to less effective or poorer decisions among older adults (dual-process model; see Peters, Hess, Västfjäll, & Auman, 2007; also Evans, Chapter 8). In this section we will highlight not only the instances in which age-related deficits are observed but also situations in which deficits are not present. We will also consider the impact of goals and motivations on the aging decision maker.

In the real world, individuals are often charged with making decisions in the face of gains, losses, risks, and uncertainty; the ability to decide advantageously in these situations is of great importance. Laboratory-based studies of decision making in the presence of the aforementioned factors have frequently utilized the Iowa Gambling Task (IGT), originally developed by Bechara and colleagues (Bechara, Damasio, Damasio, & Anderson, 1994), which presents individuals with the opportunity to either gain or lose large monetary amounts. In the IGT, there are four decks of cards, and each card has either a positive (gain) or negative (loss) monetary

amount on the reverse side. Subjects are allowed to select cards freely, one at a time, from any deck, with the task ending once they have selected 100 cards. There are always two “good” decks, which consist of smaller immediate gains and lower overall losses, and two “bad” decks, which contain very large gains but also larger long-term losses. To be successful on this task, one must learn to choose predominately from the “good” decks and avoid the “bad” decks.

Several studies suggest that, on average, older adults are more likely to make disadvantageous decisions on the IGT compared with younger adults (Denburg et al., 2007; Denburg, Tranel, & Bechara, 2005; Fein, McGillivray, & Finn, 2007). Figure 33.4 displays the average number of cards selected from the good decks (i.e., decks C and D) minus the number chosen from the bad decks (i.e., decks A and B) for both younger and older adults across blocks of 20 cards. The pattern clearly shows less advantageous decision making by older adults. Furthermore, even studies that have reported few age differences on this task have found overall flatter learning curves among older individuals (i.e., they take longer to adopt a successful strategy; see Wood, Busemeyer, Koling, Cox, & Davis, 2005). It may be the case that older adults are more sensitive to gains and less sensitive to losses than younger adults (Friedman, Castel, McGillivray, & Flores, 2010; Samanez-Larkin et al., 2007), which could partially account for their lower overall performance on the IGT. That is, individuals who place more emphasis on the larger gains, and deemphasize the larger

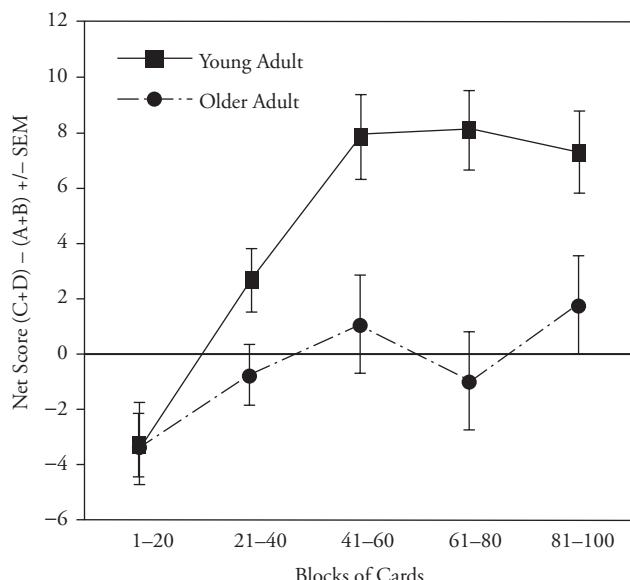

Fig. 33.4 The average number of cards selected from the good decks (C and D) minus the bad decks (A and B) across blocks of 20 cards for both younger and older adults. (From Denburg et al., 2007, reprinted with permission from John Wiley and Sons.)

losses, may continue to select cards from the “bad” decks. Alternatively, it has been suggested that these age-related differences on the IGT may in fact be a result of, or mediated by, declines in other cognitive abilities such as processing speed and explicit memory function (Henninger et al., 2010). What is particularly concerning, however, is that older individuals who perform poorly on the IGT are also more likely to fall prey to deceptive and fraudulent advertising (Denburg et al., 2007). What makes this alarming is the fact that older adults are often preferentially targeted by fraudulent schemes (American Association of Retired Persons, 1996), and thus some older adults may be at an increased risk of becoming victims of such crimes.

Despite evidence suggesting age-related deficits in decision making, a number of studies have found that older adults’ decision-making ability is not always compromised (Kim & Hasher, 2005; Kovalchik, Camerer, Grether, Plott, & Allman, 2005). Older adults, if given the opportunity, can become more adaptive and adopt different compensatory strategies (Mata, 2007), consistent with the previously discussed selective optimization with compensation theory. For instance, although older adults often review less information and take longer to process it, older adults are capable of adopting more complex, less heuristic-based decision-making strategies when the environment requires the use of such strategies (Mata, Schooler, & Rieskamp, 2007; Pachur, Mata, & Schooler, 2009) or if properly motivated (Kim, Goldstein, Hasher, & Zacks, 2005).

To illustrate this point, consider the framing effect, a phenomenon in which decisions and choices are altered by the way in which the options are presented. The most commonly known example is the Asian disease problem originally examined by Tversky and Kahneman (1981). When presented with this problem, individuals are more likely to demonstrate risk seeking in their choice when the options are framed as losses (400 out of 600 people will die), and risk aversion when the options are framed in terms of gains (200 out of 600 people will be saved; Tversky & Kahneman, 1981). If individuals rely on more automatic, heuristic processing when presented with these types of problems, they are more likely to fall victim to the framing effect. Thus, it is not surprising that older adults, who may rely on more heuristic-based processing styles due to limited resources, show larger framing effects than younger adults (Kim et al., 2005). However, when asked to provide justification for their choices

(i.e., have appropriate motivation), older adults (and younger adults) adopted a more systematic processing and no longer showed susceptibility to the language in which options were framed (Kim et al., 2005). It is also important to note that regardless of whether older adults review less information and rely on more heuristic-based processing when making decisions, reviewing less information does not necessarily lead to poorer quality of decisions (Mata & Nunes, 2010). In addition, recent work has shown that older adults actually prefer fewer choices when making decisions, and that their performance is related to numerical processing ability, general slowing, and working memory capacity (e.g., Peters et al., 2007; Reed, Mikels, & Simon, 2008; Tanius, Wood, Hanoch, & Rice, 2009).

While motivation certainly plays a role in enhancing the decision quality of older adults, goals (emotional and social goals in particular) influence decision making and choice evaluation in key ways as individuals age. Studies examining decision making within emotional or social realms have often found no age-related difference (MacPherson et al., 2002). As proposed by the socioemotional selectivity theory (SST), emotional regulation and enhancing emotional well-being may be important goals for older adults. If this is the case, then older adults may process and remember information surrounding decisions differently than do younger adults. For example, on a task assessing decisions for health care plans and doctors, it was found that older adults reviewed a greater proportion of positive compared to negative material than did younger adults, and they remembered the doctors and health plans they had chosen more positively (Lockenhoff & Carstensen, 2007). Additional studies have also found that older adults often remember their decision choices as having more positive features (Mather & Johnson, 2003) and are more satisfied with their decisions compared with younger adults (Kim, Healey, Goldstein, Hasher, & Wiprzycka, 2008).

The SST has further proposed that older adults may see time as more limited than do younger adults and thus may see their time as more “valuable.” Given this hypothesis, older adults may be less susceptible to sunk cost effects, a common decision-making bias in which people continue to invest either time or money when prior investments have been made, despite limited prospects for positive returns (see LeBoeuf & Shafir, Chapter 16). In one study, older and younger adults were presented with scenarios in which, for example, they

had paid a certain amount of money to see a movie. Participants were told to imagine that shortly into the movie, they realized that it was not very good and were not enjoying it, and were given options to stop watching or continue watching for various lengths of time (Strough, Mehta, McFall, & Schuller, 2008). Strough and colleagues found that older adults were much less likely to demonstrate the sunk cost bias (i.e., continue watching the movie) than were younger adults. Thus, at least under some circumstances older adults may make more rational, “normatively correct” decisions than do younger individuals, possibly reflecting greater consideration of whether their previous investments of either time or money are currently yielding optimal positive returns.

Summary

Research has documented substantial deficits in judgment and decision making in older adults. For example, older adults make less advantageous decisions, rely more on heuristics when forming judgments and making decisions, and often review less information compared with younger adults. However, when appropriate motivation is present, age-related differences can be reduced and older adults process information in a more deliberate and appropriate manner. Changes in emotional goals may lead older adults to focus on more positive compared to negative aspects related to the decision-making process. Lastly, changes in time horizons (i.e., awareness of limited time left in life) can, in specific instances, result in more appropriate decisions by older adults.

Problem Solving, Reasoning, and Induction

The ability to solve problems, reason logically, classify objects into appropriate categories, and to sensibly come to novel conclusions based on known facts or rules are all critical abilities required to successfully manage one’s way through life. Research presented in the following sections will address age-related declines within these specific domains (e.g., Salthouse, 2005; Thornton & Dumke, 2005), along with the impact that goals, strategies, and prior knowledge have on older adults’ performance. In addition, strategies and instances that have a positive effect on older adults’ abilities will be examined.

Problem Solving

There is evidence that the ability to effectively solve problems (see Bassok & Novick, Chapter 21)

is reduced in later adulthood. For example, a meta-analysis of 28 separate studies concluded that problem solving is not spared from typical age-related declines (Thornton & Dumke, 2005). Older adults’ performance is lower than other age groups on both traditional, laboratory-based problems (Denney & Palmer, 1981), practical problems (Denney, Pearce, & Palmer, 1982), and even on problems specifically designed to give older adults an experience advantage (e.g., what an elderly woman should do if she needs to go somewhere at night, but she cannot see well enough to drive at night and it’s too far to walk; Denney & Pearce, 1989). Older adults may also review less information and generate fewer strategies during problem solving (Berg, Meegan, & Klaczynski, 1999). Furthermore, these deficiencies in everyday problem-solving tasks among older adults have been associated with measures of executive functioning, memory, verbal ability, and speed of processing (Burton, Strauss, Hultsch, & Hunter, 2006).

Despite difficulties with problem solving later in life, it may be that practical, realistic problems differ from the types of tasks used in typical laboratory settings. Although aging has been shown to negatively impact everyday problem-solving abilities (Thornton & Dumke, 2005), these age-related differences are much smaller than those observed on traditional problem-solving tasks (Denney & Palmer, 1981), suggesting that life experience and prior knowledge can moderate age-related declines. For example, Crawford and Channon (2002) gave younger and older adults a range of everyday situations that presented problems for which they needed to generate potential solutions for (e.g., resolving an issue with a neighbor’s barking dog). They found that while older adults generated fewer solutions compared with younger adults, these solutions were of a higher quality, which could be attributed to their greater life experience in dealing with these types of everyday problems (similar to findings regarding the role of expertise late in life; see Charness, 1981a, 1981b). That is, Crawford and Channon suggest that older adults may have a more well-defined knowledge base from which to draw possible solutions and make more efficient use of such knowledge compared to younger adults.

While typical problem-solving experiments are tested in a laboratory or controlled setting, problem solving in “real-life” occurs in a more complex and social environment. Many older adults talk about their problems with friends and family members, which has led to several studies within the last

decade exploring problem solving with older adults in the context of collaboration (Cheng & Strough, 2004; Kimbler & Margrett, 2009; Strough, Cheng, & Swenson, 2002; Strough, Hicks-Patrick, Swenson, Cheng, & Barnes, 2003; Strough, McFall, Flinn, & Schuller, 2008). For example, Cheng and Strough (2004) had either individual or collaborative same-sex pairs of younger and older adults plan a cross-country trip to go to a wedding. Although younger adults took less time and performed better at planning the trip overall, collaborating in a pair was advantageous for both age groups to the same extent, illustrating another strategy older individuals may employ to maintain everyday functioning.

As some of the previously mentioned research suggests, older adults may approach interpersonal problems in a qualitatively different manner than younger adults. It has been shown that older adults may use more effective problem-solving strategies than younger adults when faced with problems that are interpersonal in nature (e.g., conflicts with friends or family; Blanchard-Fields, Mienaltowski, & Seay, 2007). Furthermore, a number of studies have highlighted the fact that older adults are more likely to use (Blanchard-Fields, Chen, & Norris, 1997; Blanchard-Fields, Jahnke, & Camp, 1995) and prefer (Watson & Blanchard-Fields, 1998) emotionally focused problem-solving strategies compared with younger adults, particularly within interpersonal contexts, although both groups tend to use problem-focused strategies more often overall (Blanchard-Fields et al., 1995). One reason why older adults may use emotionally focused strategies more often than younger individuals could stem from differences in goals between the two age groups. It has previously been suggested that maintaining emotional well-being is an important goal for older individuals (e.g., Carstensen, 1992). It has been established that prioritization of emotional regulation has a sizable influence on the types of problem-solving strategies that are likely to be utilized by older adults (Coats & Blanchard-Fields, 2008; Hoppmann, Coats, & Blanchard-Fields, 2008). That is, older adults are more likely to endorse more passive emotional regulation strategies when solving interpersonal problems (Blanchard-Fields et al., 1997; Blanchard-Fields et al., 2007; Blanchard-Fields, Stein, & Watson, 2004; Coats & Blanchard-Fields, 2008), possibly due to their desire to maintain emotional stability and balance, particularly within their interpersonal relationships.

Lastly, it is important to note that areas such as everyday problem solving are a multidimensional construct, often with little relation between the different measures used (Allaire & Marsiske, 2002; Marsiske & Willis, 1995). Furthermore, performance is also modulated by such factors as education (Thornton & Dumke, 2005) and health (Diehl, Willis, & Schaie, 1995). In addition to the factors mentioned earlier, older adults, at times, do perform better when faced with a situation relevant to their own age group, analogous to an “own-age” bias (Artistico, Orom, Cervone, Krauss, & Houston, 2010). Other factors such as positive feedback (Soederberg-Miller & West, 2010), experience, and strategic flexibility have also been shown to improve older adults’ problem-solving and decision-making abilities (Hicks-Patrick & Strough, 2004).

Reasoning

Similar to findings observed in problem solving, the capability to effectively reason is negatively impacted during aging. Difficulties in reasoning ability are apparent by looking at older adults’ performance on the Raven’s Progressive Matrices Task, which shows a clear decline across the adult life span (Salthouse, 1993, 1994; Salthouse & Skovronek, 1992). The Raven’s task requires participants to identify an appropriate option to fill in a missing cell on a matrix grid that becomes progressively more difficult across trials. Figure 33.5 contains examples of the Raven’s Matrices (Fig. 33.5a), displaying problems of varying difficulty (i.e., the number of relations within the problem). A summary of older and younger adults’ performance on this task (Fig. 33.5b) reveals significant age-related differences at all levels of difficulty.

In addition to Raven’s Matrices, age-related performance deficits have also been observed on other reasoning tasks. For example, older adults performed worse than younger adults on a propositional reasoning task that presented individuals with a series of premise pairs (e.g., A > B, B > C, C > D), and then required them to draw inferences about a new pair (e.g., A ? C) (Ryan, Moses, & Villate, 2008). On tasks assessing analogical reasoning, older adults perform less accurately compared with younger and middle-aged adults (Viskontas, Morrison, Holyoak, Hummel, & Knowlton, 2004). Viskontas and colleagues found that this age-related deficit in analogical reasoning was present even at low levels of relational complexity, and it became more pronounced when problems contained an increasing

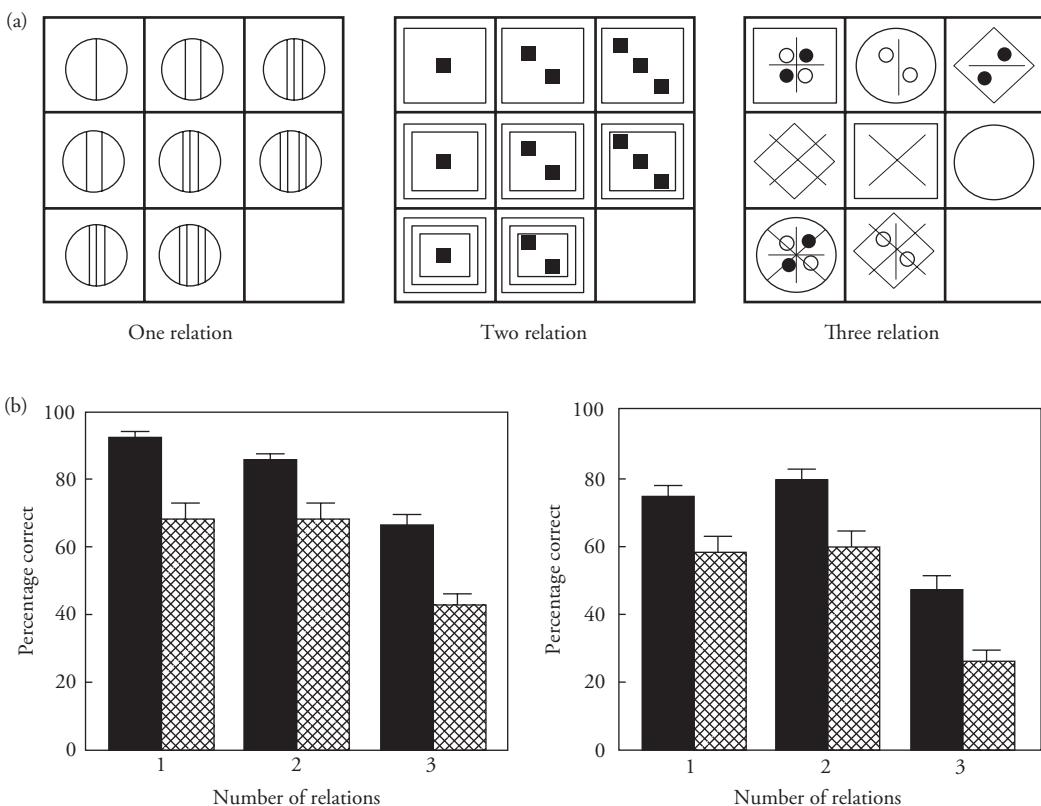

Fig. 33.5 a. A series of example patterns from Raven's Progressive Matrices Task with one, two, or three relations. Participants were given each matrix one at a time and asked to complete the missing cell with the appropriate pattern. Note that as the number of relations within a matrix increases, the task becomes more difficult to solve. b. Results for Raven's Progressive Matrices in younger adults (black bars) and older adults (gray bars). The results show significant age-related differences for both simultaneous (*left*) as well as sequential (*right*) conditions. Error bars indicate standard error of the mean. (Figures 33.5a and 5b taken from Salthouse, 1993 and reproduced with permission the British Journal of Psychology © The British Psychological Society.)

number of irrelevant traits that favored incorrect responses. Age-related declines in reasoning ability have been attributed to multiple sources, including general slowing (Salthouse, 2000), neurological changes to the prefrontal cortex (Krawczyk et al., 2008), differences in relational organization (Ryan et al., 2008), inhibitory decrements (Viskontas et al., 2004), and deficits in working memory (Kyllonen & Christal, 1990; Viskontas, Holyoak, & Knowlton, 2005).

Despite fundamental age-related differences in reasoning performance, the same mechanism may drive reasoning in both younger and older adults. For example, although older adults performed worse than younger adults on the Raven's Progressive Matrices Task, the types of errors both age groups committed (e.g., failure to identify all of the relevant variables needed to determine the correct solution, misunderstanding that some elements of the problem are not relevant to the solution) were

similar to one another, suggesting similar underlying mechanisms (Babcock, 2002; Salthouse, 1993). Furthermore, it has been found that these age-related deficits in reasoning can be reduced when using existing relational information within semantic memory (e.g., prior knowledge) as an analog for new learning (Ostreicher, Moses, Rosenbaum, & Ryan, 2010). There may even be specific situations in which older adults' lifetime of acquired wisdom and experiences result in superior reasoning abilities compared with younger adults (Grossmann et al., 2010; we return to this issue in the section on "Wisdom and Successful Aging").

Induction

Induction, or category learning (the ability to successfully place novel stimuli into one or more appropriate groups; see Rips, Smith, & Medin Chapter 11), has also been found to be susceptible to age-related declines (e.g., Filoteo & Maddox,

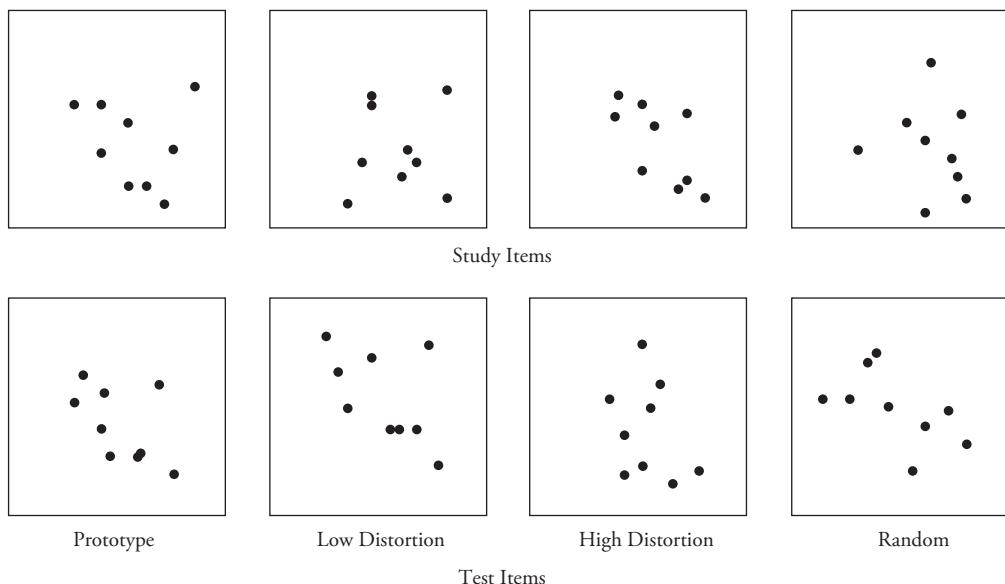

Fig. 33.6 Examples of dot patterns that are presented during study (*top*) and test (*bottom*). The study items are all distortions of the prototype dot pattern. The test items include the training prototype, high and low distortions of the prototype, and random dot patterns.

2004; Racine, Barch, Braver, & Noelle, 2006). One classic task used to assess category learning is the dot classification task (Posner & Keele, 1968). In this task participants are shown a series of dot patterns that are distortions of a predetermined prototypical pattern, examples of which are displayed at the top of Figure 33.6. Participants view a series of these patterns, and then during test are given the prototype pattern, high and low distortions of the prototype, as well as random dot patterns and are asked to categorize them (example test stimuli are displayed in the bottom portion of Fig. 33.6). Compared with younger adults, older adults have been shown to be less successful at correctly categorizing the test stimuli (Davis, Klebe, Bever, & Spring, 1998), and they retain less information about exemplars presented in the set (Hess & Slaughter, 1986). This increased difficulty in inductive learning tasks has been linked to general cognitive slowing, which can make it more difficult for older adults to successfully integrate information (Henninger et al., 2010; Mutter & Plumlee, 2009; Salthouse, 2000).

Similar to the processes involved in induction, older adults have been found to have difficulty in set-shifting (Ridderinkhof, Span, & van der Molen, 2002) and to exhibit more errors (Boone, Ghaffarian, Lesser, & Hill-Gutierrez, 1993; Rhodes, 2004) relative to younger adults on the Wisconsin Card Sorting Task. Although older adults are capable of

learning rules, the inability to appropriately switch or think “flexibly” may explain their reduced performance on induction tasks (see also Friedman & Castel, 2010; Koutstaal, 2006).

Despite increased difficulties with induction, older adults may benefit from specific learning parameters during the induction process. For example, Kornell, Castel, Eich, and Bjork (2010) demonstrated that although older adults did worse than younger adults on an assigned induction task—correctly identifying novel paintings from artists they had previously studied—both age groups benefitted from the same schedule of learning. Specifically, older and younger adults’ performance increased when exemplars from an artist were presented spaced further apart rather than massed together during the learning phase. Thus, spacing benefitted induction across both age groups, suggesting that mechanisms supporting inductive learning stay constant during aging (see also Jamieson & Rogers, 2000). Furthermore, Blieszner, Willis, and Baltes (1981) demonstrated that the ability to modify inductive learning and reasoning performance through interventions and training remains intact across the adult life span.

Summary

The areas of problem solving, reasoning, and inductive learning are subject to sizable age-related declines. It is well documented that older adults

demonstrate declines on both traditional, and to a lesser extent, everyday problem-solving tasks. In addition, much of the research conducted on older adults' reasoning capabilities reveal large age-associated decrements, even on tasks with relatively low levels of relational complexity. Although there is less research on inductive learning and aging, the existing literature supports the conclusion that older adults' capacity to learn categories is also compromised, and that they have difficulty learning categories that require rapid updating and the incorporation of new changing rules (such as on the Wisconsin Card Sorting task). However, there appear to be some contexts in which older adults are capable of performing just as well, if not better, than younger adults despite age-related cognitive declines. For example, older adults may generate fewer solutions to problems, but the quality of the solutions generated can, at times, be on par with younger adults. There is also evidence that older adults approach interpersonal problems in a qualitatively different way than younger adults, and their ability within this area of problem solving remains relatively intact. Furthermore, reasoning and induction tasks that allow older adults to utilize prior knowledge and experience also tend to show fewer age-related deficits.

Memory and Metacognition

Memory

Our memory is a vital component of who we are as individuals, and it allows us to efficiently interact with and understand the world. Not only do our memories contain information about our past experiences and what we know, but they influence our current and future actions. While there are many physical and psychological changes that accompany the aging process, one of the most oft-voiced concerns among many older adults is the decline in memory functioning. In fact, 50%–80% of older adults report subjective memory complaints (Levy-Cushman & Abeles, 1998). Older adults' subjective experience of memory difficulties has proven to be a well-founded concern, with many decades of research demonstrating that memory functioning declines with advancing age (e.g., Craik & Salthouse, 2008; Kausler, 1994). It is important to note, however, that there are numerous "types" of memory (e.g., episodic, semantic, working, procedural) and, as was shown earlier in Figure 33.1, aging may disproportionately impact these types of memory, with some, but not all, tasks associated

with age-related deficits (Craik & Salthouse, 2008; Kausler, 1994; Zacks & Hasher, 2006). Implicit or nondeclarative types of memory such as priming, skill learning, and classical conditioning, which rely more on automatic processes, generally show little to no age-related declines (e.g., Fleischman, Wilson, Gabrieli, Bienias, & Bennett, 2004; Laver, 2009; Light & Singh, 1987; Nilsson, 2003). Furthermore, semantic memory (i.e., memory for facts, world knowledge) is well preserved across the life span and in some instances, such as vocabulary knowledge (as is shown in Fig. 33.1) may even increase slightly (Lavoie & Cobia, 2007; Verhaeghen, 2003). Unlike implicit and semantic memory, however, large age-related declines are often observed in assessments of episodic memory (i.e., memory for past events) and working memory (i.e., short-term storage and manipulation of information; Verhaeghen & Salthouse, 1997).

It has been suggested that older adults' decline in explicit memory abilities can be attributed to declines in processing speed (Salthouse, 1996), attentional deficits (Craik & Byrd, 1982), and inefficient inhibitory mechanisms (Hasher & Zacks, 1988; Lustig, Hasher, & Zacks, 2007). One other potential contributor to older adults' deficiencies in episodic memory is their relative inability to form and retrieve links among single bits of information, referred to as associative memory (Castel & Craik, 2003; Naveh-Benjamin, 2000; Naveh-Benjamin, Hussain, Guez, & Bar-On, 2003; Old & Naveh-Benjamin, 2008). Examples of associative memory include (but are not limited to) remembering who said what (source memory), order of information presentation, which items appeared together (item pairs), or whether something was seen or heard. Deficits in associative memory abilities make it difficult to create new associations between event information or units, thus limiting the ability to encode information effectively and later retrieve it (Chalfonte & Johnson, 1996).

In addition to the deficits often observed on associative memory tasks, older adults show a tendency to "falsely remember" information (Jacoby & Rhodes, 2006) and may, at times, be more captured by misleading information compared to younger individuals (Jacoby, Bishara, Hessels, & Toth, 2005). It has been proposed that this tendency to misremember or falsely remember may be due to an increased reliance on more automatic memory processes such as familiarity, in light of difficulties with more controlled memory processes (i.e., precise recollection;

Jacoby & Rhodes, 2006). While the reliance on familiarity and the ability to remember the “gist” can lead to accurate recall and create conditions that allow for more flexibility within memory and transfer of learning to novel situations (Koutstaal, 2006), it also often leads to higher occurrences of false remembering. For example, Jacoby (1999) had older and younger adults read a list of words one, two, or three times (thus increasing familiarity with those words when they were read multiple times). Participants then heard a separate list they were told to remember. During test, participants were told they would see words they had both read and heard, but only to respond to words that were heard. Interestingly, the increased repetition of the read words decreased younger adults’ false recognition, but increased older adults’ false recognition, indicating that older adults were relying more on familiarity of material during responding, possibly due to difficulties with exact recollection.

Although some degree of memory loss and memory changes may be inevitable with age, research is beginning to show that even in the types of memory most vulnerable to senescent changes, the ability to remember valuable, meaningful, and goal-relevant information may remain largely intact (Zacks & Hasher, 2006). As previously discussed, the socioemotional selectivity theory posits that older and younger adults have different motivations and goals concerning social interactions and emotional regulation, and this can have an impact on what older adults attend to and remember. Older adults have been shown to preferentially attend to positive compared with negative information (Isaacowitz, Wadlinger, Goren, & Wilson, 2006; Mather & Carstensen, 2003), and this differential allocation of attention can either enhance or decrease memory for emotional information. Thus, it is not surprising that older adults frequently remember a higher proportion of positive relative to negative information (i.e., they demonstrate a positivity bias), whereas younger adults either do not show this pattern or display a negativity bias in memory on both laboratory tasks (Charles, Mather, & Carstensen, 2003; Mather & Carstensen, 2005; Mather & Knight, 2005) as well as in their spontaneous autobiographical memories (Schlagman, Schulz, & Kvavilashvili, 2006; Tomaszczyk, Fernandes, & MacLeod, 2008). Consistent with the idea that emotional biases in memory may be a result of goal-directed processes (see Molden & Higgins, Chapter 20), older adults with the most pronounced positivity bias are those

who also score highest on tests of cognitive control capabilities (Mather & Carstensen, 2005).

Similar to emotional materials, information and scenarios that utilize more real-world, realistic, or relevant materials may serve to increase attention, motivation for remembering, and allow for the use of prior knowledge, thereby mitigating age-related memory impairments. Figure 33.7 displays the results of a study conducted by Castel (2005) that examined memory for prices of everyday grocery items. If the items were realistically priced, there were no age-related associative memory impairments for prices of grocery items, whereas large age-related decrements were present when older adults were asked to remember unrealistic prices. This finding highlights what a marked impact the utilization of meaningful, “real-world” materials can have on older adults’ performance on memory tasks. That is, when required to remember information that is consistent with prior knowledge, older adults can reduce their reliance on effortful, self-initiated processes (which may be detrimentally effected in aging), improving both encoding and retrieval memory operations (Castel, 2008; Craik & Bosman, 1992; McGillivray & Castel, 2010).

Hess and colleagues (Germain & Hess, 2007; Hess et al., 2001) have investigated the role of personal relevance and its impact on memory performance in older (and younger) adults. Hess et al. (2001) found that older adults were more accurate in their recollection of information related to a narrative describing an older target person (increased relevance), compared with one describing a younger target person, and this accuracy increased in situations

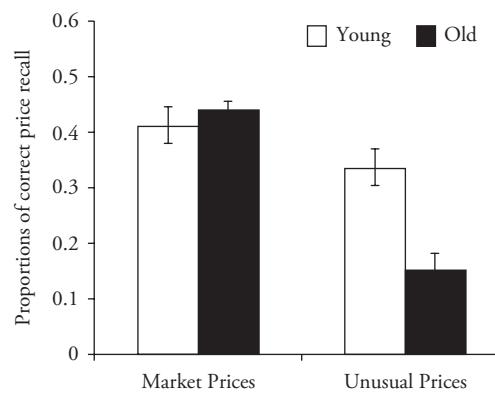

Fig. 33.7 The average proportion of correctly recalled prices by younger and older adults for the market value and unusually priced items. (From Castel, 2005. Copyright © 2005 by the American Psychological Association. Reproduced with permission.)

in which they were held accountable for their responses (increased motivation). Furthermore, older adults' memory benefitted to a greater extent from increasing motivation and relevance than did younger adults. Extending these findings, Germain and Hess (2007) demonstrated that increased relevance was strongly associated not only with memory performance but with more efficient processing, and that these effects were stronger within the older adult sample.

Motivation to remember and relevance are not always products of the to-be-remembered information but can reflect other situational variables. Adams and colleagues have investigated memory for stories, manipulating who participants (both younger and older women) were asked to retell a story to (an experimenter or a young child) (Adams, Smith, Pasupathi, & Vitolo, 2002). When the listener was an experimenter, younger adults recalled more propositional content than did older adults, but this age difference disappeared when the listener was a young child. Furthermore, when the listener was a child, both younger and older participants engaged in more elaborations and repetitions while retelling the story, but older adults were more adaptive in adjusting the complexity levels given the age of the listener. These findings underscore the importance of the context (in particular, social contexts) in which one is asked to recall information, and the degree to which differing context provides motivation to both younger and older adults.

Increasing relevance or importance of information can also serve to mitigate deficits in source memory (i.e., memory for information about the contextual details accompanying that event) so often observed among older adults. For example, no age-related differences were observed when older adults were asked to recognize whether a statement was true, false, or new (truth source), whereas large age-related differences were present when asked to identify the voice source (John or Mary said it) or whether it was a "new" statement (Rahhal, May, & Hasher, 2002). Similarly, older adults' memory performance equals younger adults' on source memory tasks when the to-be-remembered information has an emotionally relevant component (e.g., safety) (May, Rahhal, Berry, & Leighton, 2005). Lastly, recent research has shown that despite age-related memory declines, older adults are capable of remembering more important information just as well as younger adults, but this occurs at the expense of less important information (Castel, 2008; Castel, Benjamin,

Craik, & Watkins, 2002; Castel, McGillivray, & Friedman, 2011; Castel et al., in press).

Metacognition

Although this section is largely concerned with memory, it is also important to understand metacognitive processes and how these processes are affected by aging. Metacognition (or more specifically, metamemory) refers to one's awareness of his or her own memory and how it works. Metamemory includes, but is not limited to, beliefs about one's memory skills and task demands, insight into memory changes, feelings and emotions about one's memory, and knowledge of memory functioning (Dunlosky & Metcalfe, 2009). Beliefs that older and younger adults may have about their memory abilities, in turn, can influence expectations for memory performance, effort exerted during a memory task, and the degree to which one chooses to place himself or herself in demanding memory situations, and it can even influence one's actual performance (Dixon, Rust, Feltmate, & Kwong See, 2007; Lachman, 2006; Lachman & Andreoletti, 2006). Older adults are often very aware of deficits in memory performance (Hertzog & Hultsch, 2000; Levy & Leifheit-Limson, 2009), making the study of metamemory very important in terms of developing strategies to combat age-related memory decline.

Experimental studies of metamemory tasks often involve asking participants to make judgments of learning (or JOLs) about what or how much they will later remember (a form of metacognitive *monitoring*), or by asking participants what information they feel they need to restudy or study for shorter/longer periods of time (a form of metacognitive *control*). Investigations into the effects of age on these variable have been somewhat mixed. While some studies have found that old adults exhibit a larger pattern of overconfidence in their memory abilities compared with younger adults (i.e., there is a larger discrepancy between JOLs and actual memory performance; Bruce, Coyne, & Botwinick, 1982; Connor, Dunlosky, & Hertzog, 1997), other studies have found little to no age differences (Hines, Touron, & Hertzog, 2009; Lovelace & Marsh, 1985; Murphy, Sanders, Gabriesheski, & Schmitt, 1981), or more accurate performance by older adults (Hertzog, Dunlosky, Powell-Moman, & Kidder, 2002; Rast & Zimprich, 2009). In addition, recent work suggests that, relative to younger adults, older adults are also aware of how much information they have forgotten when learning and recalling lists of

items (Halamish, McGillivray, & Castel, 2011), suggesting that the monitoring of forgetting may be relatively intact in old age.

In regard to metacognitive control, Dunlosky and Connor (1997) observed that when older and younger adults were allowed to restudy words at their own pace, all participants spent more time studying items that they had been assigned lower JOLs (i.e., words they judged as more difficult to recall) compared with those words that had been given higher JOLs (i.e., judged as more likely to remember). However, younger adults exhibited this effect to a greater extent, indicating that age-related differences were present in the degree to which monitoring was used to effectively allocate study time. Dunlosky and Connor suggest that this difference in study-time allocation may even contribute to the lower overall memory performance in older adults. However, Dunlosky and Hertzog (1997) found that younger and older adults used a “functionally identical algorithm” in their selection of items for restudy, and both younger and older individuals adaptively selected to restudy the items they believed were not as well learned (Hines et al., 2009).

While the results surrounding metacognition and aging are somewhat mixed, it is encouraging that, at least under some conditions, monitoring and control over learning remains relatively intact throughout the life span. Even studies that have found sizable metacognitive deficits in older adults (e.g., Bunnell, Baken, & Richards-Ward, 1999) have also usually found that these deficits are less than those associated with actual memory ability. That is, metamemory abilities are likely better preserved in older adults than explicit memory abilities. This relative sparing suggests that older adults may be able to use metacognitive strategies to help overcome or compensate for age-related declines in memory performance.

Summary

Declines in older adults' memory abilities are perhaps one of the most widely documented findings within cognitive aging, and older adults frequently remark on their own difficulties with remembering. Older adults, more often than younger adults, remember less information overall, have difficulties forming associations between information, and are more likely to experience false or inaccurate memories. However, if the to-be-remembered information is more personally relevant, realistic (i.e., consistent with prior knowledge), valuable, or more

emotionally meaningful, age-related differences can be reduced. Research examining older adults' metacognitive abilities has yielded mixed results, with some studies documenting impairments, and others finding no age-related changes. Thus, there is at least some evidence suggesting the abilities to correctly predict one's memory abilities and monitor one's learning processes remain somewhat intact, at least compared to explicit memory abilities. This could be a result of lifelong experience “working” and learning to understand one's own dynamic memory capacities.

Expertise and Training

A majority of the theories and evidence discussed earlier in this chapter indicate that older adults' cognitive performance across several domains declines with age (e.g., Salthouse, 1985). But what role might expertise or training play in mitigating these effects? Many cultures consider old age to be associated with maturity and vast amounts of experience, as can be illustrated in the medical, musical, and even business fields (Krampe & Charness, 2006). Indeed, a majority of Fortune 500 CEOs range in age from their late 50s to early 60s. This begs the question whether older adults who are considered “experts” in a certain profession or skill are exempt from age-related declines and can function just as efficiently in their trade as their younger counterparts. What role does training have in maintaining expertise in older adulthood and how does it differ from the training of young adults? Finally, are the effects of training long lasting and differentially beneficial in older adulthood?

Expertise

The first, and arguably most important, question to consider is whether older adults who are classified as experts in a specific skill are exempt from age-related declines. The results are somewhat mixed, depending on the nature of the assessment given and how related it is to the mastered skill (Morrow et al., 2003). For example, Castel (2007) tested younger and older adults, as well as a group of retired older accountants and bookkeepers for their ability to recall object, numeric, and location information (e.g., 26 cherries in a bowl). The results revealed that the older adult experts performed just as well as the older controls in recollection of object information (skill unrelated), but those same experts outperformed younger adults (and older adults) in their memory for the numeric

information (skill related). This finding supports the notion that there are some basic limitations to expertise in old age, in the sense that mastery in one skill (recall of unrelated numbers) does not necessarily translate into high performance of another skill that is less related (recall of objects; see also Salthouse & Maurer, 1996).

However, expertise within some fields may serve to enhance certain cognitive capabilities, such that there may be some transfer effects into other domains (Chase & Ericsson, 1982; Krampe & Charness, 2006). To illustrate this point, Shimamura and colleagues (1995) examined the ability to recall prose information (pertaining to various topics) in younger, middle-aged, and older professors, as well as in college-educated younger and older adult “nonprofessor” controls. Older adult controls displayed deficits in recalling prose information relative to younger controls. However, processing and remembering dense passages is something that professors do frequently and is thus an area in which they could be considered experts. Among the groups of professors no age-related differences were found, despite the fact that the to-be-remembered material was not directly related to their fields of study. These results suggest there can be benefits for remaining highly cognitively active in old age, in that it may mitigate declines in certain memory abilities.

Similarly, Krampe and Ericsson (1996) suggest that lifelong experience and use of an acquired skill is sufficient to sustain lifelong expertise (Meinz, 2000; Meinz and Salthouse, 1998; Salthouse, 1991; Salthouse et al., 1990; but see Krampe, Engbert, & Kliegl, 2002; Krampe, Mayr, & Kliegl, 2005). This assumption was supported by Charness (1981a; 1981b) who found that although older adult chess players came up with fewer potential moves than their younger equivalents, the moves they selected were of equal quality. Thus, even older adults who are classified as experts are still susceptible to reduced cognitive resources and have to consider only the valuable or relevant information as opposed to every possible option. Indeed this “refinement” may also be associated with training or maintenance of expert skill levels, and many older adults claim that their practice is more “efficient” than when they were younger (Krampe, 1994; Krampe & Ericsson, 1996). This is consistent with the selective optimization with compensation model which claims that older adults can use novel or alternative means to counter losses in certain functions (Baltes & Baltes, 1990).

Training

Older adults, to some extent, can benefit from specific training designed to enhance or preserve cognitive abilities. A majority of studies have explored interventions to maintain, if not eliminate, age-related declines. For example, Willis et al. (2006) had older adults participate in a cognitive training intervention known as ACTIVE (Advanced Cognitive Training for Independent and Vital Elderly), which included memorial, inductive, and speed of processing training, and measured daily functions and cognitive abilities after an extensive delay (5 years). Although the training did not eliminate age-related functional declines in everyday activities, it did substantially slow their progression. Cavallini, Pagnin, and Vecchi (2003) illustrated similar findings by training working memory. Both younger and older adults benefited from the training, but younger adults' memory performance was still better than that of older adults. This study illustrates that although working memory does deteriorate in normal aging, older adults can still learn new information and strategies to counteract the decline (but see Dumitriu et al., 2010). Training can also lead to benefits in self-monitoring, making older adults more aware of what information they have not learned as well, which they should opt to study for longer periods of time (Dunlosky, Kubat-Silman, & Hertzog, 2003).

The long-lasting effects of training for older adults are comparable to those for younger adults, but daily use of the strategies learned is the best predictor of such benefits. For example, memory performance was similar to posttraining measures, given maintenance of practice for older adults after a 2-year delay (Bottiroli, Cavallini, & Vecchi, 2008). Derwinger, Neely, and Bäckman (2005) gave older adult participants either structured training or participant-generated mnemonic training. They found superior memory performance for the generated mnemonic group 8 months posttraining, even though the structured training group still showed a long-term benefit of training relative to controls (see also West, Bagwell, & Dark-Fruedeman, 2008). Benefits of training have also been demonstrated for shorter time scales. When using an incremented-difficulty approach (i.e., adding more and more intervening trials between test trials), older adults were able to correctly recollect information across increasing delays (Jennings & Jacoby, 2003). Overall, it appears as though cognitive training cannot completely eliminate declines in cognitive function (see

Hertzog, Kramer, Wilson, & Lindenberger, 2009), but it can be effective at slowing the rate of decline, especially if the training is incorporated into everyday life or the strategies used are self-generated, as the impact can be relatively long lasting.

Summary

Older adult experts are often exempt from age-related declines, but only for tasks that are related to the skill in which they acquired expertise. Even in light of declines, abilities that are frequently maintained or refined across the lifespan may allow older adults to continue to function optimally within skill-specific domains. While unable to completely stop or reverse age-related declines, cognitive training in older adulthood can slow declines via specific strategies designed to counteract specific detriments. In particular, self-generated techniques, and frequent use of learned strategies, make the benefits of training more robust and long lasting; however, the transfer of these skills to other domains is often limited.

Wisdom and Successful Aging

While it is clear that cognitive decline typically accompanies old age, many older adults are highly successful individuals who are high-functioning and are respected for their wisdom. For example, many CEOs, world leaders (or advisors), and deans of major universities are older adults who are recognized for their wisdom and expertise, and are entrusted with making important decisions and solving difficult problems (see also Salthouse, 2010). While the study and definition of wisdom is often elusive, most would conceptualize wisdom as expert knowledge or experiences that help inform future decision making and behavior (Baltes & Smith, 1990; but see Jeste et al., 2010). In addition, wisdom is often mentioned in the same breath as creativity and sometimes genius (see Sternberg, 1985, also Simonton, Chapter 25). Thus, while the concept of wisdom is still elusive in terms of a precise definition and components, it is clear that we can recognize the usefulness of wisdom, and we often turn to people rich in wisdom for guidance and trust their judgment. While various forms of cognitive processes seem to slow or are impaired in old age, it is widely believed that wisdom often increases with age and life experience. In fact, as discussed by Goldberg (2006) in his book *The Wisdom Paradox*, people associate wisdom with advancing age (Orwoll & Perlmuter, 1990) and also regard wisdom as one

of the most desirable traits (Heckhausen, Dixon, & Baltes, 1989), clearly demonstrating there are some positive aspects to arriving at old age.

In an attempt to measure the contribution of age to social wisdom, Grossmann et al. (2010) had participants read stories about intergroup and interpersonal conflicts, and they were then asked to predict the end result of these conflicts. Compared to young and middle-aged adults, the older adults used higher order reasoning schemes that emphasize the need for taking multiple perspectives, allowing for compromise, and the recognition of the limits of knowledge (Grossmann et al., 2010). This finding suggests that in contrast to other types of reasoning that are typically measured in the lab and are found to decline with age (see Salthouse, 2000), some forms of social reasoning may actually improve with age and life experience.

Research has also shown that creative pursuits are influenced by age. Lehman (1953) outlined how production of superior lyrical poetry and music typically shows a peak between the ages of 25 to 29 but also again at the age range of 80 to 84 (see also Simonton, 1998). In addition, the cognitive processes that lead to creative output at an early age may be altered or controlled by completely different mechanisms than those that contribute to creative output in old age. This is clearly an avenue for future research, but what is apparent is that the odds of producing great work is related to the number of attempts, suggesting that perseverance and wisdom may enhance creativity in older adults. In addition, people often change roles due to lifelong experience, such as taking on new jobs, teaching roles, or advisor positions, or simply by taking different perspectives due to expertise and knowledge. The use of creativity and wisdom in later life can then be linked directly to successful aging (Adams-Price, 1998). For example, while Michelangelo and Einstein had some of their most productive years at an early age, their wisdom was then often called upon later in life to provide advice and insight regarding important decisions and events. Nora Ochs recently became the oldest person ever to finish college when, at age 95, she completed a degree in history and graduated on the same day as her 21-year-old granddaughter, demonstrating that perhaps the key to creativity and enjoyment in old age is engaging in active pursuits.

According to theorists Rowe and Kahn (1998), successful aging can be defined as a combination of several key elements. These include an absence of diseases and disabilities; dealing with changes in

control, bereavement, and social support; maintaining high levels of physical and cognitive abilities; and preserving social and productive activities. From a more behaviorist perspective, toward the end of his career and well into old age himself, B.F. Skinner wrote a book on how to enjoy old age (Skinner & Vaughn, 1983). Although he outlined the numerous limiting factors associated with aging, he also focused on the many positive aspects of aging and the need to selectively focus on certain goals (c.f. Baltes & Baltes, 1990), as well as the need to have an optimistic perspective regarding life and development. While creativity, wisdom, and successful aging are central themes in life-span development, there is a clear need to better understand how specific cognitive processes and perspectives contribute to successful aging.

Conclusions and Future Directions

Although some declines in cognitive capabilities may be inevitable with age, a growing body of research has begun to emphasize the sizable impact that factors such as goals, motivation, prior knowledge, and experience have on older adults' performance across a variety of domains. In addition, given the broad and diverse changes that can accompany aging, future research needs to examine how thinking is impaired and enhanced in older adulthood by considering the effects of the factors mentioned earlier, as well as culture, wisdom, and expertise. It is not enough to document impairments, as research has identified many areas in which older adults show qualitatively different approaches to problem solving, incorporate emotional content when making decisions, and are often more experienced than younger adults. Thus, a more comprehensive and multidimensional approach to the study of age-related changes is warranted, one that considers the dynamic interaction of motivational, emotional, and biological changes and the impact these factors can have on cognitive processes (see also Hess, 2005). In addition, the manner in which older adults can judiciously determine what information is important, use that information to facilitate memory and decision making, and then communicate important information to others in an efficient manner, is an interesting avenue for future research (see also Castel, McGillivray, & Friedman, 2011). Lastly, the use of technology has greatly changed how people can access information when making decisions and when trying to remember information. Today, more and more older adults are using the Internet and hand-held devices (Charness & Boot, 2009). The

access and use of technology, and how this modifies thinking for older adults (e.g., Small, Moody, Siddarth, & Bookheimer, 2009) is an important direction for future research.

The Cognitive Neuroscience of Thought Disorder in Schizophrenia

Peter Bachman and Tyrone D. Cannon

Abstract

The term *thought disorder* most commonly refers to a constellation of impairments in communication manifested by individuals suffering from schizophrenia. Although diverse in nature, these symptoms are thought to result from the influence of one or a small number of cognitive abnormalities that affect how individuals with psychotic disorders process information. We discuss the phenomenology of thought disorder and the candidate cognitive mechanisms that may play a role in its expression. Among these, impaired executive functioning—possibly through its interaction with semantic memory—shows the greatest promise in accounting for the phenomena that comprise thought disorder. Additionally, we review a prominent model of executive control of ongoing behavior and discuss links to psychosis symptoms. We then outline a set of neurophysiological abnormalities associated with schizophrenia, or with latent genetic risk for developing the disorder, and consider how these factors may contribute to the expression of disordered thinking.

Key Words: formal thought disorder, psychosis, working memory, speech production, context, endophenotype, discourse coherence, prefrontal, temporal

Introduction

During the course of two assessment interviews, the following standardized, open-ended questions were asked of two research subjects:

[Examiner] “Can you explain the proverb, ‘Speech is the picture of the mind?’”

[Study participant] “You see the world through speech. Like my grandfather used to speak to me of Alaskans and Alsations and blood getting thicker and thinner in the Eskimo. He was against the Kents in England. I can’t smoke a Kent cigarette to this day” (p. 44, Harrow & Quinlan, 1985).

[Examiner] “Why should people pay taxes?”

[Study participant] “Taxes is an obligation as citizens of our country. To our nation, to this country, the United States. As a citizen, I think we have

an obligation. I think that’s carried to an extreme. Within reason, taxes within reason. Taxation, we have representation, so therefore we have taxation. For we formed our constitution, it was taxation without representation is treason” (p. 263, Johnston & Holzman, 1979).

Reading these two responses evokes the feeling that something is not quite right; they seem somehow disordered. For instance, the sentences comprising the first response convey messages that are only very indirectly related to each other, and the types of associations are inconsistent (e.g., concept of “speech” apparently linking the first two sentences, and the idea of participant’s grandfather—the object—linking the second and third). Consequently, rather than a linear progression toward a predictable goal, the response follows a

tangent that deviates dramatically from the content requested by the examiner. The reply to the second examiner's question does not follow such a rapidly digressing course, but instead it seems to fixate on an idea, or perhaps phrase ("taxation without representation"), indirectly related to the content of the question, seeming to repeat and elaborate on that idea or phrase in a circumstantial manner, without offering additional ideas. Both examples involve disrupted communication, which we interpret to reflect disordered underlying thought processes.

Apart from describing how these statements are disordered, understanding why the speakers produced them in such a manner is a daunting yet intellectually stimulating task. The process of comprehending and generating speech integrated into an ongoing conversation involves numerous interrelated cognitive (Levelt, 1989) and neural mechanisms (Price, 2010), any or all of which could contribute to characteristic abnormalities in speech comprehension or production. Additionally, the thought disorder apparent in these examples tends to occur within the context of a more extensive psychopathology (Andreasen & Grove, 1986), including diagnoses as diverse as schizophrenia, mood disorders, certain personality disorders, and autism (American Psychiatric Association, 2000; Andreasen & Grove, 1986). In fact, the patient quoted in the first reply was diagnosed with schizophrenia, the condition perhaps most closely associated with the presence of thought disorder (e.g., Bleuler, 1911/1950). The second quote, however, was provided by an individual who was not herself diagnosed with a psychiatric disorder but has a daughter who was diagnosed with schizoaffective disorder (a condition thought to be closely related to schizophrenia; American Psychiatric Association, 2000), highlighting the role of heritable factors contributing to significant symptom expression, even in the absence of meeting diagnostic criteria for a syndrome.

Despite the prevalence of thought disorder across diagnostic populations, we are not aware of systematic efforts to study the pathology of thought disorder across diverse conditions, looking for common disease mechanisms. Rather, most investigators have chosen to study thought disorder strictly within the context of a particular disease "entity" such as schizophrenia. However, this restriction does not necessarily go very far in simplifying the search for the ultimate causes of thought disorder. The diagnoses most closely associated with the presence of thought

disorder are among the most complex, most etiologically obscure conditions encountered in modern medicine (e.g., Abrahams & Geschwind, 2010; Schulze, 2010; Tandon, Keshavan, & Nasrallah, 2008). Considering schizophrenia, the plethora of difficulties many patients face—including a range of degraded information processing capabilities, presence of debilitating symptoms (including hallucinations and delusions), medication side effects, substantial social and occupational difficulties—defies models of etiology based on a single underlying deficit. In recognition of this complexity, psychopathology researchers have begun to dissect disorders whose manifestation coincides with the presentation of thought disorder into more fundamental phenotypic traits that ultimately participate in symptom formation. Recent work adopting this approach has demonstrated, for instance, that certain neurocognitive disruptions in schizophrenia are associated with genetic vulnerability to the illness, other traits are associated with disease expression, and some may be attributable to any number of interactions between these two (e.g., Cannon, et al., 2000; Cannon, Thompson, et al., 2002; Jaaro-Peled, Ayhan, Petnikov, & Sawa, 2010; McGrath et al., 2009; Rutten & Mill, 2009).

This more complex, integrative view of the pathology of cognitive impairment, in the context of particular disease states (Cannon & Rosso, 2002), may very well be necessary to our ultimate elucidation of the set of neurobiological and cognitive conditions that may participate in the expression of thought disorder through their collective action. In this chapter, we focus first on the role of thought disorder in psychopathology, highlighting descriptive approaches. We then shift to discussion of a prominent model of speech production and how it may map on to brain function (see Morrison & Knowlton, Chapter 6), as well as a prominent model of disordered thinking in schizophrenia, in order to help us identify neurocognitive mechanisms likely disrupted in individuals displaying thought disorder. Finally, we attempt to integrate findings from distinct levels of analysis (e.g., behavioral and molecular genetics, structural and functional neuroanatomy, experimental psychopathology), in order to characterize diverse aspects of psychiatric disorder as traits specific to disease expression, which generally tend to implicate the brain's temporal lobe structures, and traits specific to genetic vulnerability, which tend to involve more frontal lobe-mediated functions.

Defining Thought Disorder

Perhaps the most common usage of the term *thought disorder* is as shorthand for *formal thought disorder*, which refers to a taxonomy of symptoms involving abnormal speech (Andreasen, 1979, 1982). Historically, formal thought disorder has typically been conceptualized as the product of loosened associations leading to a loss of continuity between the ordered elements in the thought processes that precipitate a spoken utterance (Maher, 1991). The “formal” distinction in particular harkens back to the notion that pathologies of thought can be characterized as disorders of thought content or as disorders of thought form. In the schizophrenia literature, disordered content referred primarily to delusions, objectively false and often bizarre beliefs held with a high level of conviction (i.e., the patient maintains the belief in the face of counter-evidence; American Psychiatric Association, 2000). A common example of a delusion is the belief that people in the patient’s environment intend to harm the patient (i.e., a paranoid delusion). On the other hand, disorders of thought form were believed to involve a disorganization of underlying thought processes, reflected in abnormal speech, such as the passages quoted at the outset of this chapter. Although this form-versus-content distinction is no longer commonly used in clinical practice, factor analytic studies of symptom prevalence in schizophrenia (e.g., Liddle, 1987, Peralta, Cuesta, & Farre, 1997) have generally supported the distinction. Ratings of formal thought disorder load together with ratings of disorganized behavior on a factor distinct from delusions and hallucinations, suggesting that thought disorder symptoms indeed reflect a disorganization of ideational elements not necessarily specific to articulated speech.

Several examples of phenomena characterized as formal thought disorder are pertinent to our discussion of ideational disorganization. One category of speech abnormality is the generation of neologisms, or novel words formed by the unique integration of parts of other words. A neologism would therefore be conceptualized as the loosening of normal associative relationships between individual word parts (perhaps at the level of grammatical encoding, discussed later in this chapter). Johnston and Holzman (1979) quoted one patient as responding to an examiner’s request to define the word *remorse* by replying, “*Moisterous, being moistful*” (p. 100), combining legal word parts to form lexically invalid words.

Similarly, an affected individual’s speech may be characterized by lexically valid but unrelated words strung together to make an unintelligible statement—a loosening of associations between words. An example of this type of disordered comment is, “If things turn by rotation of agriculture or levels or timed in regard to everything . . .” (Maher, 1966, p. 395). In its extreme form clinicians sometimes refer to this type of disorganization as “word salad,” indicating that the words do not blend together in any semantically meaningful way.

Formal thought disorder may also manifest itself in an abrupt shift between indirectly related topics, representing a loosened association between ideas or clauses, within or between sentences. For example, when one patient with formal thought disorder was asked to interpret the proverb “One swallow does not make the summer,” he replied, “When swallow in your throat like a key it comes out, but not as scissors. A robin, too, it means spring” (quoted in Harrow & Quinlan, 1985, p. 429). In this instance, the patient seems to have switched from employing one meaning of the word *swallow* (i.e., the verb) to an alternate meaning (i.e., the type of bird), and then articulating a concept (i.e., “robin”) semantically related to the alternate meaning.

Perhaps even more salient in this last example than the abrupt shift is that the patient’s response seems only very tangentially consistent with the interviewer’s question. In fact, disordered speech can involve statements that are overly vague or overly concrete, or otherwise do not seem congruent with the semantic or interpersonal demands implied by the comment or question posed by the other participant in the conversation.

In contrast to the taxonomy of speech abnormalities described earlier, which follows from application of the ideational confusion definition, Andreasen (1986) developed a descriptive system of assessing thought disorder, intended to eschew traditional assumptions about the pathology resulting in disordered speech. In all, Andreasen identified 18 classes of speech abnormality, which she showed could be clustered using factor analysis into clinically meaningful categories (Andreasen & Grove, 1986).

Indeed, five of the 18 types of abnormality clustered together to comprise a “loose associations” dimension that seemed to indicate the overall level of behavioral disorganization shown by patients with psychotic disorders (Andreasen & Grove, 1986). Another distinction appeared between what the authors characterized as aspects of “positive” and

“negative” thought disorder (analogous to but not isomorphic with the positive-negative schizophrenia symptom distinction), with the former involving aspects of loosened associations (e.g., derailment) in combination with a significant level of rapidity and volume of speech (sometimes referred to as “pressure” of speech), and the latter involving speech that is impoverished in terms of average number and length utterance and/or impoverished with respect to ideational content (as was the case in the second quote cited in the Introduction). Interestingly, this positive versus negative dimension effectively discriminated thought-disordered patients with mania (in the context of bipolar disorder) from thought-disordered patients with schizophrenia.

An area of long-running controversy in the study of formal thought disorder is whether thought disorder is ultimately a disorder of thought itself or a disorder of overt speech. Specifically, rather than considering this markedly disrupted ability to communicate a speech production problem, we infer that the locus of pathology lies in the thought processes underlying the intentional production of speech (see Chaika, 1982, for additional discussion of this inference).

Unfortunately, as discussed in depth by Critchley (1964) and Maher (1991), these thought processes themselves are not directly observable. Therefore, measurement of any putative disruption must necessarily occur indirectly, usually with the assumption that the psychomotor transformation from a thought to a spoken utterance occurs with a normal range of fidelity. It is certainly worthwhile to consider whether this assumption is warranted, as doing so will provide a heuristic for considering the stages of communication that must be disrupted in order for particular “thought disorder” phenomena to be manifest.

Levelt's Model of Normal Speech Production

To provide an organizing framework for our consideration of how specific cognitive impairments may contribute to the expression of formal thought disorder, we turn first to a model of normal speech production.

As shown in Figure 34.1, Levelt and colleagues' (Indefrey & Levelt, 2004; Levelt, 1989, 1999; Levelt, Roelofs, & Meyer, 1999) model involves a serial process by which a message intended for

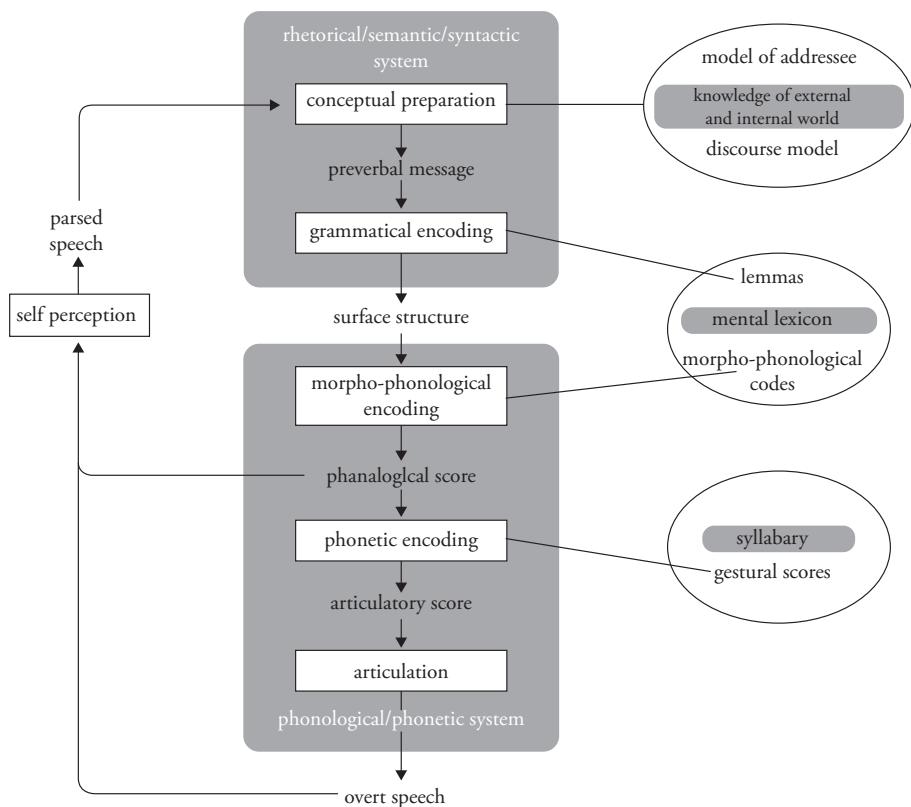

Fig. 34.1 Levelt's model of normal speech production (from Levelt, 1999).

communication moves through a succession of stages, each of which plays a unique role in transforming the message into an articulated sound wave. The first set of stages along this speech production sequence comprises what Levelt refers to as a “rhetorical/semantic/syntactic system,” responsible for filtering a given communicative intention through the speaker’s model of how the listener will perceive and understand the message, which can be influenced by the speaker’s mental model of the listener. This system also sequences ideas in a logical order and places that sequence in a propositional format (specific to linguistic expression), which includes the selection of lexical concepts, in turn triggering the retrieval of appropriate lemmas (abstract, canonical forms of words) from the mental lexicon. The retrieval of the appropriate lemmas from the mental lexicon engages the syntactic construction of the message, as lemmas must agree syntactically with each other and with the overall communicative intent of the speaker.

This retrieval of lemmas from the mental lexicon, which also entails retrieval of each lemma’s inherent morpho-phonological code, serves as a transition out of the “rhetorical/semantic/syntactic system” and into the “phonological/phonetic system.” Indeed, the lemmas’ store in the mental lexicon represents the basic stage at which semantic and phonological information is bound together.

Accordingly, the phonological codes associated with the lemmas’ various morphemes combine according to the predetermined sequence to form the syllabic structure of the message. This is a relative process, the product of which does not necessarily respect the boundaries of the superordinate lemmas. Next, during the process of phonetic encoding, the phonological score (i.e., the accumulation of the phonological syllables) retrieves a gestural, or articulatory score, completing the process by which a fully formed syntactic and phonological message retrieves an appropriate articulatory motor plan. Subsequently, articulation, the generation of overt speech, is the physical realization of the selected motor plan.

The production of overt speech, however, does not represent the final stage in Levelt’s model of speech production. In fact, the model also includes a feedback loop by which the speaker can perceive and monitor his or her own speech for errors or external interference, reengaging the model at the level of conceptual preparation in order to make appropriate corrections if necessary.

As Ditman and Kuperberg (2010) discuss, speech production models such as this one must account not only for the selection of each subsequent word but also for the maintenance of larger discourse coherence, a logical consistency between clauses contributing to the buildup of a situation model, or a gestalt meaning the speaker is attempting to communicate. When discourse coherence is successfully maintained, referents are unambiguous (e.g., pronouns substituting for objects), and there is a logical continuity between statements heard by the speaker and statements made in response (see also Garrod & Pickering, 2004).

In fact, there is a wide range of temporal scales and complex linguistic structures across which logical consistency must be maintained. Although feed-forward models of language production such as Levelt’s tend not to emphasize its influence, the role of context can be considered at each of these levels. In this sense, context could be defined as any influence other than the lexico-semantic information built into previously spoken statements. How contextual influences may affect subsequent speech will be considered at length later.

On a neural level, Indefrey and Levelt (1999) describe the functioning of Levelt’s model as implemented in a primarily left hemisphere-lateralized cortical network. They propose that the initial process of conceptual preparation occurs in a range of heteromodal and cortical association areas (typically areas specific to the stimulus leading in to the pre-set message formulation; Indefrey & Levelt, 2004), the activity of which converges with the selection of a lexical concept occurring in the left middle temporal gyrus (Indefrey & Levelt, 1999) and the pars orbitalis and pars opercularis section of the inferior frontal gyrus, medial prefrontal cortex, posterior inferior parietal cortex, and parahippocampal and posterior cingulate gyri (Price, 2010). Subsequently, Wernicke’s area (roughly the temporal-parietal junction, including the supramarginal gyrus and the posterior planum temporale) and more anterior sections of the pars opercularis segment of the inferior frontal gyrus (Price, 2010) are activated by the retrieval of phonological codes associated with retrieval and sequencing of lexical concepts, followed by activation of Broca’s area (posterior left inferior frontal cortex and anterior insula) and the left midsuperior temporal lobe, the sites at which phonological encoding continues independent of lexical information. Broca’s area then remains active and is joined by activation in other supplementary

motor areas, left putamen, and cerebellum during the process of articulation (reviewed by Price, 2010). Indefrey and Levelt (1999) further specify that self-monitoring, whether occurring covertly or overtly, activates regions of superior temporal lobe, as well as supplementary motor areas related to articulation. In addition, the most abstract levels of monitoring for discourse coherence and congruence with speaker's goals and models of listener's understanding are almost certain to engage prefrontal areas (especially dorsolateral prefrontal cortex) and superior temporal gyrus (e.g., Sassa et al., 2007).

Thought Disorder or Speech Disorder?

Referring to Level's model of normal speech production (Fig. 34.1), we can consider each of the putative processing stages and attempt to infer what the observable product of "lesioning" each in isolation would sound like. Let us first examine the processing stage most closely affiliated with the actual act of speaking, the process of physical articulation. If an intact would-be utterance moves into the stage of physical articulation, only to be compromised, one might expect the output to contain the intended words, encoded grammatically, but spoken in a manner that systematically distorts the articulatory score of the phrase. Such a spoken product would not resemble formally disordered thought, but instead the product of conditions such as dysarthria or speech apraxia (Dronkers, Redfern, & Knight, 1999), two disorders familiar to neurologists and speech pathologists.

Similarly, if the lesion underlying formal thought disorder involved the process of phonetic encoding, one would expect spoken output to resemble speech characteristic of what Dodd and Crosbie (2010) refer to as "speech programming deficit disorder," in which speech is produced fluently, but the distorted phonological score would yield speech devoid of normal patterns of pitch and syllabification—perhaps sounding severely slurred—in the absence of dysarthria or speech apraxia.

The immediately preceding stage, morpho-phonological encoding, the first point in the process at which a word's phonological code is processed independently of semantic content, has also been shown to be compromised in isolation, specifically in patients suffering from an anomic aphasia, or a word-finding deficit (Indefrey & Levelt, 1999). Typically, such patients describe a sense of frustration over feeling that they have particular verbal concepts in mind but cannot retrieve the phonological code; that is, they cannot think of how to say the corresponding

word. Certainly this condition is debilitating, but apart from the superficial similarity with thought blocking (sometimes considered a feature of negative formal thought disorder but not a construct included in Andreasen's and Grove's system), anomic aphasia does not resemble formal thought disorder.

Finally, having ruled out deficits in the stages of speech production comprising Levelt's (1989, 1999) phonological/phonetic system, we work backward to the stage at which lemmas are selected and retrieved from the mental lexicon, initiating the grammatical encoding process. Agrammatic patients, such as patients suffering from Broca's aphasia, are characterized by speech in which words are selected and ordered appropriately, but the particular form of each word is not adjusted to accommodate the grammatical demands of nearby words or the phrase as a whole (e.g., verbs are not conjugated correctly; Indefrey & Levelt, 2004). Although, as apparent in the quotes at the beginning of the chapter, patients with formal thought disorder make grammatical mistakes in their speech, it is not clear that they make such mistakes more frequently than non-thought-disordered individuals do.

Evidence does exist (Andreasen & Grove, 1986; Berenbaum & Barch, 1995), however, that patients with formal thought disorder show a small, but significant level of word substitution and approximation, which is the predictable consequence of faulty retrieval of lemmas from the mental lexicon, the initial process occurring under the heading of grammatical encoding. We therefore conclude that we can rule out lesion to all processing stages occurring after lemma retrieval, up to and including the articulation of overt speech. The etiology of formal thought disorder must therefore exist somewhere along the way through the rhetorical/semantic/syntactic system (including application of a mental model of the listener and conceptual preparation) and/or in the self-monitoring feedback loop. Although where one draws the line between "thought" and "speech" is somewhat of a philosophical issue, we propose that all processes comprising these two suspect components certainly warrant the label "thought," justifying the term *formal thought disorder*, rather than *speech disorder*.

Overview of Cognitive Models of Thought Disorder

The first major psychological discussion of the pathology of thought disorder was provided by Eugen Bleuler, a Swiss psychiatrist and theorist contemporary

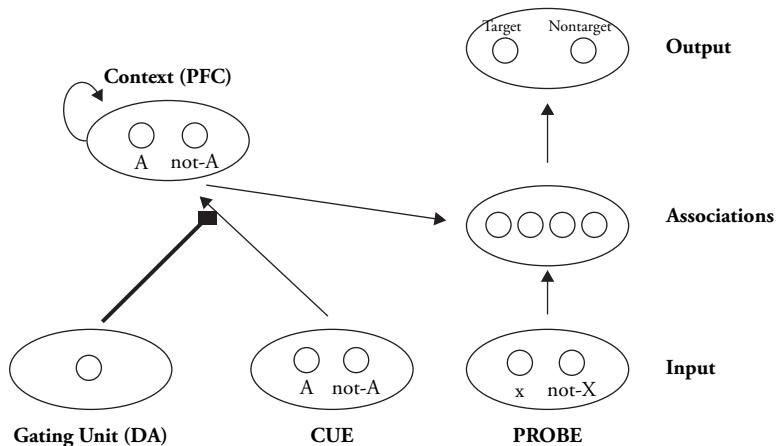

Fig. 34.2 Cohen, Braver, and colleagues' model of information processing disruption in schizophrenia (from Braver, Barch, & Cohen, 1999). PFC, prefrontal cortex.

to both Sigmund Freud, founder of modern clinical psychology, and Wilhelm Wundt, often cited as the founder of modern experimental psychology. Based on his observation of patients with psychotic disorders, such as schizophrenia, Bleuler (1911/1950) argued that the etiology of psychosis involves a fundamental “loosening of associations” between ideational elements, which results in a conceptual disorganization that manifests itself in disordered speech (in addition to other symptoms), an idea preserved almost exactly in its original form in more contemporary definitions of thought disorder, as discussed earlier.

Furthermore, Bleuler's conceptualization of the pathology of psychosis is analogous to more contemporary cognitive explanations of disordered information processing (e.g., Andreasen et al., 1999; Goldman-Rakic, 1995; Oltmanns & Neale, 1975; Silverstein, Kovacs, Corry, & Valone, 2000), as he proposed that a critical parameter of a fundamental *cognitive* mechanism is abnormal and that the consequences of this single cognitive “lesion” account for the diverse phenomena observed in the behavior of many psychiatric patients. One contemporary cognitive model—perhaps the dominant psychological model currently informing cognitive neuroscience research on schizophrenia—holds that schizophrenia patients' abnormal prefrontal functioning curtails normal integration of thought and behavior, as indicated by the inability to use contextual information in the efficient guidance of ongoing, goal-directed behavior.

Guided Activation Model

Jonathan Cohen, Earl Miller, and their colleagues (Braver, Barch, & Cohen, 1999; Braver et al., 2001;

Cohen, Barch, Carter, & Servan-Schreiber, 1999; Cohen & Servan-Schreiber, 1992; Miller & Cohen, 2001) have proposed a heuristic model of prefrontal control of ongoing behavior that has been applied extensively to characterize cognitive impairment in schizophrenia (see Fig. 34.2). By this logic, information processing deficits observed in schizophrenia patients result from a disturbance in the interaction between a prefrontal cortical module specialized for the representation, active maintenance, and updating of information regarding goal states, and a more posterior system responsible for the generation of sensory representations and the storage of learned behavioral contingencies. An individual's repertoire of stimulus-response associations must be directly accessible to the behavioral selection process that bridges the gap between the encoding of a stimulus and the execution of a response. Accordingly, the existence of a pathway allowing interaction between these stored behavioral contingencies (i.e., long-term memories, including motor plans) and the goal representation module allows this type of context information to influence the selection and execution of ongoing behavioral plans, ideally biasing behavior in a goal-appropriate manner (Braver et al., 1999). Context information, such as goal state, therefore mediates the selection of learned associations, which would otherwise be dictated by environmental stimuli. Cohen, Miller, and colleagues (Miller & Cohen, 2001) place particular emphasis on the idea that the prefrontal cortex representation module pushes competing, mutually inhibitory neural assemblies closer to activation, and in the case of a representation of behavior, closer to execution, but it does not necessarily select them outright. Goals,

and other context information, therefore guide the activation of behaviors, making them more or less likely to occur, given present circumstances.

To serve this function, context information must be represented and maintained in a manner that leaves it both buffered against interference (from task-irrelevant stimuli) and available to be updated as required by changing task demands. In an extreme example, this system must be capable of exercising cognitive control: utilizing information from a previous stimulus to favor the processing of relevant information and to suppress processing of irrelevant information, and then selecting appropriate goal-directed behavior, even in the face of competition from more salient behavioral responses.

Citing computational evidence (Braver et al., 1999), the investigators argue that variable efficiency of the interaction between the context-processing module and the learned behavioral contingencies module could in fact account for schizophrenia patients' reduced sensitivity to context information. They elaborate (Braver et al., 1999) that a gating mechanism must exist between the two modules, allowing context information to be encoded and maintained without interference from irrelevant perceptual information under certain circumstances; and at other times, making context information available for updating or to influence activation in the association storage module. Disrupted information processing in schizophrenia is therefore the consequence of failure of this "gate" between the association storage module and the context-processing module to properly open and close, degrading the ability of goal-related information to bias response selection.

In support of their model, Cohen, Braver, and colleagues (Cohen et al., 1999) have presented data from schizophrenia patients and controls performing three tasks: a single-trial version of the Stroop task, a lexical disambiguation task, and a "one-back" continuous performance task requiring subjects to continuously match each stimulus with the stimulus presented immediately prior (Cohen & Servan-Schreiber, 1992). In each task, the difficulty of maintaining context information and using it to select appropriate behavior was manipulated by varying the length of time during which context information must be maintained prior to response selection, as well as the salience of task-appropriate responses relative to task-inappropriate responses (i.e., the demand for cognitive control during the behavioral selection process). The investigators

argued that, overall, schizophrenia patients display a differential insensitivity to context information. This insensitivity interacted with variable information maintenance demands in two out of three experiments (Cohen et al., 1999). Additionally, the investigators reported a significant negative correlation between context sensitivity and severity of disorganization symptoms (including formal thought disorder) among schizophrenia patients, suggesting that the ability to effectively and flexibly bind ideational elements to an appropriate context underlies both the production of organized speech and successful performance on these context-heavy tasks.

Cohen, Braver, and colleagues have also offered evidence supporting a different but related aspect of their model: the assertion that context information is actively maintained, updated, and buffered against interference in the prefrontal cortex (chiefly, dorsolateral prefrontal areas; Barch et al., 1997; Braver et al., 1997; Braver, Reynolds, & Donaldson, 2003; Cohen et al., 1997). Additionally, Miller and Cohen (2001; see also Duncan, 2001; Kane & Engle, 2002) have reviewed evidence that the prefrontal cortex also modulates activity in regions of the brain associated with modality-specific buffers, specifically by holding long-term memories at a high level of activation.

On a functional anatomical level, these findings support Miller and Cohen's conception of the prefrontal cortex as a pan-modal modulator of modality-specific information processing centers, facilitating the selection of goal-appropriate behavior. Incorporating an additional level of analysis, Cohen, Braver, and colleagues cite evidence (Braver et al., 1999) that phasic dopamine activity modulates the gate between the prefrontal context-processing module and the individual's repertoire of learned behavioral contingencies. More recent work has indeed supported the role of phasic dopamine signaling in the updating and stabilization of representations; however, this work has pointed more reliably to dopamine signaling in the dorsal basal ganglia (reviewed by Simpson, Kellendonk, & Kandel, 2010) and how it may affect prefrontal-striatal circuits responsible for selecting and maintaining information in an active state (e.g., Landu, Lal, O'Neil, Baker, & Jagust, 2009; McNabb & Klingberg, 2008). Although further clarification is needed, the importance of dopamine signaling in modulating these prefrontal-striatal circuits is certainly evident.

In addition to being able to account qualitatively for the cognitive deficits the model was designed to simulate (Braver et al., 1999), the proposition that schizophrenia patients fail to appropriately use context information to guide ongoing behavior in goal-directed manner certainly has face validity. One might argue, however, that any behavior judged to be abnormal, or more specifically, deficient with respect to a given goal state, could be explained by a failure of this context-processing mechanism. The concept most critical to differentiating such general failures of goal-directed behavior from those reflecting disruptions of context processing is cognitive control. Specifically, patients will perform a given task correctly when the correct behavioral response is somehow most salient or dominant with respect to other potential responses; in this case, the representation of context and the prepotency of the correct response are redundant mechanisms. When the correct response is less salient, or less "prepotent" than an incorrect, distracter response, patients will tend to choose the distracter. Nonpsychotic subjects, conversely, will be more capable of using representations of context to inhibit the prepotent distracter and select the appropriate, less salient behavioral response; that is, they will be more capable of exercising cognitive control.

This focus on cognitive control therefore represents a critical step in the development of this model and allows it to benefit from additional specification regarding the neural correlates of cognitive control (e.g., Braver et al., 2003) and both neural and cognitive mechanisms underlying recognition and resolution of response conflict (Botvinick et al., 2001). Along these same lines, demonstration of how the heuristic guided activation model may subsume fully elaborated computational models of specific cognitive tasks, such as the Context Maintenance and Retrieval model of free recall performance in verbal memory tasks (Polyn, Norman, & Kahana, 2009), will aid in the generation of additional, testable hypotheses.

An issue awaiting resolution also bears mentioning: the mechanism by which particular behavioral responses acquire their levels of salience, or prepotency. Cohen, Braver, and colleagues refer to behavioral learning principles to account for how associations are formed between particular pieces of context information and specific outcomes (Braver et al., 1999), linking context information to incentive salience and therefore to behavioral response salience. However, they do not account for the

initial identification and categorization of pieces of information (unless a stochastic process of sampling reward value from among the set of available stimuli is assumed), nor do they argue that associations between behaviors, context information, and outcomes will generalize across situations. This ambiguity aside, as we shall discuss, this model provides critical theoretical traction in our attempt to understand how information processing abnormalities might contribute to the manifestation of thought disorder.

Studies of Information Processing Deficits Related to Formal Thought Disorder

To help us fill in the gap in available theory between mechanisms underlying information processing ability and the mechanisms generating organized, goal-directed speech, we turn to the literature on experimental approaches to studying the pathology of formal thought disorder. Thankfully, this work has been examined capably in a meta-analysis performed by Kerns and Berenbaum (2002), who organize the range of published hypotheses involving specific cognitive impairments associated with formal thought disorder into four general categories.

The first of these categories includes investigations of cognitive mechanisms relatively proximal to speech production (e.g., Barch & Berenbaum, 1996; Goldberg et al., 1998). As alluded to earlier, Kerns and Berenbaum (2002) report only a very minor relationship between impairment in what Levelt would consider the phonological/phonetic system (Indefrey & Levelt, 1999) and ratings of thought disorder. Furthermore, they argue that this tenuous relationship is carried entirely by measures of anomia and word substitution and approximation, deficits likely related to the retrieval of lemmas from the mental lexicon (Indefrey & Levelt, 1999). The vast majority of clinical phenomena related to formal thought disorder (Andreasen & Grove, 1986), however, is left unaccounted for by deficient speech production.

Kerns and Berenbaum's (2002) second category of hypothesized deficit involves increased amount of activation spreading automatically between nodes in semantic networks, resulting in increased priming of nearby semantic associates of a target word, raising the probability that one of these nontarget words will be retrieved and integrated into ongoing speech. This is a relatively intense area of study in schizophrenia research (for a review, see Minzenberg, Ober, & Vinogradov, 2002). Investigators looking

for evidence of abnormal semantic network priming have reported seemingly contradictory findings, with some showing evidence of hyperpriming at tested nodes (suggesting increased amount of activation spreading throughout the network; Spitzer, Brauh, Hermle, & Maier, 1993; Spitzer et al. 1994; Weisbrod, Maier, Harig, Himmelsbach, & Spitzer, 1998) and others showing evidence of hypoprimeing at tested nodes (suggestive of a reduced amount of activation; Besche et al., 1997; Blum & Freides, 1995; Kostova, Passerieux, Laurent, & Hardy-Bayle, 2003). These contradictory data prompted the suggestion that thought disordered patients actually experience an increase in *distance* of automatic activation spread, while maintaining an overall level of activation comparable with controls, effectively yielding an increased number of nodes activated, with none activated to as high of a degree as controls' nodes (Spitzer et al., 1994). Kuperberg, Kreher, and Ditman (2010) provide an informative review of semantic activation studies among schizophrenia patients and frame this activation distance versus activation intensity argument in terms of automatic spread of activation (which is increased in distance among patients) and controlled retrieval of semantic information (a circumstance in which patients show decreased activation in semantic networks).

Along these lines, Kerns and Berenbaum (2002) highlight the contribution of impairment in the controlled retrieval of information from semantic memory, which may itself have an abnormal structure due to the cumulative effects of a chronic inability to encode semantic information. Relevant studies (e.g., Allen, Liddle, & Frith, 1993; Goldberg et al., 1998; Kerns & Berenbaum, 2002) tend to employ fluency tasks, requiring retrieval of information from semantic memory by means such as a controlled implementation of a retrieval strategy (Jacoby, 1991; Ruff, Light, Parker, & Levin, 1997). In agreement with conclusions offered by Minzenberg and colleagues (2002) and Baving and colleagues (2001), who argue that semantic retrieval is most consistently and robustly impaired in schizophrenia patients when a high degree of controlled processing is required, Kerns and Berenbaum (2002) present evidence of a strong, consistent association between this type of semantic processing abnormality and presence of formal thought disorder, especially when evident as poverty of speech.

Evidence of impaired semantic retrieval associated with formal thought disorder suggests a failure in the smooth integration of stored information

with incoming information and response selection. Specifically, information from (long-term) semantic memory is continuously retrieved and integrated into comprehension and online production of verbal behavior. Failure of this fluid integration therefore may recruit more capacity-limited, controlled processing resources, likely involving activation of left inferior prefrontal cortex, to facilitate the otherwise automatic selection of semantic information (Gold & Buckner, 2002; Indefrey & Levelt, 1999). Interestingly, Kerns (2007) has demonstrated in work with schizophrenia patients that impaired performance in an experimental controlled retrieval task correlates specifically with poverty of speech, or what Andreasen and Grove refer to as "negative thought disorder."

This process of semantic memory retrieval and integration itself is very likely to be modulated (see Ragland, Yoon, Minzenberg, & Carter, 2007) by the subject of Kerns and Berenbaum's (2002) fourth category of cognitive deficit contributing to formal thought disorder, namely, impaired executive functioning. As a composite construct, Kerns and Berenbaum demonstrate that executive function abnormality is strongly related to the presence of formal thought disorder. Of course, executive function itself entails a number of critical subsystems (Baddeley, 1986), including a mechanism for processing context information (and effectively inhibiting irrelevant, noncontext information), a mechanism for allocation of attentional capacity serving to maintain information over a delay, and a mechanism for monitoring one's own behavior, including speech.

CONTEXT/SELECTIVE ATTENTION

Consistent with Cohen's and Braver's implementation of the guided activation model, there is considerable evidence that thought-disordered patients suffer from abnormal processing of context information. In fact, Levelt's model of speech production incorporates context information at numerous stages, such as during conceptual preparation (when interpersonal context is considered, for instance). In addition, the process of lexical selection may be influenced by discourse context (Horn & Ward, 2001), which describes the representation of previously uttered verbal information one must hold in mind in order to ensure that subsequent utterances will show adequate structural continuity with and semantic and conceptual relevance to the overarching conversation (Ditman & Kuperberg, 2010).

Numerous investigators have examined schizophrenia patients' capacity to use discourse context to guide selection of verbal behaviors. For instance, a significant body of work (Benjamin & Watt, 1969; Cohen & Servan-Schreiber, 1992; Kuperberg, McGuire, & David, 1998; Sitnikova, Salisbury, Kuperberg, & Holcomb, 2002) involves using various lexical disambiguation tasks, which require the subject to use context information from preceding clauses to determine the relevant meaning of a homograph, or a word with multiple possible definitions. These and other investigators have generally concluded that patients with psychotic disorders fail to demonstrate sensitivity to the biasing influence of preceding context information. Notably, this conclusion complements Chapman's and Chapman's (1973) argument that patients fail to demonstrate sensitivity to discourse context only when it suggests a homograph's nondominant meaning. They characterized this deficit as "excessive yielding to normal biases," or a tendency to utilize dominant meanings—what Ditman and Kuperberg (2010) refer to as an overreliance on lexico-semantic associations, rather than discourse context. For instance, when one patient was asked to interpret the proverb "One swallow does not make a summer," he responded, "When you swallow something, it could be all right, but the next minute you could be coughing, and dreariness and all kind of miserable things coming out of your throat" (quoted in Harrow & Quinlan, 1985, p. 436). The patient clearly demonstrated a bias toward the more dominant meaning of the word "swallow," despite the fact that the context of the question implied the nondominant meaning.

Of course, excessive yielding to normal biases is the logical complement of Cohen's and Braver's cognitive control mechanism, which is defined by its ability to overcome these normal biases. Accordingly, Cohen, Braver, and colleagues argue (Braver et al., 2001) that an individual's representation of discourse context, as well as his or her goals for the interaction (e.g., make a particular point, communicate in a certain manner) comprise context information, guiding the ongoing implementation of related semantic concepts. Failure to encode, update, and/or maintain this context information therefore leads to a failure to utilize discourse context to constrain and select subsequent verbal output, appearing to the observer as a relative lack of association between units of language output.

Moreover, if failure to encode, maintain, or implement context information is in fact a mechanism

underlying formal thought disorder, it may explain a long-held piece of clinical wisdom: Disordered speech is more likely to be elicited by abstract, ambiguous, open-ended stimuli (such as the general question posed to the quoted subjects at the beginning of this chapter, or even Rorschach inkblots; Johnston & Holzman, 1979) than by specific, closed-ended prompts. In other words, the fewer structural demands and intermediate goal states provided explicitly, the more difficult it is to practice cognitive control. Under these circumstances, not only is specific context information either never encoded or lost from active maintenance, but the context-processing module loses the concomitant ability to inhibit the activation of competing pieces of information, exposing the system to increased memory retrieval interference (Anderson & Spellman, 1995) and subsequent loss of goal orientation in produced speech. Among nonpsychiatric control subjects, Kerns and colleagues (2004) demonstrated that increased encoding and maintenance of context information, associated with increased prefrontal activation, predicted subsequent use of context-appropriate responses.

CAPACITY ALLOCATION

Given this continued focus on cognitive control as critical to information processing abnormalities related to formal thought disorder, it is important to discuss the allocation of working memory capacity, a process shown to involve activation of dorsolateral prefrontal cortex as well as more modality-specific regions of posterior cortex (e.g., Garavan, Ross, Li, & Stein, 2000), as well as capacity availability itself, which appears to be reflected in the activity of dorsolateral (Callicott et al., 1999) and ventrolateral prefrontal cortex (Rypma, Berger, & D'Esposito, 2002). Numerous studies (e.g., Docherty & Gordinier, 1999; Harvey & Pedley, 1989; Nuechterlein & Dawson, 1984) have found correlational evidence of a relationship between working memory capacity and aspects of formal thought disorder. Attempting to clarify the direction of this relationship, Barch and Berenbaum (1994) report that, among non-ill subjects, reduction in overall processing capacity (achieved through a dual-task manipulation) is associated with decreases in verbosity and syntactic complexity, verbal phenomena included in formal thought disorder. Kerns (2007) followed this work up more recently in specifying that disorganized speech—separate from impoverished speech—is most strongly associated with experimental measures of reduced working

memory capacity among schizophrenia patients. Melinder and Barch (2003) extended this approach to include psychotic patients, showing that they too show increased negative thought disorder with decreasing availability of working memory capacity. These results are particularly noteworthy because the investigators were able to demonstrate, at least under highly controlled circumstances employing a model system, that reduced processing capacity can actually cause speech to become disordered. Whether this mechanism accounts for the observed correlation between reduced processing capacity and thought disorder among patients remains to be determined. Nevertheless, this represents one instance out of many in which schizophrenia research has suggested that working memory capacity may act as a bottleneck, limiting the production and/or implementation of abstract ideas (e.g., Glahn, Cannon, Gur, Ragland, & Gur, 2000; Silver, Feldman, Bilker, & Gur, 2003).

SELF-MONITORING

Levett (1989) argues that effective communication requires the speaker to monitor his or her own speech and to self-correct any erroneous utterances. Interestingly, schizophrenia patients show an impairment in the ability to self-correct erroneous behaviors (e.g., Malenka, Angel, Hampton, & Berger, 1982), which may result from patients' failure to notice errors spontaneously or their failure to recruit additional cognitive control resources to recover from errors and cope with increased task difficulty (van Veen & Carter, 2006). Alternatively, uncertainty regarding the source of erroneous speech may also explain patients' failure to self-correct. Several investigators have shown that patients have difficulty determining whether speech was self-generated, especially under high distortion (e.g., Kumari et al., 2010). In at least one case, this failure was significantly associated with a greater number of verbal derailments (i.e., switching tangentially between topics of discussion; Barch & Berenbaum, 1996).

INTEGRATION OF COGNITIVE DEFICITS CONTRIBUTING TO FORMAL THOUGHT DISORDER

Taken together, these findings suggest a model in which deficits in semantic memory retrieval and executive functions contribute to the expression of formal thought disorder. A study published by Titone and colleagues (2000) provides an example

of this type of interaction. The authors reported the results of a semantic priming study in which particular meanings of otherwise semantically ambiguous words were biased either moderately or strongly by the context of a preceding sentence. The presentation of potentially biasing semantic information was carried out in a manner to increase the likelihood that more controlled retrieval of semantic information would be utilized. Schizophrenia patients showed a pattern of priming identical to controls in the strong context bias condition but exhibited a greater degree of priming in the moderate context bias condition (i.e., patients' showed priming effects for both relatively dominant and relatively subordinate meanings, while controls showed priming facilitation only for subordinate meanings). The authors point out that retrieval of a particular meaning of a word requires not only activation of the word within a semantic network but also inhibition of nearby, less relevant meanings. Patients were able to perform this selection process normally when strong context bias was present, but when this influence was more subtle, patients' degraded retrieval-related inhibitory mechanism failed to filter out alternate meanings, creating interference with the most immediately relevant meaning. Similarly, Ditman and Kuperberg (2010) extended the approach to examine discourse context across sentences, showing that patients successfully maintain and utilize very strong, highly restrictive context; however, patients again failed to use less restrictive context information in subsequent sentences. Therefore, to the extent that the Ditman and Kuperberg study indeed engaged controlled processing mechanisms and therefore did not rely entirely on the automatic spread of activation in a semantic network, the results support the hypothesis that disordered speech results from disrupted executive-assisted semantic memory retrieval mechanisms involving both abnormal activation-based retrieval of information from semantic memory and impaired inhibition of irrelevant, non-context information.

Ex Cogito, Dementia

As the foregoing discussion illustrates, cognitive characterization of thought disorder has many merits, not the least of which is the ability to predict patient performance data in a variety of experimental cognitive tasks. In addition, these models converge with descriptive analyses of the experience of thought disorder in patients with psychotic disorders. Nevertheless, demonstrating that a particular

neurocognitive impairment *could* account for a particular behavioral abnormality does not necessarily demonstrate that the impairment *does* cause the abnormal behavior to occur.

Indeed, more than four decades of intensive neuroscientific investigation have failed to identify conclusively a single defining lesion in patients with schizophrenia or other forms of psychosis. Rather, these syndromes manifest with deficits to many neural systems across several levels of analysis. In light of this complexity, we apply an analytic framework that has become the dominant paradigm in psychopathology research—that is, the endophenotype approach (Gottesman & Gould, 2003)—to theoretical accounts of information processing impairment, including thought disorder. The basic premise of the endophenotype approach is that a given clinical syndrome such as schizophrenia is composed of multiple neurocognitive trait deficits, each of which may be determined by at least partially independent mechanisms. A major consequence of this model is that a certain trait deficit may be necessary but not sufficient for the phenotypic manifestation of a syndrome; thus, the trait deficit will be shared by individuals with a vulnerability to the syndrome (e.g., patients' biological relatives), regardless of whether they manifest the syndrome phenotypically. Other deficits may be specific to individuals who manifest the syndrome phenotypically; these latter deficits may thus potentiate the expression of a symptom in those who carry vulnerability (i.e., those who have deficits in other neurocognitive domains that are necessary but not sufficient for overt disease expression). To develop this framework further in the context of a discussion of thought disorder, it will first be useful to explicate a number of facts about the genetic epidemiology and clinical neuroscience of schizophrenia (also see Green & Dunbar, Chapter 7).

The Genetic Epidemiology of Schizophrenia

Although we are aware of only very limited work on the heritability of formal thought disorder itself (Levy et al., 2010), a great deal of evidence is available demonstrating that genetic factors contribute substantially to the development of schizophrenia, accounting for about 80% of liability to developing the disorder. The transmission pattern, however, is complex, involving at least several different genes as well as environmental factors (Cannon, Kaprio, Lonnqvist, Huttunen, & Koskenvuo, 1998; Tsuang & Faraone, 1999; Tsuang, Stone, & Faraone, 1999).

One consequence of the complexity of the inheritance pattern in schizophrenia is that an individual may carry some degree of genetic predisposition to the illness without expressing it phenotypically—or at least without expressing it to a degree severe enough to meet diagnostic criteria. Stated differently, only a subset of genetically vulnerable individuals actually develops a psychotic disorder. For many with such a genetic predisposition, an environmental contribution (to which genetically predisposed individuals might be differentially sensitive) to development of a psychotic disorder is also required. Among the environmental factors that may be involved, prenatal and perinatal complications, particularly those associated with fetal hypoxia, or oxygen deprivation, are robustly associated with an increased risk for schizophrenia. Complications associated with fetal hypoxia are also of interest because fetal oxygen deprivation represents a plausible mechanism for explaining much of the structural pathology of the brain detected in neuroimaging studies of adult schizophrenia patients (Cannon, 1997).

Applying the conclusion that such genetic and environmental influences aggregate together (additively or interactively) to determine an individual's risk for expressing a psychotic disorder to the study of neurocognitive traits helps demonstrate which of such traits are likely necessary, but not sufficient, for the expression of a psychosis phenotype (or to the expression of any phenotype, including specific symptoms, for example). Specifically, deficits related entirely to the genetic diathesis for developing the given phenotype may be necessary but clearly are not sufficient for the manifestation of that phenotype. This endophenotype should be present in any individual carrying the genetic vulnerability. Consequently, if one member of a set of monozygotic twins (who, by definition have identical genomes) displays a vulnerability-specific trait, the other must as well. In addition, any trait not shared by both monozygotic twins must result to some degree from the influence of unique environmental events (in particular, those related causally to the disorder or those that reflect consequences of having the disorder or being treated for it).

Neural System Abnormalities in Schizophrenia

While neither the specific neurobiological processes associated with the expression of formal thought disorder nor those associated with psychosis in general have been definitively isolated,

disturbances in prefrontal and temporo-limbic systems and their interconnections are likely to play critical roles in both (Cohen & Servan-Schreiber, 1992; Grace, Moore, & O'Donnell, 1998; Gray et al., 1991). The prefrontal cortex—the region of the brain most often associated with formal thought disorder (Goghari, Sponheim, & MacDonald, 2010)—is believed to support higher order cognitive processes such as working memory, the strategic allocation of attention, reasoning, planning, and other forms of abstract thought (Goldman-Rakic, 1995; Kane & Engle, 2002; Miller & Cohen, 2001; also see Morrison & Knowlton, Chapter 6). Medial temporal lobe structures (i.e., hippocampus, amygdala) and adjacent temporal cortex are involved in learning and recall of episodic and other relational information, emotion (especially the amygdala), and certain aspects of language processing (Squire & Zola, 1996).

Neuropsychological studies have shown that, against a background of generalized information processing impairment, schizophrenia patients show profound deficits in the areas of both long-term and working memory (Cannon et al., 2000; Saykin et al., 1994). These deficits appear not to be merely secondary effects of impaired attention, disease chronicity, or medication exposure (Cirillo & Seidman, 2003). Such findings have been corroborated by evidence of abnormal physiologic activity (i.e., altered blood flow) in prefrontal and temporal lobe regions in patients with schizophrenia during performance of tests assessing these same domains of functioning (Berman, Torrey, Daniel, & Weinberger, 1992; Callicott et al., 1998; Heckers et al., 1998; Yurgelun-Todd et al., 1996). At the structural-anatomical level, schizophrenia patients show a variety of volumetric changes throughout the brain, including reduced cortical, hippocampal, and thalamic volumes (Shenton, Dickey, Frumin, & McCarley, 2001). Recent neuroimaging work demonstrates a greater degree of reduction in frontal and temporal cortical volumes compared with posterior cortical volumes (Sun, Stuart et al., 2009; Sun, van Erp et al., 2009). Additionally, the white matter tracts supporting communication between these critical frontal areas and other modality-specific regions are affected (Karlgodt et al., 2008; Rosenberger et al., 2008).

PREFRONTAL CORTEX AND WORKING MEMORY DEFICITS

Several lines of evidence suggest that working memory deficits and associated abnormalities in

prefrontal cortical structure and function are reflective of an inherited diathesis to schizophrenia. In a Finnish twin sample, Cannon and colleagues found that impaired performance on tests of spatial working memory capacity and structural abnormalities in polar and dorsolateral prefrontal regions varied in a dose-dependent fashion with degree of genetic loading for schizophrenia (Cannon et al., 2000, 2002; Glahn et al., 2002). Interestingly, global and dorsolateral prefrontal volumetric deficits have been found to correlate with performance deficits on tests sensitive to diverse working memory processes (Maher, Manschreck, Woods, Yurgelun-Todd, & Tsuang, 1995; Seidman et al., 1994).

Initial functional neuroimaging studies examining the neural correlates of patients' working memory deficits provided what appeared to be highly discrepant findings, with some reporting prefrontal hypoactivation among patients and others reporting relative hyperactivation (see Karlsgodt et al., 2009, for a review). However, careful consideration of these results demonstrated that at least three factors may play a critical role in modulating prefrontal activity. Among these are individual and group differences in functional and structural connectivity between prefrontal regions and other neural structures recruited during working memory performance (Glahn et al., 2005; Karlsgodt et al., 2008), reinforcing the notion that no locus of brain activity can be characterized entirely without consideration of its interconnectivity with other regions.

Behavioral performance achieved during task performance also has received increased scrutiny (Callicott et al., 2003; Manoach, 2003), with at least one demonstration that behavioral performance may statistically moderate prefrontal activation, placing the relative hypo- versus hyperactivation debate squarely within the context of task performance (Van Snellenberg, Torres, & Thornton, 2006). Finally, when behavioral performance is controlled, the efficiency of neural activation—the relative change in neural activity per unit increase in behavioral performance—has drawn attention. In fact, a robust group-wise difference in the function associating behavior and neural activation in a given brain region (Karlsgodt et al., 2007) offers a physiological explanation for decreased activation among patients failing to maintain information in working memory and for increased activation among patients performing working memory tasks successfully. Figure 34.3 illustrates this phenomenon, whereby patients' accurate performance on a spatial

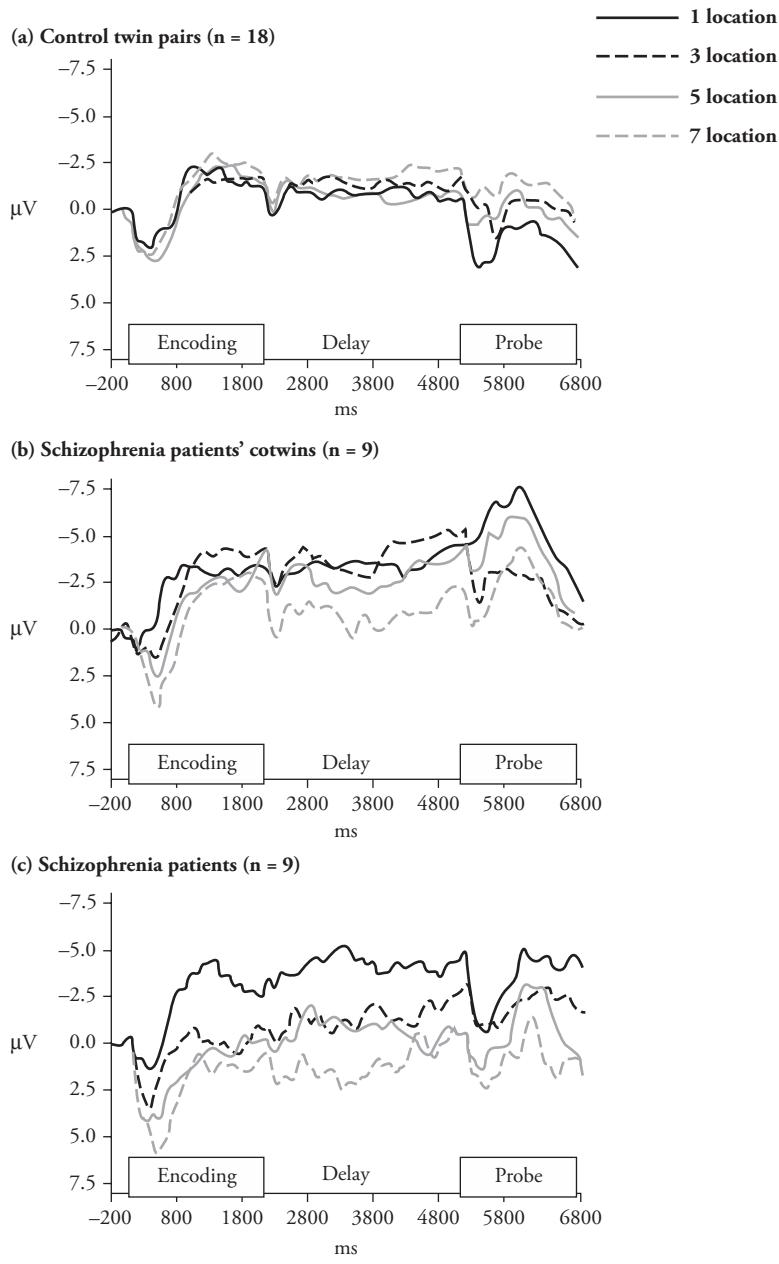

Fig. 34.3 Event-related potential (ERP) waveforms at a centroparietal electrode location, elicited by memory set stimulus onset, displayed at each memory load level for controls (*a*), patients' co-twins (*b*), and schizophrenia patients (*c*). Waveforms were low-pass filtered at 16 Hz (24-dB/oct roll-off) for display purposes only (from Bachman et al., 2009).

working memory task engages a much greater range of slow-wave event-related potential activity than controls show, with patients' non-ill co-twins intermediate (Bachman et al., 2009).

However, the nature of the pathological mechanism underlying these abnormal brain-behavior relationships is not obvious. Rather than a loss of neurons or interneurons, it has been suggested

that gross gray matter volume decrements reflect a reduction of interneuronal neuropil—the space between neural cells, consisting largely of dendrites and synapses—in the prefrontal region in patients with schizophrenia, resulting in impaired working memory functioning due to hypoactive dopaminergic modulation of pyramidal cell activity (Goldman-Rakic & Selemon, 1997). Rather than

subcortical dopaminergic dysregulation, in this case dopamine would be acting within the cortex (although affecting a distinct set of receptors). This prediction has been supported by a positron emission tomography (PET) investigation that found significantly decreased dopamine receptor binding in the prefrontal cortex of schizophrenia patients (Okubo et al., 1997). Notably, dopamine receptor reduction predicted certain types of symptoms, as well as working memory impairment (but also see Abi-Dargham et al., 2002). It is also of interest in this context that treatment with medication modulating cortical dopamine levels is associated with normalization of blood flow in the prefrontal cortex and increased behavioral accuracy during performance of a working memory test (Honey & Watt, 1999).

Another, not mutually exclusive mechanism potentially explaining a significant degree of dysfunction involves the parvalbumin-expressing subpopulation of GABA neurons in the dorsolateral aspect of the prefrontal cortex, which appear to play a privileged role in regulating the timing of oscillatory activity within localized cortical circuits, and also reach mature levels of functioning along a trajectory that appears to mirror increased incidence of schizophrenia and other psychotic illnesses (Lewis & González-Burgos, 2008).

Given that abnormalities of working memory and prefrontal structure and function are associated with genetic liability to schizophrenia, it should be possible to identify specific genes that underlie these disturbances, especially in light of accumulating evidence of physiological abnormality. Weinberger and colleagues have reported on a number of associations between variations at particular genetic loci and prefrontal activation during working memory performance (Tan, Callicott, & Weinberger, 2009). Among these, the MET/VAL polymorphism of the COMT gene (located on chromosome 22) may modulate the efficiency of prefrontal activation, with VAL alleles promoting more rapid breakdown of synaptic dopamine leading to prefrontal hypo-function in patients with schizophrenia (Egan et al., 2001). However, this line of work has also demonstrated that even attempts to identify "intermediate phenotypes" that map particular genes to the physiological networks supporting behavior inevitably meet with considerable complexity, including epistatic interactions between target genes and expression of functionally related molecules (e.g., COMT and GAD1 co-expression; Straub et al., 2007).

We have been interested in another potential susceptibility locus that may affect prefrontal function in schizophrenia, this one on chromosome 1. Cannon et al. (2005) found that inherited variations in the DISC1 gene are associated with schizophrenia diagnosis, reduced prefrontal and medial temporal lobe gray matter, and impaired sociability and memory functioning. Furthermore, using an inducible transgenic animal model, Li and colleagues (2007) demonstrated that interfering with DISC1 during development results in reductions in dendritic complexity and synaptic density as well as impairments in sociability and working memory, paralleling the findings in patients. Taken together, these findings support the view that inherited disruptions in neural connectivity affecting gray matter underlie important dimensions of schizophrenia, including disruptions in working memory.

Together, these findings strongly implicate genetic factors as playing a role in the abnormalities of prefrontal cortex and working memory in schizophrenia. Because deficits on tests sensitive to working memory have also been observed in children at elevated genetic risk (Cosway et al., 2000), it is tempting to conclude that disturbances in the prefrontal cortex in schizophrenia are reflective of an inherited vulnerability to the disorder that is present from early in life. Nevertheless, patients with schizophrenia have been found to show even greater disturbances in dorsolateral prefrontal cortex function and structure than their non-ill monozygotic co-twins (Cannon et al., 2002). Thus, while genetic factors may cause patients and some of their first-degree relatives to share a certain degree of compromise in prefrontal cortical systems, nongenetic disease-specific influences cause the dorsolateral prefrontal cortex to be further deviant in the patients.

TEMPORAL LOBE AND EPISODIC MEMORY DEFICITS

Several microscopic abnormalities of the hippocampus have been documented in schizophrenia, including alterations in neuronal density (Falkai & Bogerts, 1986; Huttenlocher, 1979; Jeste & Lohr, 1989; Zaidel, Esiri, & Harrison, 1997), size (Arnold, 2000; Benes, Sorensen, & Bird, 1991), and orientation (Conrad, Abebe, Austin, Forsythe, & Scheibel, 1991; Conrad & Scheibel, 1987; Kovelman & Scheibel, 1984). These hippocampal volume decrements appear to be present at disease onset (Bilder et al., 1995; Velakoulis et al., 1999) and also appear to be present to some degree in healthy biological

relatives of schizophrenia patients, suggesting hippocampal volume is related to the genetic diathesis for developing schizophrenia (Lawrie et al., 1999; Seidman et al., 1999, 2002). Postmortem and magnetic resonance imaging (MRI) studies of schizophrenia patients, however, have reported positive correlations between hippocampal volume and age at onset (Bogerts et al., 1990; Dauphinais et al., 1990; Stefanis et al., 1999; Van Erp et al., 2002), suggesting a relationship between hippocampal volume and the disease process, complicating any simple interpretation. One possible explanation is that only very subtle structural abnormalities (Wood et al., 2010) coincide with significant metabolic dysregulation (Schobel et al., 2009) of critical hippocampal subfields prior to psychosis onset. The initial episode of psychosis may then alter the structure of the hippocampus, leaving it vulnerable to factors that aggregate with illness chronicity (Velakoulis et al., 2006).

From a neurocognitive perspective, impaired declarative memory processes that depend on the integrity of the hippocampus (Faraone et al., 2000) have been examined extensively among adult schizophrenia patients. In particular, patients show greatest mnemonic deficits when learning depends upon relational encoding between a target stimulus and contextual information (van Erp et al., 2008).

Similar behavioral impairments in long-term memory have been reported in both high-risk adolescents (Byrne, Hodges, Grant, Owens, & Johnstone, 1999; Seidman et al., 2010) and nonpsychotic relatives of schizophrenia patients (Cannon et al., 1994), suggesting that they derive in part from an inherited genotype. However, because long-term memory deficits are specifically more pronounced in patients compared with their own healthy monozygotic co-twins, nongenetic, disease-specific factors must also be involved (Cannon et al., 2000; van Erp et al., 2008). Importantly, two studies have shown a significant relationship between deficits in verbal declarative memory and smaller hippocampal volumes in relatives of schizophrenia patients (O'Driscoll et al., 2001; Seidman et al., 2002).

Given the putative importance of the hippocampus to verbal and executive function, and therefore its possible role in producing disordered speech, it is of interest to revisit the issue of genetic versus environmental contributions to hippocampal integrity. Compared to other parts of the brain, the hippocampus is acutely vulnerable to hypoxic-ischemic damage (Vargha-Khadem et al., 1997; Zola & Squire, 2001), that is, insult temporarily depriving neural cells of

oxygen. In monozygotic twins discordant for schizophrenia, relatively reduced hippocampal volume in the ill twin was significantly related to the presence of labor-delivery complications and to prolonged labor, both risk factors associated with fetal oxygen deprivation (McNeil, Cantor-Graae, & Weinberger, 2000). Van Erp and colleagues found, in a Helsinki birth cohort, that schizophrenia patients who experienced fetal hypoxia have smaller hippocampal volumes than in those who did not, a difference not noted within unaffected siblings and healthy comparison subjects (Van Erp et al., 2002). At the same time, hippocampal volume differences occurred in a stepwise fashion with increase in genetic vulnerability for developing schizophrenia (consistent with the findings of Seidman et al., 2002), suggesting that, in patients with schizophrenia spectrum disorders, hippocampal volume is influenced in part by schizophrenia susceptibility genes and an interaction of these genes with experience of fetal hypoxia. Together, these findings indicate that while hippocampal volume in healthy subjects is under substantial genetic control, hippocampal volume in schizophrenia patients and their relatives appears to be influenced to a greater extent by unique and shared environmental factors (Van Erp et al., 2002).

Integrating Cognitive Models and Endophenotypes

A number of useful links exist between the cognitive models of disrupted information processing in schizophrenia patients reviewed in the first part of this chapter and the research on neurocognitive endophenotypes in schizophrenia just summarized. At the cognitive level of analysis, there appear to be two mechanisms necessary for the expression of formal thought disorder: an executive, online processing system, responsible for the encoding, maintenance, and updating of goal-related information (context information in the Guided Activation model), and an integrated system involving the consolidation and storage of semantic and episodic information (Kerns, 2007).

In terms of the endophenotype framework developed earlier, individuals at elevated genetic risk, but not expressing the schizophrenia phenotype, show mildly impaired functioning of executive systems and related working memory and attention components. These executive processing deficits therefore appear to be associated with the diathesis, which is necessary but not sufficient for the development of thought disorder. Beyond this diathesis, the

abnormal interaction of executive and semantic memory systems—likely in service of controlled retrieval of information, and its integration into coherent, logically consistent discourse—is associated with a psychosis-specific factor, itself related to both genetic vulnerability and exposure to environmental risk factors. Individuals with schizophrenia and their unaffected co-twins show a qualitatively similar pattern of prefrontal structural and functional abnormality, somewhat greater in severity in the patients. Patients and their relatives additionally show temporal lobe abnormalities; however, the degree of difference in temporal lobe abnormality between schizophrenia patients and genetically vulnerable individuals is significantly larger than the corresponding difference in prefrontal abnormality.

Taken together, these results suggest that mild impairment in prefrontal cortex and associated degradation of online cognitive processing systems (i.e., executive functions, including working memory and selective attention), comprise a necessary but not sufficient (i.e., contributing) cause of thought disorder, which itself derives from a genetic diathesis to developing a psychotic disorder such as schizophrenia. An additional factor, related etiologically to exposure to an environmental insult interacting with genetic predisposition, and also necessary but not sufficient for the expression of schizophrenia, involves disrupted interaction between an executive, online processing system and a semantic memory storage and selection system, loosely mapping onto schizophrenia patients' prefrontal and temporal lobe abnormalities, respectively. That is, abnormalities in both the prefrontal/executive-related circuitry and in the temporal lobe circuitry (i.e., medial temporal lobe for episodic memory and nearby middle temporal gyrus for semantic memory; Kircher et al., 2001) may be required to account for the full range of thought disorder observed in patients with schizophrenia, while only the former may be required to account for the subtler thought disturbances seen in genetically vulnerable individuals who do not manifest the full schizophrenia syndrome phenotypically. Of course, it is also possible that severity of phenotypic thought disorder scales with severity of compromise of both components of the system, rather than to their conjunction *per se*. Further work is needed to segregate these two possibilities.

Conclusions and Future Directions

In summary, research related to the cognitive, genetic, and neural pathologies of thought disorder

in general, and schizophrenia specifically, has necessarily taken on a complex, interactive structure. As we have seen, cognitive models designed to predict particular behavioral outcomes can in fact help researchers understand the functional correlates of anatomical abnormalities measured between genetically defined risk groups. Similar permutations involving these and numerous other levels of analysis equip us with heuristics that guide our struggle to unravel the complexities of neuropsychiatric phenomena such as formal thought disorder. We have attempted to present such a heuristic framework, based on links we have observed between bodies of research into the pathology of thought disorder, some of these links crossing between levels of analysis, ideally helping us to map genetic, neurological, and cognitive systems onto each other.

Along the way to accomplishing this integrative goal, a great deal more work needs to be done. Ideally, the parsing of formal thought disorder into necessary and sufficient functional components will be complemented by further study of the physiological and genetic variations associated with the production of abnormal speech. This line of work will likely be facilitated by cognitive neuroscience's growing ability to study the activity of particular brain mechanisms during the production of speech, overcoming previously prohibitive practical obstacles caused by movement artifacts detrimental to work utilizing common neuroscientific research modalities (e.g., Costa, Strijkers, Martin, & Thierry, 2009). Prior to these methodological advances, only speech production studies employing *covert* vocalization were practical; however, these investigations typically fall short of describing compellingly aspects of formal thought disorder itself, to a phenomenon measured entirely in terms of *overt* speech production.

Additional progress in the study of thought disorder involves application of paradigms from the emerging field of social cognitive neuroscience (e.g., Adolphs, 2003; Wood, 2003) to the study of interpersonal deficits in schizophrenia (e.g., Penn, Ritchie, Francis, Combs, & Martin, 2002; Pinkham, Penn, Perkins, & Lieberman, 2003), including the distinctly interpersonal task of verbal communication (Grossman & Harrow, 1996; Racenstein, Penn, Harrow, & Schleser, 1999). For instance, the study of communication deviance (including aspects of formal thought disorder) within the families of patients with psychotic disorder diagnoses, or patients thought to be at high risk for developing a psychotic disorder, has been an area of active

research for some time (e.g., Docherty, 1995; Sass, Gunderson, Singer, & Wynne, 1984; Wahlberg et al., 2000). Applying this established framework to the examination of neuronal correlates of receptive and productive aspects of intrafamily communication—potentially distinct from communication with nonfamily members due to the role of factors such as increased interpersonal familiarity and less predictable affective modulation of cognitive processes involved in communication—offers a novel perspective with the potential to reinvigorate this important line of thought disorder research.

Another area of thought disorder research deserving of continued attention involves the study of formal thought disorder in populations other than those currently meeting diagnostic criteria for a major mental illness. Although modern antipsychotic medications appear to be relatively effective at helping psychotic patients organize their speech (e.g., Wirshing et al., 1999), significant levels of thought disorder often appear noticeable in groups of patients who would not typically be treated with therapeutic doses of such medications (Andreasen & Grove, 1986).

For instance, examination of a large sample of individuals judged to be at significantly elevated risk for developing a psychotic disorder (in part because they were displaying some psychotic symptoms, only at a level of intensity and/or frequency below diagnostic threshold) found a significant level of formal thought disorder (Woods et al., 2009). Furthermore, communication disturbance in this population has been linked to attentional impairment (Cannon et al., 2002) and to elevated, inefficient activation of prefrontal language areas during a discourse monitoring task (Sabb et al., 2010). These and similar findings raise interesting questions regarding the potential utility of formal thought disorder as a prodromal indicator of psychosis, as well as the potential benefits of symptom-based treatment outside the context of a major psychiatric diagnosis.

Scientific Thinking and Reasoning

Kevin N. Dunbar and David Klahr

Abstract

Scientific thinking refers to both thinking about the *content* of science and the set of *reasoning processes* that permeate the field of science: induction, deduction, experimental design, causal reasoning, concept formation, hypothesis testing, and so on. Here we cover both the history of research on scientific thinking and the different approaches that have been used, highlighting common themes that have emerged over the past 50 years of research. Future research will focus on the collaborative aspects of scientific thinking, on effective methods for teaching science, and on the neural underpinnings of the scientific mind.

Keywords: scientific reasoning, causal reasoning, hypothesis testing, analogical reasoning in science, problem solving, conceptual change, computational modeling, constructivism, science education, cognitive development, educational neuroscience

There is no unitary activity called “scientific discovery”; there are activities of designing experiments, gathering data, inventing and developing observational instruments, formulating and modifying theories, deducing consequences from theories, making predictions from theories, testing theories, inducing regularities and invariants from data, discovering theoretical constructs, and others.

—Simon, Langley, & Bradshaw, 1981, p. 2

What Is Scientific Thinking and Reasoning?

There are two kinds of thinking we call “scientific.” The first, and most obvious, is thinking about the *content* of science. People are engaged in scientific thinking when they are reasoning about such entities and processes as force, mass, energy, equilibrium, magnetism, atoms, photosynthesis, radiation, geology, or astrophysics (and, of course, cognitive psychology!). The second kind of scientific thinking includes the set of *reasoning processes* that permeate

the field of science: induction, deduction, experimental design, causal reasoning, concept formation, hypothesis testing, and so on. However, these reasoning processes are not unique to scientific thinking: They are the very same processes involved in everyday thinking. As Einstein put it:

The scientific way of forming concepts differs from that which we use in our daily life, not basically, but merely in the more precise definition of concepts and conclusions; more painstaking and systematic choice of experimental material, and greater logical economy. (The Common Language of Science, 1941, reprinted in Einstein, 1950, p. 98)

Nearly 40 years after Einstein’s remarkably insightful statement, Francis Crick offered a similar perspective: that great discoveries in science result not from extraordinary mental processes, but rather from rather common ones. The greatness of the discovery lies in the thing discovered.

I think what needs to be emphasized about the discovery of the double helix is that the path to it was, scientifically speaking, fairly commonplace. What was important was *not the way it was discovered*, but the object discovered—the structure of DNA itself. (Crick , 1988, p. 67; emphasis added)

Under this view, scientific thinking involves the same general-purpose cognitive processes—such as induction, deduction, analogy, problem solving, and causal reasoning—that humans apply in non-scientific domains. These processes are covered in several different chapters of this handbook: Rips, Smith, & Medin, Chapter 11 on induction; Evans, Chapter 8 on deduction; Holyoak, Chapter 13 on analogy; Bassok & Novick, Chapter 21 on problem solving; and Cheng & Buehner, Chapter 12 on causality. One might question the claim that the highly specialized procedures associated with doing science in the “real world” can be understood by investigating the thinking processes used in laboratory studies of the sort described in this volume. However, when the focus is on major scientific breakthroughs, rather than on the more routine, incremental progress in a field, the psychology of problem solving provides a rich source of ideas about how such discoveries might occur. As Simon and his colleagues put it:

It is understandable, if ironic, that ‘normal’ science fits . . . the description of expert problem solving, while ‘revolutionary’ science fits the description of problem solving by novices. It is understandable because scientific activity, particularly at the revolutionary end of the continuum, is concerned with the discovery of new truths, not with the application of truths that are already well-known . . . it is basically a journey into unmapped terrain. Consequently, it is mainly characterized, as is novice problem solving, by trial-and-error search. The search may be highly selective—but it reaches its goal only after many halts, turnings, and back-trackings. (Simon, Langley, & Bradshaw, 1981, p. 5)

The research literature on scientific thinking can be roughly categorized according to the two types of scientific thinking listed in the opening paragraph of this chapter: (1) One category focuses on thinking that directly involves scientific *content*. Such research ranges from studies of young children reasoning about the sun-moon-earth system (Vosniadou & Brewer, 1992) to college students reasoning about chemical equilibrium (Davenport, Yaron, Klahr, &

Koedinger, 2008), to research that investigates collaborative problem solving by world-class researchers in real-world molecular biology labs (Dunbar, 1995). (2) The other category focuses on “general” cognitive processes, but it tends to do so by analyzing people’s problem-solving behavior when they are presented with relatively complex situations that involve the integration and coordination of several different types of processes, and that are designed to capture some essential features of “real-world” science in the psychology laboratory (Bruner, Goodnow, & Austin, 1956; Klahr & Dunbar, 1988; Mynatt, Doherty, & Tweney, 1977).

There are a number of overlapping research traditions that have been used to investigate scientific thinking. We will cover both the history of research on scientific thinking and the different approaches that have been used, highlighting common themes that have emerged over the past 50 years of research.

A Brief History of Research on Scientific Thinking

Science is often considered one of the hallmarks of the human species, along with art and literature. Illuminating the thought processes used in science thus reveal key aspects of the human mind. The thought processes underlying scientific thinking have fascinated both scientists and nonscientists because the products of science have transformed our world and because the process of discovery is shrouded in mystery. Scientists talk of the chance discovery, the flash of insight, the years of perspiration, and the voyage of discovery. These images of science have helped make the mental processes underlying the discovery process intriguing to cognitive scientists as they attempt to uncover what really goes on inside the scientific mind and how scientists really think. Furthermore, the possibilities that scientists can be taught to think better by avoiding mistakes that have been clearly identified in research on scientific thinking, and that their scientific process could be partially automated, makes scientific thinking a topic of enduring interest.

The cognitive processes underlying scientific discovery and day-to-day scientific thinking have been a topic of intense scrutiny and speculation for almost 400 years (e.g., Bacon, 1620; Galilei, 1638; Klahr, 2000; Tweney, Doherty, & Mynatt, 1981). Understanding the nature of scientific thinking has been a central issue not only for our understanding of science but also for our understanding of what it is to be human. Bacon’s *Novum Organum* in 1620

sketched out some of the key features of the ways that experiments are designed and data interpreted. Over the ensuing 400 years philosophers and scientists vigorously debated about the appropriate methods that scientists should use (see Giere, 1993). These debates over the appropriate methods for science typically resulted in the espousal of a particular type of reasoning method, such as induction or deduction. It was not until the Gestalt psychologists began working on the nature of human problem solving, during the 1940s, that experimental psychologists began to investigate the cognitive processes underlying scientific thinking and reasoning.

The Gestalt psychologist Max Wertheimer pioneered the investigation of scientific thinking (of the first type described earlier: thinking about scientific content) in his landmark book *Productive Thinking* (Wertheimer, 1945). Wertheimer spent a considerable amount of time corresponding with Albert Einstein, attempting to discover how Einstein generated the concept of relativity. Wertheimer argued that Einstein had to overcome the structure of Newtonian physics at each step in his theorizing, and the ways that Einstein actually achieved this restructuring were articulated in terms of Gestalt theories. (For a recent and different account of how Einstein made his discovery, see Galison, 2003.) We will see later how this process of overcoming alternative theories is an obstacle that both scientists and nonscientists need to deal with when evaluating and theorizing about the world.

One of the first investigations of scientific thinking of the second type (i.e., collections of general-purpose processes operating on complex, abstract, components of scientific thought) was carried out by Jerome Bruner and his colleagues at Harvard (Bruner et al., 1956). They argued that a key activity engaged in by scientists is to determine whether a particular instance is a member of a category. For example, a scientist might want to discover which substances undergo fission when bombarded by neutrons and which substances do not. Here, scientists have to discover the attributes that make a substance undergo fission. Bruner et al. saw scientific thinking as the testing of hypotheses and the collecting of data with the end goal of determining whether something is a member of a category. They invented a paradigm where people were required to formulate hypotheses and collect data that test their hypotheses. In one type of experiment, the participants were shown a card such as one with two borders and three green triangles. The participants

were asked to determine the concept that this card represented by choosing other cards and getting feedback from the experimenter as to whether the chosen card was an example of the concept. In this case the participant may have thought that the concept was green and chosen a card with two green squares and one border. If the underlying concept was green, then the experimenter would say that the card was an example of the concept. In terms of scientific thinking, choosing a new card is akin to conducting an experiment, and the feedback from the experimenter is similar to knowing whether a hypothesis is confirmed or disconfirmed. Using this approach, Bruner et al. identified a number of strategies that people use to formulate and test hypotheses. They found that a key factor determining which hypothesis-testing strategy that people use is the amount of memory capacity that the strategy takes up (see also Morrison & Knowlton, Chapter 6; Medin et al., Chapter 11). Another key factor that they discovered was that it was much more difficult for people to discover negative concepts (e.g., not blue) than positive concepts (e.g., blue). Although Bruner et al.'s research is most commonly viewed as work on concepts, they saw their work as uncovering a key component of scientific thinking.

A second early line of research on scientific thinking was developed by Peter Wason and his colleagues (Wason, 1968). Like Bruner et al., Wason saw a key component of scientific thinking as being the testing of hypotheses. Whereas Bruner et al. focused on the different types of strategies that people use to formulate hypotheses, Wason focused on whether people adopt a strategy of trying to confirm or disconfirm their hypotheses. Using Popper's (1959) theory that scientists should try and falsify rather than confirm their hypotheses, Wason devised a deceptively simple task in which participants were given three numbers, such as 2-4-6, and were asked to discover the rule underlying the three numbers. Participants were asked to generate other triads of numbers and the experimenter would tell the participant whether the triad was consistent or inconsistent with the rule. They were told that when they were sure they knew what the rule was they should state it. Most participants began the experiment by thinking that the rule was even numbers increasing by 2. They then attempted to confirm their hypothesis by generating a triad like 8-10-12, then 14-16-18. These triads are consistent with the rule and the participants were told yes, that the triads were indeed consistent with the rule. However, when

they proposed the rule—even numbers increasing by 2—they were told that the rule was incorrect. The correct rule was numbers of increasing magnitude! From this research, Wason concluded that people try to confirm their hypotheses, whereas normatively speaking, they should try to disconfirm their hypotheses. One implication of this research is that confirmation bias is not just restricted to scientists but is a general human tendency.

It was not until the 1970s that a general account of scientific reasoning was proposed. Herbert Simon, often in collaboration with Allan Newell, proposed that scientific thinking is a form of problem solving. He proposed that problem solving is a search in a problem space. Newell and Simon's theory of problem solving is discussed in many places in this handbook, usually in the context of specific problems (see especially Bassok & Novick, Chapter 21). Herbert Simon, however, devoted considerable time to understanding many different scientific discoveries and scientific reasoning processes. The common thread in his research was that scientific thinking and discovery is not a mysterious magical process but a process of problem solving in which clear heuristics are used. Simon's goal was to articulate the heuristics that scientists use in their research at a fine-grained level. By constructing computer programs that simulated the process of several major scientific discoveries, Simon and colleagues were able to articulate the specific computations that scientists could have used in making those discoveries (Langley, Simon, Bradshaw, & Zytkow, 1987; see section on "Computational Approaches to Scientific Thinking"). Particularly influential was Simon and Lea's (1974) work demonstrating that concept formation and induction consist of a search in two problem spaces: a space of instances and a space of rules. This idea has influenced problem-solving accounts of scientific thinking that will be discussed in the next section.

Overall, the work of Bruner, Wason, and Simon laid the foundations for contemporary research on scientific thinking. Early research on scientific thinking is summarized in Tweney, Doherty and Mynatt's 1981 book *On Scientific Thinking*, where they sketched out many of the themes that have dominated research on scientific thinking over the past few decades. Other more recent books such as *Cognitive Models of Science* (Giere, 1993), *Exploring Science* (Klahr, 2000), *Cognitive Basis of Science* (Carruthers, Stich, & Siegal, 2002), and *New Directions in Scientific and Technical Thinking* (Gorman, Kincannon, Gooding,

& Tweney, 2004) provide detailed analyses of different aspects of scientific discovery. Another important collection is Vosniadou's handbook on conceptual change research (Vosniadou, 2008). In this chapter, we discuss the main approaches that have been used to investigate scientific thinking.

How does one go about investigating the many different aspects of scientific thinking? One common approach to the study of the scientific mind has been to investigate several key aspects of scientific thinking using abstract tasks designed to mimic some essential characteristics of "real-world" science. There have been numerous methodologies that have been used to analyze the genesis of scientific concepts, theories, hypotheses, and experiments. Researchers have used experiments, verbal protocols, computer programs, and analyzed particular scientific discoveries. A more recent development has been to increase the ecological validity of such research by investigating scientists as they reason "live" (in vivo studies of scientific thinking) in their own laboratories (Dunbar, 1995, 2002). From a "Thinking and Reasoning" standpoint the major aspects of scientific thinking that have been most actively investigated are problem solving, analogical reasoning, hypothesis testing, conceptual change, collaborative reasoning, inductive reasoning, and deductive reasoning.

SCIENTIFIC THINKING AS PROBLEM SOLVING

One of the primary goals of accounts of scientific thinking has been to provide an overarching framework to understand the scientific mind. One framework that has had a great influence in cognitive science is that scientific thinking and scientific discovery can be conceived as a form of problem solving. As noted in the opening section of this chapter, Simon (1977; Simon, Langley, & Bradshaw, 1981) argued that both scientific thinking in general and problem solving in particular could be thought of as a search in a problem space. A problem space consists of all the possible states of a problem and all the operations that a problem solver can use to get from one state to the next. According to this view, by characterizing the types of representations and procedures that people use to get from one state to another it is possible to understand scientific thinking. Thus, scientific thinking can be characterized as a search in various problem spaces (Simon, 1977). Simon investigated a number of scientific discoveries by bringing participants into the laboratory, providing the participants with the data that a scientist had access to, and getting the participants to reason

about the data and rediscover a scientific concept. He then analyzed the verbal protocols that participants generated and mapped out the types of problem spaces that the participants search in (e.g., Qin & Simon, 1990). Kulkarni and Simon (1988) used a more historical approach to uncover the problem-solving heuristics that Krebs used in his discovery of the urea cycle. Kulkarni and Simon analyzed Krebs's diaries and proposed a set of problem-solving heuristics that he used in his research. They then built a computer program incorporating the heuristics and biological knowledge that Krebs had before he made his discoveries. Of particular importance are the search heuristics that the program uses, which include experimental proposal heuristics and data interpretation heuristics. A key heuristic was an unusualness heuristic that focused on unusual findings, which guided search through a space of theories and a space of experiments.

Klahr and Dunbar (1988) extended the search in a problem space approach and proposed that scientific thinking can be thought of as a search through two related spaces: an hypothesis space and an experiment space. Each problem space that a scientist uses will have its own types of representations and operators used to change the representations. Search in the hypothesis space constrains search in the experiment space. Klahr and Dunbar found that some participants move from the hypothesis space to the experiment space, whereas others move from the experiment space to the hypothesis space. These different types of searches lead to the proposal of different types of hypotheses and experiments. More recent work has extended the dual-space approach to include alternative problem-solving spaces, including those for data, instrumentation, and domain-specific knowledge (Klahr & Simon, 1999; Schunn & Klahr, 1995, 1996).

SCIENTIFIC THINKING AS HYPOTHESIS TESTING

Many researchers have regarded testing specific hypotheses predicted by theories as one of the key attributes of scientific thinking. Hypothesis testing is the process of evaluating a proposition by collecting evidence regarding its truth. Experimental cognitive research on scientific thinking that specifically examines this issue has tended to fall into two broad classes of investigations. The first class is concerned with the types of reasoning that lead scientists astray, thus blocking scientific ingenuity. A large amount of research has been conducted on the potentially

faulty reasoning strategies that both participants in experiments and scientists use, such as considering only one favored hypothesis at a time and how this prevents the scientists from making discoveries. The second class is concerned with uncovering the mental processes underlying the generation of new scientific hypotheses and concepts. This research has tended to focus on the use of analogy and imagery in science, as well as the use of specific types of problem-solving heuristics.

Turning first to investigations of what diminishes scientific creativity, philosophers, historians, and experimental psychologists have devoted a considerable amount of research to "confirmation bias." This occurs when scientists only consider one hypothesis (typically the favored hypothesis) and ignore other alternative hypotheses or potentially relevant hypotheses. This important phenomenon can distort the design of experiments, formulation of theories, and interpretation of data. Beginning with the work of Wason (1968) and as discussed earlier, researchers have repeatedly shown that when participants are asked to design an experiment to test a hypothesis they will predominantly design experiments that they think will yield results consistent with the hypothesis. Using the 2-4-6 task mentioned earlier, Klayman and Ha (1987) showed that in situations where one's hypothesis is likely to be confirmed, seeking confirmation is a normatively incorrect strategy, whereas when the probability of confirming one's hypothesis is low, then attempting to confirm one's hypothesis can be an appropriate strategy. Historical analyses by Tweney (1989), concerning the way that Faraday made his discoveries, and experiments investigating people testing hypotheses, have revealed that people use a confirm early, disconfirm late strategy: When people initially generate or are given hypotheses, they try and gather evidence that is consistent with the hypothesis. Once enough evidence has been gathered, then people attempt to find the boundaries of their hypothesis and often try to disconfirm their hypotheses.

In an interesting variant on the confirmation bias paradigm, Gorman (1989) showed that when participants are told that there is the possibility of error in the data that they receive, participants assume that any data that are inconsistent with their favored hypothesis are due to error. Thus, the possibility of error "insulates" hypotheses against disconfirmation. This intriguing hypothesis has not been confirmed by other researchers (Penner & Klahr, 1996),

but it is an intriguing hypothesis that warrants further investigation.

Confirmation bias is very difficult to overcome. Even when participants are asked to consider alternate hypotheses, they will often fail to conduct experiments that could potentially disconfirm their hypothesis. Tweney and his colleagues provide an excellent overview of this phenomenon in their classic monograph *On Scientific Thinking* (1981). The precise reasons for this type of block are still widely debated. Researchers such as Michael Doherty have argued that working memory limitations make it difficult for people to consider more than one hypothesis. Consistent with this view, Dunbar and Sussman (1995) have shown that when participants are asked to hold irrelevant items in working memory while testing hypotheses, the participants will be unable to switch hypotheses in the face of inconsistent evidence. While working memory limitations are involved in the phenomenon of confirmation bias, even groups of scientists can also display confirmation bias. For example, the controversy over cold fusion is an example of confirmation bias. Here, large groups of scientists had other hypotheses available to explain their data yet maintained their hypotheses in the face of other more standard alternative hypotheses. Mitroff (1974) provides some interesting examples of NASA scientists demonstrating confirmation bias, which highlight the roles of commitment and motivation in this process. See also MacPherson and Stanovich (2007) for specific strategies that can be used to overcome confirmation bias.

Causal Thinking in Science

Much of scientific thinking and scientific theory building pertains to the development of causal models between variables of interest. For example, do vaccines cause illnesses? Do carbon dioxide emissions cause global warming? Does water on a planet indicate that there is life on the planet? Scientists and nonscientists alike are constantly bombarded with statements regarding the causal relationship between such variables. How does one evaluate the status of such claims? What kinds of data are informative? How do scientists and nonscientists deal with data that are inconsistent with their theory?

A central issue in the causal reasoning literature, one that is directly relevant to scientific thinking, is the extent to which scientists and nonscientists alike are governed by the search for causal mechanisms (i.e., how a variable works) versus the search for statistical data (i.e., how often variables co-occur).

This dichotomy can be boiled down to the search for qualitative versus quantitative information about the paradigm the scientist is investigating. Researchers from a number of cognitive psychology laboratories have found that people prefer to gather more information about an underlying mechanism than covariation between a cause and an effect (e.g., Ahn, Kalish, Medin, & Gelman, 1995). That is, the predominant strategy that students in simulations of scientific thinking use is to gather as much information as possible about how the objects under investigation work, rather than collecting large amounts of quantitative data to determine whether the observations hold across multiple samples. These findings suggest that a central component of scientific thinking may be to formulate explicit mechanistic causal models of scientific events.

One type of situation in which causal reasoning has been observed extensively is when scientists obtain unexpected findings. Both historical and naturalistic research has revealed that reasoning causally about unexpected findings plays a central role in science. Indeed, scientists themselves frequently state that a finding was due to chance or was unexpected. Given that claims of unexpected findings are such a frequent component of scientists' autobiographies and interviews in the media, Dunbar (1995, 1997, 1999; Dunbar & Fugelsang, 2005; Fugelsang, Stein, Green, & Dunbar, 2004) decided to investigate the ways that scientists deal with unexpected findings. In 1991–1992 Dunbar spent 1 year in three molecular biology laboratories and one immunology laboratory at a prestigious U.S. university. He used the weekly laboratory meeting as a source of data on scientific discovery and scientific reasoning. (He termed this type of study "in vivo" cognition.) When he looked at the types of findings that the scientists made, he found that over 50% of the findings were unexpected and that these scientists had evolved a number of effective strategies for dealing with such findings. One clear strategy was to reason causally about the findings: Scientists attempted to build causal models of their unexpected findings. This causal model building results in the extensive use of collaborative reasoning, analogical reasoning, and problem-solving heuristics (Dunbar, 1997, 2001).

Many of the key unexpected findings that scientists reasoned about in the in vivo studies of scientific thinking were inconsistent with the scientists' preexisting causal models. A laboratory equivalent of the biology labs involved creating a situation in

which students obtained unexpected findings that were inconsistent with their preexisting theories. Dunbar and Fugelsang (2005) examined this issue by creating a scientific causal thinking simulation where experimental outcomes were either expected or unexpected. Dunbar (1995) has called the study of people reasoning in a cognitive laboratory “*in vitro*” cognition. These investigators found that students spent considerably more time reasoning about unexpected findings than expected findings. In addition, when assessing the overall degree to which their hypothesis was supported or refuted, participants spent the majority of their time considering unexpected findings. An analysis of participants’ verbal protocols indicates that much of this extra time was spent formulating causal models for the unexpected findings. Similarly, scientists spend more time considering unexpected than expected findings, and this time is devoted to building causal models (Dunbar & Fugelsang, 2004).

Scientists know that unexpected findings occur often, and they have developed many strategies to take advantage of their unexpected findings. One of the most important places that they anticipate the unexpected is in designing experiments (Baker & Dunbar, 2000). They build different causal models of their experiments incorporating many conditions and controls. These multiple conditions and controls allow unknown mechanisms to manifest themselves. Thus, rather than being the victims of the unexpected, they create opportunities for unexpected events to occur, and once these events do occur, they have causal models that allow them to determine exactly where in the causal chain their unexpected finding arose. The results of these *in vivo* and *in vitro* studies all point to a more complex and nuanced account of how scientists and nonscientists alike test and evaluate hypotheses about theories.

The Roles of Inductive, Abductive, and Deductive Thinking in Science

One of the most basic characteristics of science is that scientists assume that the universe that we live in follows predictable rules. Scientists reason using a variety of different strategies to make new scientific discoveries. Three frequently used types of reasoning strategies that scientists use are inductive, abductive, and deductive reasoning. In the case of inductive reasoning, a scientist may observe a series of events and try to discover a rule that governs the event. Once a rule is discovered, scientists can extrapolate from the rule to formulate theories of observed and yet-to-be-observed phenomena. One example is the discovery

using inductive reasoning that a certain type of bacterium is a cause of many ulcers (Thagard, 1999). In a fascinating series of articles, Thagard documented the reasoning processes that Marshall and Warren went through in proposing this novel hypothesis. One key reasoning process was the use of induction by generalization. Marshall and Warren noted that almost all patients with gastric entritis had a spiral bacterium in their stomachs, and he formed the generalization that this bacterium is the cause of stomach ulcers. There are numerous other examples of induction by generalization in science, such as Tycho De Brea’s induction about the motion of planets from his observations, Dalton’s use of induction in chemistry, and the discovery of prions as the source of mad cow disease. Many theories of induction have used scientific discovery and reasoning as examples of this important reasoning process.

Another common type of inductive reasoning is to map a feature of one member of a category to another member of a category. This is called categorical induction. This type of induction is a way of projecting a known property of one item onto another item that is from the same category. Thus, knowing that the Rous Sarcoma virus is a retrovirus that uses RNA rather than DNA, a biologist might assume that another virus that is thought to be a retrovirus also uses RNA rather than DNA. While research on this type of induction typically has not been discussed in accounts of scientific thinking, this type of induction is common in science. For an influential contribution to this literature, see Smith, Shafir, and Osherson (1993), and for reviews of this literature see Heit (2000) and Medin et al. (Chapter 11).

While less commonly mentioned than inductive reasoning, abductive reasoning is an important form of reasoning that scientists use when they are seeking to propose explanations for events such as unexpected findings (see Lombrozo, Chapter 14; Magnani, et al., 2010). In Figure 35.1, taken from King (2011), the differences between inductive, abductive, and deductive thinking are highlighted. In the case of abduction, the reasoner attempts to generate explanations of the form “if situation X had occurred, could it have produced the current evidence I am attempting to interpret?” (For an interesting analysis of abductive reasoning see the brief paper by Klahr & Masnick, 2001). Of course, as in classical induction, such reasoning may produce a plausible account that is still not the correct one. However, abduction does involve the generation of new knowledge, and is thus also related to research on creativity.

Like humans, robots can use various methods of reasoning. The methods may or may not be sound, but they provide ways to form hypotheses and suggest experiments that can be performed to test those hypotheses.

Fig. 35.1 The different processes underlying inductive, abductive, and deductive reasoning in science. (Figure reproduced from King 2011.)

Turning now to deductive thinking, many thinking processes that scientists adhere to follow traditional rules of deductive logic. These processes correspond to those conditions in which a hypothesis may lead to, or is deducible to, a conclusion. Though they are not always phrased in syllogistic form, deductive arguments can be phrased as “syllogisms,” or as brief, mathematical statements in which the premises lead to the conclusion. Deductive reasoning is an extremely important aspect of scientific thinking because it underlies a large component of how scientists conduct their research. By looking at many scientific discoveries, we can often see that deductive reasoning is at work. Deductive reasoning statements all contain information or rules that state an assumption about how the world works, as well as a conclusion that would necessarily follow from the rule. Numerous discoveries in physics such as the discovery of dark matter by Vera Rubin are

based on deductions. In the dark matter case, Rubin measured galactic rotation curves and based on the differences between the predicted and observed angular motions of galaxies she deduced that the structure of the universe was uneven. This led her to propose that dark matter existed. In contemporary physics the CERN Large Hadron Collider is being used to search for the Higgs Boson. The Higgs Boson is a deductive prediction from contemporary physics. If the Higgs Boson is not found, it may lead to a radical revision of the nature of physics and a new understanding of mass (Hecht, 2011).

The Roles of Analogy in Scientific Thinking

One of the most widely mentioned reasoning processes used in science is analogy. Scientists use analogies to form a bridge between what they already know and what they are trying to explain, understand, or discover. In fact, many scientists have claimed that

the making of certain analogies was instrumental in their making a scientific discovery, and almost all scientific autobiographies and biographies feature one particular analogy that is discussed in depth. Coupled with the fact that there has been an enormous research program on analogical thinking and reasoning (see Holyoak, Chapter 13), we now have a number of models and theories of analogical reasoning that suggest how analogy can play a role in scientific discovery (see Gentner, Holyoak, & Kokinov, 2001). By analyzing several major discoveries in the history of science, Thagard and Croft (1999), Nersessian (1999, 2008), and Gentner and Jeziorski (1993) have all shown that analogical reasoning is a key aspect of scientific discovery.

Traditional accounts of analogy distinguish between two components of analogical reasoning: the target and the source (Holyoak, Chapter 13; Gentner, 2010). The target is the concept or problem that a scientist is attempting to explain or solve. The source is another piece of knowledge that the scientist uses to understand the target or to explain the target to others. What the scientist does when he or she makes an analogy is to map features of the source onto features of the target. By mapping the features of the source onto the target, new features of the target may be discovered, or the features of the target may be rearranged so that a new concept is invented and a scientific discovery is made. For example, a common analogy that is used with computers is to describe a harmful piece of software as a computer virus. Once a piece of software is called a virus, people can map features of biological viruses, such as that it is small, spreads easily, self-replicates using a host, and causes damage. People not only map individual features of the source onto the target but also the systems of relations. For example, if a computer virus is similar to a biological virus, then an immune system can be created on computers that can protect computers from future variants of a virus. One of the reasons that scientific analogy is so powerful is that it can generate new knowledge, such as the creation of a computational immune system having many of the features of a real biological immune system. This analogy also leads to predictions that there will be newer computer viruses that are the computational equivalent of retroviruses, lacking DNA, or standard instructions, that will elude the computational immune system.

The process of making an analogy involves a number of key steps: retrieval of a source from memory, aligning the features of the source with those of the

target, mapping features of the source onto those of the target, and possibly making new inferences about the target. Scientific discoveries are made when the source highlights a hitherto unknown feature of the target or restructures the target into a new set of relations. Interestingly, research on analogy has shown that participants do not easily use remote analogies (see Gentner et al., 1997; Holyoak & Thagard 1995). Participants in experiments tend to focus on the sharing of a superficial feature between the source and the target, rather than the relations among features. In his *in vivo* studies of science, Dunbar (1995, 2001, 2002) investigated the ways that scientists use analogies while they are conducting their research and found that scientists use both relational and superficial features when they make analogies. Whether they use superficial or relational features depends on their goals. If their goal is to fix a problem in an experiment, their analogies are based upon superficial features. However, if their goal is to formulate hypotheses, they focus on analogies based upon sets of relations. One important difference between scientists and participants in experiments is that the scientists have deep relational knowledge of the processes that they are investigating and can hence use this relational knowledge to make analogies (see Holyoak, Chapter 13 for a thorough review of analogical reasoning).

Are scientific analogies always useful? Sometimes analogies can lead scientists and students astray. For example, Evelyn Fox-Keller (1985) shows how an analogy between the pulsing of a lighthouse and the activity of the slime mold *dictyostelium* led researchers astray for a number of years. Likewise, the analogy between the solar system (the source) and the structure of the atom (the target) has been shown to be potentially misleading to students taking more advanced courses in physics or chemistry. The solar system analogy has a number of misalignments to the structure of the atom, such as electrons being repelled from each other rather than attracted; moreover, electrons do not have individual orbits like planets but have orbit clouds of electron density. Furthermore, students have serious misconceptions about the nature of the solar system, which can compound their misunderstanding of the nature of the atom (Fischler & Lichtfeld, 1992). While analogy is a powerful tool in science, like all forms of induction, incorrect conclusions can be reached.

Conceptual Change in Science

Scientific knowledge continually accumulates as scientists gather evidence about the natural world.

Over extended time, this knowledge accumulation leads to major revisions, extensions, and new organizational forms for expressing what is known about nature. Indeed, these changes are so substantial that philosophers of science speak of “revolutions” in a variety of scientific domains (Kuhn, 1962). The psychological literature that explores the idea of revolutionary conceptual change can be roughly divided into (a) investigations of how scientists actually make discoveries and integrate those discoveries into existing scientific contexts, and (b) investigations of nonscientists ranging from infants, to children, to students in science classes. In this section we summarize the adult studies of conceptual change, and in the next section we look at its developmental aspects.

Scientific concepts, like all concepts, can be characterized as containing a variety of “knowledge elements”: representations of words, thoughts, actions, objects, and processes. At certain points in the history of science, the accumulated evidence has demanded major shifts in the way these collections of knowledge elements are organized. This “radical conceptual change” process (see Keil, 1999; Nersessian, 1998, 2002; Thagard, 1992; Vosniadou, 1998, for reviews) requires the formation of a new conceptual system that organizes knowledge in new ways, adds new knowledge, and results in a very different conceptual structure. For more recent research on conceptual change, *The International Handbook of Research on Conceptual Change* (Vosniadou, 2008) provides a detailed compendium of theories and controversies within the field.

While conceptual change in science is usually characterized by large-scale changes in concepts that occur over extensive periods of time, it has been possible to observe conceptual change using *in vivo* methodologies. Dunbar (1995) reported a major conceptual shift that occurred in immunologists, where they obtained a series of unexpected findings that forced the scientists to propose a new concept in immunology that in turn forced the change in other concepts. The drive behind this conceptual change was the discovery of a series of different unexpected findings or anomalies that required the scientists to both revise and reorganize their conceptual knowledge. Interestingly, this conceptual change was achieved by a group of scientists reasoning collaboratively, rather than by a scientist working alone. Different scientists tend to work on different aspects of concepts, and also different concepts, that when put together lead to a rapid change in entire conceptual structures.

Overall, accounts of conceptual change in individuals indicate that it is indeed similar to that of conceptual change in entire scientific fields. Individuals need to be confronted with anomalies that their preexisting theories cannot explain before entire conceptual structures are overthrown. However, replacement conceptual structures have to be generated before the old conceptual structure can be discarded. Sometimes, people do not overthrow their original conceptual theories and through their lives maintain their original views of many fundamental scientific concepts. Whether people actively possess naive theories, or whether they appear to have a naive theory because of the demand characteristics of the testing context, is a lively source of debate within the science education community (see Gupta, Hammer, & Redish, 2010).

Scientific Thinking in Children

Well before their first birthday, children appear to know several fundamental facts about the physical world. For example, studies with infants show that they behave as if they understand that solid objects endure over time (e.g., they don't just disappear and reappear, they cannot move through each other, and they move as a result of collisions with other solid objects or the force of gravity (Baillargeon, 2004; Carey, 1985; Cohen & Cashon, 2006; Duschl, Schweingruber, & Shouse, 2007; Gelman & Baillargeon, 1983; Gelman & Kalish, 2006; Mandler, 2004; Metz, 1995; Munakata, Casey, & Diamond, 2004). And even 6-month-olds are able to predict the future location of a moving object that they are attempting to grasp (Von Hofsten, 1980; Von Hofsten, Feng, & Spelke, 2000). In addition, they appear to be able to make nontrivial inferences about causes and their effects (Gopnik et al., 2004).

The similarities between children's thinking and scientists' thinking have an inherent allure and an internal contradiction. The allure resides in the enthusiastic wonder and openness with which both children and scientists approach the world around them. The paradox comes from the fact that different investigators of children's thinking have reached diametrically opposing conclusions about just how “scientific” children's thinking really is. Some claim support for the “child as a scientist” position (Brewer & Samarpungavan, 1991; Gelman & Wellman, 1991; Gopnik, Meltzoff, & Kuhl, 1999; Karmiloff-Smith, 1988; Sodian, Zaitchik, & Carey, 1991; Samarpungavan, 1992), while others offer serious challenges to the view (Fay & Klahr, 1996;

Kern, Mirels, & Hinshaw, 1983; Kuhn, Amsel, & O'Laughlin, 1988; Schauble & Glaser, 1990; Siegler & Liebert, 1975.) Such fundamentally incommensurate conclusions suggest that this very field—children's scientific thinking—is ripe for a conceptual revolution!

A recent comprehensive review (Duschl, Schweingruber, & Shouse, 2007) of what children bring to their science classes offers the following concise summary of the extensive developmental and educational research literature on children's scientific thinking:

- Children entering school already have substantial knowledge of the natural world, much of which is implicit.
- What children are capable of at a particular age is the result of a complex interplay among maturation, experience, and instruction. What is developmentally appropriate is not a simple function of age or grade, but rather is largely contingent on children's prior opportunities to learn.
- Students' knowledge and experience play a critical role in their science learning, influencing four aspects of science understanding, including (*a*) knowing, using, and interpreting scientific explanations of the natural world; (*b*) generating and evaluating scientific evidence and explanations, (*c*) understanding how scientific knowledge is developed in the scientific community, and (*d*) participating in scientific practices and discourse.
- Students learn science by actively engaging in the practices of science.

In the previous section of this article we discussed conceptual change with respect to scientific fields and undergraduate science students. However, the idea that children undergo radical conceptual change in which old "theories" need to be overthrown and reorganized has been a central topic in understanding changes in scientific thinking in both children and across the life span. This radical conceptual change is thought to be necessary for acquiring many new concepts in physics and is regarded as the major source of difficulty for students. The factors that are at the root of this conceptual shift view have been difficult to determine, although there have been a number of studies in cognitive development (Carey, 1985; Chi, 1992; Chi & Roscoe, 2002), in the history of science (Thagard, 1992), and in physics education (Clement, 1982; Mestre, 1991) that give detailed accounts of the changes

in knowledge representation that occur while people switch from one way of representing scientific knowledge to another.

One area where students show great difficulty in understanding scientific concepts is physics. Analyses of students' changing conceptions, using interviews, verbal protocols, and behavioral outcome measures, indicate that large-scale changes in students' concepts occur in physics education (see McDermott & Redish, 1999, for a review of this literature). Following Kuhn (1962), many researchers, but not all, have noted that students' changing conceptions resemble the sequences of conceptual changes in physics that have occurred in the history of science. These notions of radical paradigm shifts and ensuing incompatibility with past knowledge-states have called attention to interesting parallels between the development of particular scientific concepts in children and in the history of physics. Investigations of nonphysicists' understanding of motion indicate that students have extensive misunderstandings of motion. Some researchers have interpreted these findings as an indication that many people hold erroneous beliefs about motion similar to a medieval "impetus" theory (McCloskey, Caramazza, & Green, 1980). Furthermore, students appear to maintain "impetus" notions even after one or two courses in physics. In fact, some authors have noted that students who have taken one or two courses in physics can perform worse on physics problems than naive students (Mestre, 1991). Thus, it is only after extensive learning that we see a conceptual shift from impetus theories of motion to Newtonian scientific theories.

How one's conceptual representation shifts from "naive" to Newtonian is a matter of contention, as some have argued that the shift involves a radical conceptual change, whereas others have argued that the conceptual change is not really complete. For example, Kozhevnikov and Hegarty (2001) argue that much of the naive impetus notions of motion are maintained at the expense of Newtonian principles even with extensive training in physics. However, they argue that such impetus principles are maintained at an implicit level. Thus, although students can give the correct Newtonian answer to problems, their reaction times to respond indicate that they are also using impetus theories when they respond. An alternative view of conceptual change focuses on whether there are real conceptual changes at all. Gupta, Hammer and Redish (2010) and Disessa (2004) have conducted detailed investigations of changes

in physics students' accounts of phenomena covered in elementary physics courses. They have found that rather than students possessing a naive theory that is replaced by the standard theory, many introductory physics students have no stable physical theory but rather construct their explanations from elementary pieces of knowledge of the physical world.

Computational Approaches to Scientific Thinking

Computational approaches have provided a more complete account of the scientific mind. Computational models provide specific detailed accounts of the cognitive processes underlying scientific thinking. Early computational work consisted of taking a scientific discovery and building computational models of the reasoning processes involved in the discovery. Langley, Simon, Bradshaw, and Zytkow (1987) built a series of programs that simulated discoveries such as those of Copernicus, Bacon, and Stahl. These programs had various inductive reasoning algorithms built into them, and when given the data that the scientists used, they were able to propose the same rules. Computational models make it possible to propose detailed models of the cognitive subcomponents of scientific thinking that specify exactly how scientific theories are generated, tested, and amended (see Darden, 1997, and Shrager & Langley, 1990, for accounts of this branch of research). More recently, the incorporation of scientific knowledge into computer programs has resulted in a shift in emphasis from using programs to simulate discoveries to building programs that are used to help scientists make discoveries. A number of these computer programs have made novel discoveries. For example, Valdes-Perez (1994) has built systems for discoveries in chemistry, and Fajtlowicz has done this in mathematics (Erdos, Fajtlowicz, & Staton, 1991).

These advances in the fields of computer discovery have led to new fields, conferences, journals, and even departments that specialize in the development of programs devised to search large databases in the hope of making new scientific discoveries (Langley, 2000, 2002). This process is commonly known as "data mining." This approach has only proved viable relatively recently, due to advances in computer technology. Biswal et al. (2010), Mitchell (2009), and Yang (2009) provide recent reviews of data mining in different scientific fields. Data mining is at the core of drug discovery, our understanding of the human genome, and our understanding

of the universe for a number of reasons. First, vast databases concerning drug actions, biological processes, the genome, the proteome, and the universe itself now exist. Second, the development of high throughput data-mining algorithms makes it possible to search for new drug targets, novel biological mechanisms, and new astronomical phenomena in relatively short periods of time. Research programs that took decades, such as the development of penicillin, can now be done in days (Yang, 2009).

Another recent shift in the use of computers in scientific discovery has been to have both computers and people make discoveries together, rather than expecting that computers make an entire scientific discovery. Now instead of using computers to mimic the entire scientific discovery process as used by humans, computers can use powerful algorithms that search for patterns on large databases and provide the patterns to humans who can then use the output of these computers to make discoveries, ranging from the human genome to the structure of the universe. However, there are some robots such as ADAM, developed by King (2011), that can actually perform the entire scientific process, from the generation of hypotheses, to the conduct of experiments and the interpretation of results, with little human intervention. The ongoing development of scientific robots by some scientists (King et al., 2009) thus continues the tradition started by Herbert Simon in the 1960s. However, many of the controversies as to whether the robot is a "real scientist" or not continue to the present (Evans & Rzhetsky, 2010, Gianfelici, 2010; Haufe, Elliott, Burian, & O'Malley, 2010; O' Malley, 2011).

Scientific Thinking and Science Education

Accounts of the nature of science and research on scientific thinking have had profound effects on science education along many levels, particularly in recent years. Science education from the 1900s until the 1970s was primarily concerned with teaching students both the content of science (such as Newton's laws of motion) or the methods that scientists need to use in their research (such as using experimental and control groups). Beginning in the 1980s, a number of reports (e.g., American Association for the Advancement of Science, 1993; National Commission on Excellence in Education, 1983; Rutherford & Ahlgren, 1991) stressed the need for teaching scientific thinking skills rather than just methods and content. The addition of scientific thinking skills to the science curriculum

from kindergarten through adulthood was a major shift in focus. Many of the particular scientific thinking skills that have been emphasized are skills covered in previous sections of this chapter, such as teaching deductive and inductive thinking strategies. However, rather than focusing on one particular skill, such as induction, researchers in education have focused on how the different components of scientific thinking are put together in science. Furthermore, science educators have focused upon situations where science is conducted collaboratively, rather than being the product of one person thinking alone. These changes in science education parallel changes in methodologies used to investigate science, such as analyzing the ways that scientists think and reason in their laboratories.

By looking at science as a complex multilayered and group activity, many researchers in science education have adopted a constructivist approach. This approach sees learning as an active rather than a passive process, and it suggests that students learn through constructing their scientific knowledge. We will first describe a few examples of the constructivist approach to science education. Following that, we will address several lines of work that challenge some of the assumptions of the constructivist approach to science education.

Often the goal of constructivist science education is to produce conceptual change through guided instruction where the teacher or professor acts as a guide to discovery, rather than the keeper of all the facts. One recent and influential approach to science education is the inquiry-based learning approach. Inquiry-based learning focuses on posing a problem or a puzzling event to students and asking them to propose a hypothesis that could explain the event. Next, the student is asked to collect data that test the hypothesis, make conclusions, and then reflect upon both the original problem and the thought processes that they used to solve the problem. Often students use computers that aid in their construction of new knowledge. The computers allow students to learn many of the different components of scientific thinking. For example, Reiser and his colleagues have developed a learning environment for biology, where students are encouraged to develop hypotheses in groups, codify the hypotheses, and search databases to test these hypotheses (Reiser et al., 2001).

One of the myths of science is the lone scientist suddenly shouting “Eureka, I have made a discovery!” Instead, *in vivo* studies of scientists (e.g.,

Dunbar, 1995, 2002), historical analyses of scientific discoveries (Nersessian, 1999), and studies of children learning science at museums have all pointed to collaborative scientific discovery mechanisms as being one of the driving forces of science (Atkins et al., 2009; Azmitia & Crowley, 2001). What happens during collaborative scientific thinking is that there is usually a triggering event, such as an unexpected result or situation that a student does not understand. This results in other members of the group adding new information to the person’s representation of knowledge, often adding new inductions and deductions that both challenge and transform the reasoner’s old representations of knowledge (Chi & Roscoe, 2002; Dunbar, 1998). Social mechanisms play a key component in fostering changes in concepts that have been ignored in traditional cognitive research but are crucial for both science and science education. In science education there has been a shift to collaborative learning, particularly at the elementary level; however, in university education, the emphasis is still on the individual scientist. As many domains of science now involve collaborations across scientific disciplines, we expect the explicit teaching of heuristics for collaborative science to increase.

What is the best way to teach and learn science? Surprisingly, the answer to this question has been difficult to uncover. For example, toward the end of the last century, influenced by several thinkers who advocated a constructivist approach to learning, ranging from Piaget (Beilin, 1994) to Papert (1980), many schools answered this question by adopting a philosophy dubbed “discovery learning.” Although a clear operational definition of this approach has yet to be articulated, the general idea is that children are expected to learn science by reconstructing the processes of scientific discovery—in a range of areas from computer programming to chemistry to mathematics. The premise is that letting students discover principles on their own, set their own goals, and collaboratively explore the natural world produces deeper knowledge that transfers widely.

The research literature on science education is far from consistent in its use of terminology. However, our reading suggests that “discovery learning” differs from “inquiry-based learning” in that few, if any, guidelines are given to students in discovery learning contexts, whereas in inquiry learning, students are given hypotheses and specific goals to achieve (see the second paragraph of this section for a definition of inquiry-based learning). Even though thousands of schools have adopted discovery learning as an

alternative to more didactic approaches to teaching and learning, the evidence showing that it is more effective than traditional, direct, teacher-controlled instructional approaches is mixed, at best (Lorch et al., 2010; Minner, Levy, & Century, 2010). In several cases where the distinctions between direct instruction and more open-ended constructivist instruction have been clearly articulated, implemented, and assessed, direct instruction has proven to be superior to the alternatives (Chen & Klahr, 1999; Toth, Klahr, & Chen, 2000). For example, in a study of third- and fourth-grade children learning about experimental design, Klahr and Nigam (2004) found that many more children learned from direct instruction than from discovery learning. Furthermore, they found that among the few children who did manage to learn from a discovery method, there was no better performance on a far transfer test of scientific reasoning than that observed for the many children who learned from direct instruction.

The idea of children learning most of their science through a process of self-directed discovery has some romantic appeal, and it may accurately describe the personal experience of a handful of world-class scientists. However, the claim has generated some contentious disagreements (Kirschner, Sweller, & Clark, 2006; Klahr, 2010; Taber, 2009; Tobias & Duffy, 2009), and the jury remains out on the extent to which most children can learn science that way.

Conclusions and Future Directions

The field of scientific thinking is now a thriving area of research with strong underpinnings in cognitive psychology and cognitive science. In recent years, a new professional society has been formed that aims to facilitate this integrative and interdisciplinary approach to the psychology of science, with its own journal and regular professional meetings.¹ Clearly the relations between these different aspects of scientific thinking need to be combined in order to produce a truly comprehensive picture of the scientific mind.

While much is known about certain aspects of scientific thinking, much more remains to be discovered. In particular, there has been little contact between cognitive, neuroscience, social, personality, and motivational accounts of scientific thinking. Research in thinking and reasoning has been expanded to use the methods and theories of cognitive neuroscience (see Morrison & Knowlton, Chapter 6). A similar

approach can be taken in exploring scientific thinking (see Dunbar et al., 2007). There are two main reasons for taking a neuroscience approach to scientific thinking. First, functional neuroimaging allows the researcher to look at the entire human brain, making it possible to see the many different sites that are involved in scientific thinking and gain a more complete understanding of the entire range of mechanisms involved in this type of thought. Second, these brain-imaging approaches allow researchers to address fundamental questions in research on scientific thinking, such as the extent to which ordinary thinking in non-scientific contexts and scientific thinking recruit similar versus disparate neural structures of the brain.

Dunbar (2009) has used some novel methods to explore Simon's assertion, cited at the beginning of this chapter, that scientific thinking uses the same cognitive mechanisms that all human beings possess (rather than being an entirely different type of thinking) but combines them in ways that are specific to a particular aspect of science or a specific discipline of science. For example, Fugelsang and Dunbar (2009) compared causal reasoning when two colliding circular objects were labeled balls or labeled subatomic particles. They obtained different brain activation patterns depending on whether the stimuli were labeled balls or subatomic particles. In another series of experiments, Dunbar and colleagues used functional magnetic resonance imaging (fMRI) to study patterns of activation in the brains of students who have and who have not undergone conceptual change in physics. For example, Fugelsang and Dunbar (2005) and Dunbar et al. (2007) have found differences in the activation of specific brain sites (such as the anterior cingulate) for students when they encounter evidence that is inconsistent with their current conceptual understandings. These initial cognitive neuroscience investigations have the potential to reveal the ways that knowledge is organized in the scientific brain and provide detailed accounts of the nature of the representation of scientific knowledge. Petitto and Dunbar (2004) proposed the term "educational neuroscience" for the integration of research on education, including science education, with research on neuroscience. However, see Fitzpatrick (in press) for a very different perspective on whether neuroscience approaches are relevant to education. Clearly, research on the scientific brain is just beginning. We as scientists are beginning to get a reasonable grasp of the inner workings of the subcomponents of the scientific mind (i.e., problem solving, analogy, induction). However, great advances remain to be made

concerning how these processes interact so that scientific discoveries can be made. Future research will focus on both the collaborative aspects of scientific thinking and the neural underpinnings of the scientific mind.

Barbara A. Spellman and Frederick Schauer

Abstract

The legal profession has long claimed that there are process-based differences between legal reasoning—that is, the thinking and reasoning of lawyers and judges—and the reasoning of those without legal training. Whether those claims are sound, however, is a subject of considerable debate. We describe the importance in the legal system of using categorization and analogy, following rules and authority, and the odd task of “fact finding.” We frame these topics within the debate between two views of legal reasoning: the traditional view—that when deciding a case, judges are doing something systematic and logical that only legally trained minds can do; and the Legal Realist view—that judges reason in much the same way as ordinary people do, and that they first come to conclusions and then go back to justify them with the law rather than using the law to produce their conclusions in the first place.

Key Words: legal reasoning, psychology and law, reasoning, analogy, precedent, jury decision making

Introduction

In the 1973 film *The Paper Chase*, the iconic Professor Kingsfield announced to his class of first-year law students: “You teach yourself the law. I train your minds. You come in here with a skull full of mush, and if you survive, you’ll leave thinking like a lawyer.” In claiming to teach students to think like lawyers, Kingsfield echoed the assumptions of centuries of legal ideology. In the 17th century, the great English judge Edward Coke glorified the “artificial reason” of the law (Coke, 1628, ¶ 97b), and from then until now lawyers and judges have believed that legal thinking and reasoning is different from ordinary thinking and reasoning, even from very good ordinary thinking and reasoning. Moreover, the difference, as Kingsfield emphasized, has long been thought to be one of process and not simply of content. It is not only that those with legal training know legal rules that laypeople do not. Rather, lawyers and judges are believed, at least by lawyers and judges, to employ techniques

of argument, reasoning, and decision making that diverge from those of even expert nonlawyer reasoners and decision makers.

Our chapter begins by describing three important distinctions: between what people typically mean by “legal reasoning” and other types of reasoning that occur in the legal system; between two competing views of how such reasoning is done; and between law and fact. The heart of the chapter deals with four thinking and reasoning processes that are common in legal reasoning: following rules, categorization, analogy, and fact finding. We then discuss whether legal decision making requires particular expertise and examine some of the peculiarities of legal decision-making procedures generally. We end with some ideas for future research.

The Who, How, and What of Legal Reasoning

What is meant by “legal reasoning”? Who does it, how is it done, and which parts of it do we think

are unique? We sketch answers to these questions in the text that follows.

“Legal Reasoning” Versus Reasoning Within the Legal System

Legal reasoning, strictly speaking, must be distinguished from the full universe of reasoning and decision making that happens to take place within the legal system. Juries, for example, make decisions in court that have legal consequences, but no one claims that the reasoning of a juror is other than that of the ordinary person, even though the information that jurors receive is structured by legal rules and determinative of legal outcomes. There has been extensive psychological research on jury decision making (for example, Diamond & Rose, 2005; Hastie, 1993), and we discuss some of it in this chapter in the section on “Fact Finding.” But when Coke and Kingsfield were glorifying legal reasoning, they were thinking of lawyers and judges and not of lay jurors. Similarly, police officers, probation officers, and even the legislators who make the laws are undeniably part of the legal system, yet the typical claims about the distinctiveness of legal reasoning do not apply to them. Clearly, the institutions and procedures of the legal system affect decision making, but the traditional claims for the distinctiveness of legal reasoning go well beyond claims of mere institutional and procedural differentiation. The traditional claim is that certain legal professionals—lawyers and judges—genuinely reason differently, rather than employ standard reasoning under different institutional procedures.

Thus, the term “legal reasoning” refers to reasoning by a subset of people involved in the legal system; it also refers to a subset of what that subset of people reason about. Television portrayals notwithstanding, a large part of what lawyers do consists of tasks such as negotiating, drafting contracts, writing wills, and managing uncontested dealings with the administrative bureaucracy. These lawyers’ functions are important in understanding the legal system in its entirety, yet they are rarely alleged to involve distinctive methods of thought, except insofar as they are performed with an eye toward potential legal challenges and litigation. Therefore, we focus in this chapter on trials and appeals because that is the domain about which claims for the distinctiveness of legal reasoning are most prominent.

Two Views of Legal Reasoning

In this chapter we examine forms of reasoning that are allegedly concentrated in, even if not

exclusive to, the legal system. But we also address the long history of skeptical challenges to the legal profession’s traditional claims about the distinctiveness of its methods. From the 1930s to the present, theorists and practitioners typically described as Legal Realists (or just “Realists”) have challenged the belief that legal rules and court precedents substantially influence legal outcomes (Frank, 1930; Llewellyn, 1930; Schlegel, 1980). Rather, say the Realists, legal outcomes are primarily determined by factors other than those that are part of the formal law. These nonlegal factors might include the personality of the judge, for example, as well as the judge’s moral and political ideology and her reactions to the facts of the particular situation presented.

The Realists’ claim that such nonlegal considerations are an important part of judicial decision making should come as little surprise to most psychologists. After all, the Realist challenge is largely consistent with the research on motivated reasoning (Braman, 2010). Because decision makers are often focused on reaching specific desired conclusions, the motivation to reach an antecedently desired conclusion will affect their information search and recall, as well as other components of the decision-making process (Kunda, 1987, 1990; Molden & Higgins, 2005; Chapter 20). Insofar as this research is applicable to judges, then, the Realists would claim that judges are frequently motivated to reach specific outcomes in specific cases for reasons other than the existence of a relevant legal rule. They might, for example, sympathize with one party in the particular case. Or they might believe, more generally, for example, that labor unions should ordinarily prevail against corporations (Kennedy, 1986), or that the police should be supported in their fight against typically guilty defendants, or that commerce flows more smoothly if the norms of the business community rather than the norms of the law are applied to commercial transactions (Twining, 1973). These nonlegal and outcome-focused motivations, say the Realists, would lead judges to retrieve legal rules and precedents selectively in light of that motivation, locating and using only or disproportionately the rules and precedents supporting the result generated by their nonlegal outcome preferences in a particular dispute.

Indeed, the same point is supported by the research on confirmation bias (see Nickerson, 1998, for a review). This research teaches us that both novice and expert decision makers are inclined to design their tasks in ways that yield results consistent with

their initial beliefs (Fiedler, 2011). In light of what we know about motivated reasoning and confirmation bias, therefore, it is plausible that judges often consult the formal law only after having tentatively decided how the case, all or many things other than the law considered, ought to come out. The judges would then select or interpret the formal law to support outcomes reached on other grounds, as the Realists contend, rather than using the formal law to produce those outcomes in the first place, as the traditional view of legal reasoning maintains.

The traditional view of “thinking like a lawyer” does not deny that motivated reasoning and confirmation bias influence the decisions of ordinary people. It does deny, however, that these phenomena are as applicable to expert legal reasoners as they are to laypeople. Indeed, it is telling that nominees for judicial appointments, especially nominees to the Supreme Court testifying before the Senate Judiciary Committee at their confirmation hearings, persistently pretend not to be Realists. They deny that any policy or outcome preferences they might happen to have will influence their judicial votes, claiming instead that their job is simply to follow the law.¹ The judicial nominees thus join the claims of Kingsfield and countless others that the forms of thinking and reasoning that characterize human beings in general are exactly the forms of thinking and reasoning that lawyers and judges are trained to avoid. Whether such avoidance can actually be taught or actually occurs, however, are empirical questions, and not the articles of faith they were for Kingsfield. The question of whether lawyers and judges really are better than laypeople at avoiding the consequences of motivated reasoning, confirmation bias, and other impediments to law-generated results is one that lies at the heart of the traditional claims for the distinctiveness of legal reasoning. In this chapter, we consequently discuss not only the traditional view of legal reasoning but also the research examining the extent to which the model of reasoning described by the traditional view accurately characterizes the arguments of lawyers and the decision making of the judges to whom they argue.

The Distinction Between Law and Fact

The distinction between questions of law and questions of fact is crucial to understanding legal decision making. Indeed, questions of fact are primary in important ways, because the initial question in any legal dispute is the question of what

happened—the question of fact. How fast was the Buick going when it collided with the Toyota? Who came into the bank with a gun and demanded money from the teller? Did the shopkeeper actually promise the customer that the lawnmower she bought would last for 5 years? In typical usage we think of “facts” as things that are known to be true. But in the courtroom, relevant facts may be unknown or in dispute. Thus, the first thing that the “trier of fact,” be it jury or judge, must do is “fact finding”—that is, deciding what actually happened.

Knowing what happened is important and preliminary, but knowing what happened does not answer the *legal* question—the question of what consequences flow from what happened. If a prospective employee proves that the company that did not hire him refuses to hire anyone over the age of 50, has the company violated the law, and, if so, what is the penalty? If the defendant in a murder case drove a getaway car but did not shoot anyone, is he subject to the same criminal penalty as an accomplice who actually did the shooting? If the Buick that someone purchased from a Buick dealer turns out to be defective, is the dealer responsible or only the manufacturer?

In the United States it is common to think of juries as determining questions of fact and judges as deciding questions of law. However, this simple dichotomy is misleading. Although juries generally do not decide questions of law (though they are required to apply the law to the facts in order to reach a verdict), judges *do* decide questions of fact. In many countries, there are no juries at all. And even though most countries with a common-law (English) legal heritage have juries for many criminal trials, only in the United States are there still juries for civil lawsuits between private parties.

Even in the United States, juries are far less common than one would suspect from television portrayals of the legal system. Partly because of settlement and plea bargaining, partly because only certain types of cases involve the right to a jury, partly because sometimes the opposing parties agree to have a judge decide the case, partly because of alternative dispute resolution, and partly because many cases are dismissed or otherwise resolved by judges on legal grounds before trial, jury trials are rare. In fact, only about 1% of initiated cases in the United States reach trial at all, and many of those are tried by a judge sitting without a jury (Galanter, 2004). Often, therefore, the issues of fact as well as law are decided by the judge.

And even when there is a jury, many preliminary factual issues will have been decided by the judge. In criminal cases, for example, factual questions about arguably illegal searches and seizures or confessions—Did the police have probable cause to conduct a search? Was the defendant given the requisite warnings before being interrogated?—are determined by the judge. In civil cases with a jury, judges decide many issues of fact in determining preliminary procedural issues and making rulings on the admissibility of evidence—Did the defendant answer the complaint within the required 20-day period? Can an expert in automobile design testify as an expert about tire failure?

The psychological issues implicated by decisions about disputed questions of fact are not necessarily the same as those involved in determining what the law is. And thus we deal separately, much later, with the psychology of factual determination in law. For now, however, it is worth noting that many of the claims about a distinctively legal reasoning pertain to the resolution of uncertain questions about the law rather than about what happened. Determining what the law requires, especially when the law is uncertain, involves the kind of legal reasoning that Kingsfield celebrated and Supreme Court nominees endorse. Learning how to make such determinations is a large part of the training of lawyers, and a substantial component of legal practice, especially in appellate courts. It is precisely when rules or precedents are unclear or generate uncomfortable outcomes that the use of rules, precedents, analogies, and authority becomes most important, and these are the forms of reasoning that are central to the alleged distinctiveness of legal reasoning. We turn to those forms of reasoning now.

Rules

Following, applying, and interpreting formal, written, and authoritative rules, as well as arguing within a framework of such rules, are important tasks for lawyers and judges, and they are consequently emphasized in the standard picture of legal reasoning. The psychology literature does not address this kind of rule following *per se*; however, to a psychologist the processes involved in deciding “easy” cases seem to involve deductive reasoning (see Evans, Chapter 8), whereas those for “hard” cases seem to involve categorization (see Rips et al., Chapter 11) and analogy (see Holyoak, Chapter 13).

The distinction between easy cases and hard cases is widely discussed in the legal literature. In an easy

case, a single and plainly applicable rule gives unambiguous guidance and, as applied to the situation at hand, appears to give the right result. Suppose a law says: “If someone does A, then he gets consequence B.” Richard comes along, blatantly does A, and then gets consequence B. Rule followed; justice done; everyone (except Richard) is happy. But what we illustrate next is that not all rules are so simple, nor can they be so simply and rewardingly applied. Several types of difficulties can arise, making the application of the rules uncertain or, perhaps, undesirable. What are those difficulties that create hard cases and how do judges resolve them? It depends whether you ask a traditionalist or a Realist.

Defining Hard Cases

There are three kinds of hard cases: ones in which the language of an applicable rule is unclear; ones in which it is unclear which of several rules apply; and ones in which the language of a plainly applicable rule is clear but produces what the interpreter, applier, decision maker, or enforcer of the rule believes is the wrong outcome.

UNCLEAR RULES

Legal rules often do not give a clear answer. A famous example in the legal literature involves a hypothetical rule prohibiting vehicles in a public park (Hart, 1958; Schauer, 2008a). When the question is whether that rule prohibits ordinary cars and trucks, the application of the rule is straightforward. Cars are widely understood to be vehicles, vehicles are prohibited according to the rule, and therefore cars, including this car, are prohibited. That people can and sometimes do reason in such a deductive or syllogistic way when they are given clear rules and presented with clear instances of application is well established (Evans, Barston, & Pollard, 1983; Rips, 2001).

But what about bicycles, baby carriages, wheelchairs, and skateboards, none of which are either clearly vehicles or clearly not vehicles? Faced with such an instance, what would a judge do? One standard view is that the judge would then have discretion to decide the issue as she thought best. Perhaps the judge would try to determine the purpose behind the rule, or perhaps she would try to imagine what the original maker of the rule would have thought should be done in such a case. But whatever the exact nature of the inquiry, the basic idea is that the judge would struggle to determine what the unclear rule *really* means in this situation and would then decide the case accordingly.

The view that judges are searching for guidance from even unclear rules is part of the standard ideology of the lawyers and judges. But that view may be at odds with psychological reality. Freed from the strong constraints of a plainly applicable rule, the research on motivated reasoning suggests that the judge would be likely to decide how, on the basis of a wide range of political, ideological, personal, and contextual factors, she believes the case ought to come out (Braman, 2010). Having come to that conclusion, a conclusion not substantially dependent on the legal rule at all, the judge would then describe that result as being the one most consistent with the purpose behind the rule. And if the judge then looked for evidence of the purpose behind the rule, or evidence of what the rule maker intended in making the rule, much of what we know about confirmation bias (Nickerson, 1998) would suggest that the judge would not engage in the search for purpose or intent with an entirely open mind, but rather would be likely to find the evidence of purpose or intent that supported the outcome the judge had initially preferred.

The latter and more skeptical explanation is entirely consistent with the Legal Realist view about rules. In 1929 Joseph Hutcheson, a Texas-based federal judge, wrote an influential article (Hutcheson, 1929) challenging the traditional picture of legal reasoning. He claimed that it is a mistake to suppose that in the typical case that winds up in court the judge would first look to the text of the rule, the purpose behind the rule, the evidence of legislative intent, and the like in order to decide the case. Rather, Hutcheson argued, the judge would initially, and based largely on the particular facts of the case rather than the law, come up with an initial “hunch” about how the case ought to be decided. Then, and only then, would the judge seek to find a rule to support that result or seek to interpret a fuzzy rule in such a way as to justify that result. Subsequent Realists (e.g., Frank, 1930) reinforced this theme, albeit rarely with systematic empirical research.

Thus, the debate between traditional and Legal Realist view about rule following might also be cast in the language of the contemporary research on dual-process methods of thinking (Evans, 2003, 2008; Sloman, 1996; see Evans, Chapter 8; Stanovich, Chapter 22).² System 1 reasoning is quick and intuitive, whereas System 2 reasoning is more logical, systematic, and deliberative (Stanovich, 1999), and the traditional view of legal reasoning relies heavily on a System 2 model of decision making. The Realist

perspective, as exemplified by Hutcheson’s reference to a “hunch,” sees even judicial reasoning as having heavy doses of quick, intuitive, and perhaps heuristic System 1 decision making. (These are sometimes viewed as two separate reasoning systems and sometimes as the ends of a reasoning continuum.) The question remains as to which method of decision making more accurately reflects the reality of judging. Several legal scholars have suggested that judges, just like ordinary people, often come quickly to an intuitive decision but then sometimes override that decision with deliberation. They state, “The intuitive system appears to have a powerful effect on judges’ decision making” (Guthrie, Rachlinski, & Wistrich, 2007, p. 43) and then suggest various ways in which the legal system should increase the likelihood that judges will use System 2 reasoning in deciding cases. Note, however, that when the systems are in opposition it is not always the case that the intuitive system is wrong and the deliberative system is right; it can also turn out the other way (Evans, 2008).

WHEN RULES PROLIFERATE

The second type of hard cases consists of those to which multiple but inconsistent clear rules apply. Is a truck excluded from the park by the “no vehicles in the park” rule, or is it permitted by another rule authorizing trucks to make deliveries wherever necessary? Such instances of multiple and inconsistent rules make the Realist challenge to the conventional picture especially compelling in a legal system in which many rules might plausibly apply to one event. In countries with civil law systems,³ legislatures attempt to enact explicit and clear legal rules covering all conceivable situations and disputes. Such rules are collected in a comprehensive code; therefore, the existence of multiple and inconsistent rules applying to the same event is, at least in theory, rare. Even the outcome-motivated judge might well find that the law plainly did not support the preferred outcome, and that would almost certainly be the end of the matter.

The situation is different in English-origin common-law countries,⁴ where much of the law is made by judges in the process of deciding particular cases. Law making in common-law systems is less systematic than in civil law countries, and common-law judges and legislatures are less concerned than their civil law counterparts with ensuring that new rules fit neatly with all of the existing legal rules. As a result, it is especially in common-law countries that

multiple and inconsistent rules may apply to the same event, allowing for more decisions that seem to be based on motivated reasoning. Moreover, even when a judge does not have a preferred outcome, when there are multiple potentially applicable rules, the judge's background and training, among other things, will influence which rules are retrieved and which are ignored (Spellman, 2010). In addition, if judges, like other people, seek coherence and consistency in their thinking, they may select legal rules and sources that are consistent with the others they have retrieved and ignore those that would make coherence more difficult (Holyoak & Simon, 1999; Simon, Pham, Le, & Holyoak, 2001).

WHEN RULES GIVE THE WRONG ANSWER

Although there can be problems with vague rules and multiple rules, as described earlier, typically the words of a plainly applicable rule, conventionally interpreted, do indicate an outcome, just as the "no vehicles in the park" rule indicates an outcome in a case involving a standard car or truck. But leading to an obvious outcome is not the end of the story. Because rules are generalizations drafted in advance of specific applications (Schauer, 1991), there is the possibility, as with any generalization, that the rule, if strictly or literally followed, will produce what appears to be a bad result in a specific situation. In *Riggs v. Palmer* (1889), for example, a case decided by the New York Court of Appeals, the pertinent statute provided clearly, and without relevant exception, that anyone named in a will could claim his inheritance upon the death of the testator (i.e., the person who wrote the will). The problem in *Riggs*, however, was that the testator died because his grandson, the beneficiary, had poisoned him, and did so precisely and intentionally in order to claim his inheritance as soon as possible. Thus, the question in *Riggs* was whether a beneficiary who murdered the testator could inherit from him. More generally, the question was whether the justice or equity or fairness of the situation should prevail over the literal wording of the rule.

Cases like *Riggs* are legion, and the issues they present raise important issues about the nature of law and legal decisions (Dworkin, 1986). But they also implicate equally important psychological questions. When a rule points in one direction and the all-things-considered right answer points in another, under what conditions, and how often, will people—be they legally trained or not—put aside their best moral or pragmatic judgment in favor of what the rule commands?

If the traditional story is sound, we would expect those with legal training to attach greater value to the very fact of the existence of a legal rule, and thus to prefer the legally generated but morally or pragmatically wrong result more often than those without such training. It turns out, however, that very little research has addressed precisely this question. On the one hand, research has found that law students (Furgeson, Babcock, & Shane, 2008b) and federal law clerks (recent law school graduates) working for federal judges (Furgeson, Babcock, & Shane, 2008a) are affected by their policy preferences in drawing conclusions about the law. On the other hand, there are data indicating that judges are better able to put aside their ideologies than law students in evaluating evidence (Redding & Reppucci, 1999). Most relevantly, legally trained experimental subjects tend to prefer formal rules of justice more often than those without legal training (Schweitzer et al., 2008). Still, the research can best be described as limited, presumably owing to the difficulties in securing judges and lawyers as experimental subjects. And, of course, any study finding differences between groups along the law-training continuum (laypeople, law students, law clerks, lawyers, judges) must consider not only legal training and experience but also selection and self-selection effects (e.g., who chooses to go into law; who is chosen to become a judge) when drawing causal conclusions.

Deciding Hard Cases

It is important to understand the types of difficulties generated by hard cases because litigation, and especially litigation at the appellate stage, is disproportionately about hard cases. Easy cases are plentiful, at least if we understand "cases" to refer to all disputes or even all instances of application of the law (Schauer, 1985). But if the law is clear and if the clear law produces a plausible or palatable outcome, few people would take the case to court in the first place. Only where two opposing parties each believe they have a reasonable chance of winning will the dispute actually arrive in court, and also, to an even greater extent, when disputants decide whether to appeal. As a result of this legal selection effect (Lederman, 1999; Priest & Klein, 1984), the disputes that produce litigation and judicial opinions will disproportionately represent hard cases, with the easy cases—the straightforward application of clear law—not arriving in court at all.

This selection effect is greatest with respect to decisions by the Supreme Court of the United States,

which can choose the cases it will hear. It is asked to formally decide about 9,000 cases per year but considers only about 70 per year with full written and oral arguments. And with respect to these 70 cases, the existing research, mostly by empirical political scientists, supports the conclusion that the political attitudes of the Justices—how they feel about abortion and affirmative action, for example, as a policy matter—is a far better predictor of how they will vote than is the formal law (Segal & Spaeth, 2004). This research is not experimental; rather, it involves coding Justices on a variety of attributes and coding cases on a variety of attributes and then analyzing what predicts what. For example, Justices are coded on such things as age (at the time of the decision), gender, race, residence, political party at the time of nomination; cases are coded on such things as topic, types of litigants, and the applicability of various precedents and legal rules. The conclusion of much of this research is that we can better predict legal outcomes, at least in the Supreme Court and to some extent in other appellate courts, if we know a judge's prelegal policy preferences than if we understand the applicable rules and precedents. To the extent that this research is sound, therefore, it may support the view that the Supreme Court, ironically to some, is the last place we should look to find distinctively legal reasoning (but see Shapiro, 2009, for a critique of these analyses).

Categorization

Questions about rule following obviously implicate important issues of categorization. Do we categorize a skateboard as a vehicle or as a toy? Do we categorize Elmer Palmer, the young man who murdered his grandfather in order to accelerate his inheritance, as a murderer, as a beneficiary, or possibly even as both?

Because legal outcomes are determined by something preexisting called "the law," those outcomes require placing any new event within an existing category. When the category is specified by a written rule with a clear semantic meaning for the pertinent application, as with the category "vehicle" when applied to standard automobiles in the "no vehicles in the park" rule, the freedom of the decision maker is limited by the plausible extensions of the specified category. Often, however, there is no such clear written rule that is literally applicable to the case at hand, sometimes because the rule is vague (consider the Constitution's requirement that states grant "equal protection of the laws" and the constitutional

prohibition on "cruel and unusual punishments"), sometimes because a case arises within the vague penumbra of a rule (as with the skateboard case under the "no vehicles in the park" rule), and often because in common-law systems the relevant law is not contained in a rule with a fixed verbal formulation but instead is in the body of previous judicial decisions. In such cases the task of categorization is more open ended, and decision makers must make less constrained judgments of similarity and difference in order to determine which existing legal category best fits with a new instance.

Legal Categories

The view that legal reasoning and legal expertise is a matter of using and understanding the categories of the law rather than the categories of the prelegal world is one whose iconic expression comes from an apocryphal anecdote created by Oliver Wendell Holmes:

There is a story of a Vermont justice of the peace before whom a suit was brought by one farmer against another for breaking a churn. The justice took time to consider, and then said that he had looked through the statutes and could find nothing about churning, and gave judgment for the defendant. (Holmes, 1897, pp. 474–475)

The point of the anecdote derives from the fact that a justice of the peace would have been a lay decider of minor controversies, not a real judge with legal training and legal expertise. And thus Holmes can be understood as claiming that only an untrained bumpkin could have imagined that "churn" was the relevant legal category. That this is Holmes's point is made clear shortly thereafter, when he says that

[a]pplications of rudimentary rules of contract or tort are tucked away under the heads of Railroads or Telegraphs or... Shipping..., or are gathered under an arbitrary title which is thought likely to appeal to the practical mind, such as Mercantile Law. If a man goes into law it pays to be a master of it, and to be a master of it means to look straight through all the dramatic incidents and to discern the true basis for prophecy. (Holmes, 1897, p. 475)

For Holmes, "railroad" and "telegraph" are lay categories, and "contract" and "tort" are legal categories, and one mark of legal expertise and legal reasoning is the ability to use legal rather than lay categories. This is still not a very strong claim about

the distinctiveness of legal reasoning, for the difference that Holmes identifies is one of content and not of process. The lawyer does not think or reason differently from the layman, Holmes might be understood as saying, but thinks and reasons the same way, albeit with different categories and thus with different content (Spellman, 2010). If legal reasoning does not involve substantially different processes from ordinary reasoning, the strongest claims of the traditional view of legal reasoning are weakened. But if legal reasoning employs the distinctive categories and content of the law, and if these categories in fact determine many legal outcomes, the strongest claims of Legal Realism are weakened as well. By applying substantially (even if not completely) ordinary reasoning to substantially (even if not completely) law-created content and categories, legal reasoning may turn out to have its own special characteristics, but not in ways that either the traditionalists or the Realists maintained.

Relational Categories

We believe that the categories that the law uses tend to be relational categories—categories created on the basis of the relations that one item has with another, rather than on the basis of the attributes of single items taken in isolation (i.e., involving predicates that take at least two objects). That law is principally concerned with the way in which one person or thing is connected or related to another should not be surprising. After all, the law is about regulating interactions and exchanges among people—that is, relations. Take the category of “contract.” Suppose someone wants to know whether Judy and Jerry have entered into a contract. Nearly all personal details about Judy and Jerry are irrelevant, as are nearly all details about what they have contracted for. What *is* relevant is whether Jerry owned the property, whether Judy made what the law defines as an offer, and whether Jerry responded with what the law defines as acceptance. Similarly, suppose that Beth has done something to Brian. Whether that “something” is being hit, libeled, or kidnapped, it is again typically the relation of what one did to the other that matters. And so too with the questions involved in a finding of negligence: Did John harm James? Did John have a duty of care toward James? Again, relations are key. Note that sometimes it does matter whether the person is under 18 (and so can’t sign a contract) or over 35 (and so is eligible to be President of the United States). And sometimes it matters whether a person

is male or female, Black or White, famous or non-famous. But most of the time it is only the relations between the parties that matter. Indeed, the traditional contrast between the “rule of law” and the “rule of men” [sic] stresses the impersonality of the law, and thus its emphasis on the relational “what” rather than the personal “who.”

Despite the large psychology literature on categorization, there has been relatively little work on relational categories (see Gentner & Kurtz, 2005). However, we do know that just like category members from standard categories prime other category members, category members from relational categories prime other category members (e.g., “bird-nest” primes “bear-cave” by activating the relation “lives-in;” Spellman, Holyoak, & Morrison, 2001). We also know that relations are generally more important than attributes for analogical reasoning. Thus, when someone is trained on which relations exist and matter, analogical reminding can be useful for retrieving analogies that can help make a legal argument. How analogy is used in legal reasoning is the topic of the next section.

Precedent and Analogy

In common-law systems much of the law is not to be found in the explicitly written rules enacted by legislatures or adopted by administrative agencies, but in the decisions of judges. And because when judges reach decisions and thus make law they are expected to take account of previous decisions—precedents—the interpretation of precedents is an important part of common-law decision making. In common-law systems, and increasingly in civil law systems, law develops incrementally as decisions in particular cases build on previous decisions. Understanding how to use previous decisions to make an argument or decision in the current dispute is consequently a substantial component of legal reasoning. Previous decisions play a large role in legal reasoning, but they do so in two very different ways (Schauer, 2008c).

“Vertical” Precedent

First, and possibly of less significance in hard cases, is the obligation of a judge to follow the decision of a higher controlling court (hence “vertical”) even if she disagrees with that decision. This is the strong form of constraint by precedent, and it resembles the constraints of an explicitly written rule. When there is a previous decision on the same question (just as when there is an explicit rule plainly covering some

application), the law *tells* the judge what her decision should be. Consider, for example, the obligations of judges with respect to the Supreme Court's decision in *Miranda v. Arizona* (1966), the case in which the Court required police officers to advise a suspect in custody of his rights to remain silent and have a lawyer prior to questioning. *Miranda* was controversial when it was decided and has remained controversial since. Many citizens, police officers, and even judges believe that *Miranda* was a mistaken decision. Nevertheless, a judge in a court below the Supreme Court is not permitted to substitute her judgment for that of the higher court. If the question arises in a lower court as to whether the statements of a suspect who was not advised of his rights can be used against him, the lower court judge who thinks that the answer to this question ought to be "yes" is obliged by the Supreme Court's decision in *Miranda* to answer "no." Obviously there will be difficult cases in which it is not clear whether the defendant was in custody, or whether he was being interrogated, or whether he waived his *Miranda* rights.⁵ In such hard cases a judge's views about *Miranda*'s wisdom will likely influence her decisions about the application of the precedent. But in the easy cases—the cases that present the *same* question that the Supreme Court decided in *Miranda*—the lower court judge is obliged by the system to decide the question as it has already been decided even if, without the constraint of precedent, she would have reached a different decision.

"Horizontal" Precedent

The constraint of precedent, at least in theory, applies horizontally as well as vertically. That is, judges are obliged to follow previous decisions of their *own* court even if, again, they disagree with those decisions. In theory, a Supreme Court Justice who in 2010 disagrees with the Court's 1973 decision in *Roe v. Wade* (1973) is obliged by what is known as the doctrine of *stare decisis*—"stand by what is decided"—to follow that decision. At least with respect to the Supreme Court, however, the data indicate that the constraint of *stare decisis* is a weak one, having little force in explaining the votes of the Justices (Brenner & Spaeth, 1995; Schauer, 2008b; Segal & Spaeth, 1996). Unlike the obligation to follow the ruling of a higher court, which is largely respected when the decision of the higher court is clear, the obligation to follow an earlier decision of the same court appears to be perceived by judges as weak.

The obligation of a judge to follow a precedent that is exactly "on point" is an important aspect of legal reasoning and the self-understanding of the legal system, but its effect is rarely seen in appellate courts. When it is clear that some dispute is the same as that which has already been decided, the dispute will usually be resolved prior to reaching the appellate court. The cases that do end up being decided on appeal, again by virtue of the selection effect, are overwhelmingly ones in which past decisions do not obviously control the current dispute but exert their influence in a less direct way. Because the idea of following precedent so pervades the legal consciousness, drawing on and arguing from past decisions even when they are not directly controlling is a ubiquitous feature of legal reasoning, argument, and decision making.

The Role of Analogical Reasoning

Using previous decisions that are not exactly like the current question in order to guide, persuade, and justify is a process that is heavily dependent on, or perhaps identical to, analogical reasoning (Spellman, 2004). Understanding the legal system's use of analogical reasoning is accordingly vitally important for understanding the methods of legal reasoning and argument. Consider, for example, the decision of the New York Court of Appeals in *Adams v. New Jersey Steamboat Company* (1896), a case frequently discussed in the literature on analogical reasoning in law (e.g., Spellman, 2010; Weinreb, 2005). The case concerned the degree of responsibility of the owner of a steamboat that contained sleeping quarters to an overnight passenger whose money had been stolen when, allegedly because of the company's negligence, a burglar broke into the passenger's stateroom. No existing legal rule controlled the case, and no previous decision had raised or decided the same question. And it turned out that two different bodies of law—two different lines of precedent—were each potentially applicable. If the law pertaining to the open sleeping compartments ("berths") in railroad cars applied, the steamboat company would not be liable to the passenger. But if the law about innkeepers' responsibility to their guests was applicable, then the passenger could recover.

The *Adams* case presents a classic case of analogical reasoning in law. Although some prominent skeptics about analogical reasoning argue that judges, like the judges in *Adams*, simply make a policy-based choice of a general rule (Greenawalt, 1992, p. 200) and mask it in the language of similarity (Alexander,

1996; Posner, 2006), such an approach is inconsistent with what we know about analogical reasoning. Applying the research on analogy to the *Adams* case, we can understand how each side was trying to get the judges to apply a different well-understood source—either the law of innkeepers or the law of railroads—to a less well-understood target—a stateroom on a steamboat.

So is a steamboat more similar to an inn or to a train? We suspect that most people would answer “train,” but that is not the relevant question. How about: Is the stateroom on a steamboat more similar to a room at an inn or to a sleeping berth on a railroad? That is a tougher question, and one might be tempted to ask (as one should when dealing with categorization generally; see Chapter 10), “Similar with respect to what?” Here the answer might be, “With respect to how much the plaintiff had the right to expect security of his possessions while he slept.” Given the situations—that one can lock one’s room at the inn and one’s stateroom on the steamboat but not one’s berth on the train; given that the room at the inn and the stateroom are more private than the sleeping berth on the train; and, perhaps, given that one paid extra for a room and a stateroom (the court’s decision did not include many details)—it is easy to argue that the steamboat and inn are similar in that the owner gives the traveler an implied guarantee that he and his possessions will be safe while sleeping.

In fact, the court applied the law of innkeepers rather than the law of railroads, and such a decision might be explained in terms of a distinction between surface and relational similarities (Holyoak & Koh, 1987). The successful analogy—between the steamboat and the inn—was not the one in which the objects were similar, but rather the one in which the legal relations between the relevant parties were similar. Developing expertise in law, which we assume the judges possessed, means seeing through the surface similarities and understanding which relational similarities matter.⁶ Note that in saying that the relevant legal category in *Adams* was a category that connects inns and steamboat accommodations (the category of those who offer sleeping accommodations, perhaps) rather than one that connects steamboats and railroads (means of transportation), the court based its categorization decision on a legal rather than a lay category.

Is this kind of reasoning substantially different between those who are legally trained and those who are not? Consider an experiment that compared law

students to undergraduates (Braman & Nelson, 2007, Exp. 2). The subjects (96 undergraduates and 77 law students) read an article summarizing the facts of a target case, but they did not know the result, and they also read one version of a potentially relevant previously decided case—which varied between subjects on two factors of possible legal relevance. The undergraduates rated the precedent as more similar to the target case than did the law students. The law students perceived similarity and difference between the cases in light of legal and not lay categories. Although the determination of similarity and difference is likely to be domain dependent (Medin, Lynch, & Solomon, 2000), it does not follow from the fact that particular similarities that are important in one domain are unimportant in another that the very process of determining similarity varies according to domain. Thus, although there may be differences between legal reasoners and ordinary reasoners, the differences, insofar as they are a function of knowledge attained in legal training and practice, may be better characterized as content based rather than process based.

Possession of legal knowledge may thus explain the difference between legally trained and non-legally trained reasoners. But given that most judges are legally trained, and given that both sides present the potentially relevant cases supporting their sides to the judges, why are there disputes over the appropriate analogy to use? The Realists would say that the judges have a desired outcome and then pick the appropriate analogies to justify their decisions. But perhaps people (and judges) choose relevant analogies (or precedents) as better or worse, applicable or inapplicable, not because of any particular desired outcome but rather because of their own preexisting knowledge and the way they frame their questions (Spellman, 2010; Spellman & Holyoak, 1992, 1996).

Fact Finding

As described earlier, an important type of decision making in legal proceedings is “fact finding” and most of the factual determinations in legal proceedings are made by judges. Many of these determinations are made in the course of preliminary proceedings and many are made in trials in which there is no jury. Yet although fact finding is done far more often by judges than by juries, most of the research about fact finding has been done on juries. One reason may be that juries feature prominently in television and movie trials, and as a result researchers may believe they are more prevalent

in nontheatrical legal proceedings than they really are (Spellman, 2006). Another reason might be that lay jurors are far more likely to resemble the typical experimental subjects used by psychology researchers. Using findings based on experiments with university undergraduates to draw conclusions about the decision-making practices of judges may involve significant problems of external validity, but the greater similarity between lay undergraduates and lay jurors significantly lessens these problems (Bornstein, 1999).

Fact Finding by Juries

Perhaps the most important dimension of jury fact finding is the way in which the information that juries receive is carefully controlled by the law of evidence. Evidence law is based on the assumption that jurors will overvalue or otherwise misuse various items of admittedly relevant information, and the rules of evidence thus exclude some relevant evidence because of a distrust of the reasoning capacities of ordinary people. There is a general rule of evidence (FRE 403) that a judge may exclude relevant evidence "if its probative value is substantially outweighed by a danger of...unfair prejudice, confusing the issues, misleading the jury..." More specifically, for example, the information that the defendant in a robbery case has committed robbery in the past is typically excluded from jury consideration, even though a rational decision maker would recognize that such evidence, even if hardly conclusive, is far from irrelevant.⁷ Similarly, the exclusion of hearsay evidence—evidence of what someone else (who is not now testifying) said was true, rather than what a witness perceived as true—is based on the notion that juries will give too much weight to what was said by a person who is not appearing in court. Yet this fear entails excluding from consideration evidence that ordinary decision makers would consider relevant to the decision to be made. In ordinary life, people rely frequently on hearsay to inform themselves about what happened and often make judgments about ambiguous or unknown current behavior based on past behavior. The fact that the law of evidence excludes so much of what figures prominently in everyday reasoning is accordingly perhaps the most important feature of evidence law.

When jurors are the fact finders, they may receive two types of instructions from the trial judge. The first are immediate instructions during the trial: to forget information they have heard or to use some information for one purpose but not for another (obvious)

other one. For example, a witness might blurt out that he knew the defendant because they had been in prison for robbery at the same time. If the defense lawyer objects and makes a motion to strike, and the judge sustains, she will immediately instruct the jury to disregard that evidence. There is much data supporting the conclusion that jurors typically do not disregard such evidence (Steblay et al., 2006). The jury is still out, however, on the question of whether it is that jurors *cannot* disregard or *choose not* to disregard. There is strong evidence that under some conditions the failure is intentional (e.g., Sommers & Kassin, 2001), but it is likely that under other conditions jurors are simply unable to disregard what they already know.

The second type of instructions comes just before jurors deliberate: They are instructed about both the content of the law specific to the case at hand and about general procedures they should use to decide the case. The latter include the mandate that they decide the case in accordance with the instructed law, and not on the basis of what they think is the right result. Thus, an important question, one about which there has been considerable research, is the extent to which jurors actually understand judge's instructions (see Diamond & Rose, 2005, and Ogloff & Rose, 2005, for reviews).

Although considerable recent efforts have aimed at making instructions more comprehensible, the research suggests that jurors typically do not understand very much of the judge's instructions, including specific instructions about elements of the crime and general instructions about the burden of proof (Ogloff & Rose, 2005). Some of this gap between instructions given and instructions comprehended may be a function of the fact that judges are more concerned with legal accuracy in language of the instruction (so the case will not be overturned on appeal) than they are with maximum comprehension by the jury. But much of the gap may follow from the difficulty that experts in general have of understanding the perspective of nonexperts in their own field.

Although jurors often do not understand the judge's instructions, that does not imply that they will deliver an erroneous verdict. It turns out that juries tend to deliver the correct verdict, at least where the measure of correctness is what the judge would have decided were there no jury. Various studies over the years, using different methodologies, have shown that a judge's and jury's decisions about the same cases are typically in accord

(see Diamond & Rose, 2005). However, each one of these studies has at least one serious methodological flaw. Still, overall, it seems that even though jurors may not appreciate the nuances of the applicable law, they are reliable in getting a general sense of who ought to prevail. (As far as we can tell, none of the research has focused explicitly on the decisions of jurors who do not understand the instructions in cases in which the justice of the situation and the law point in opposite directions, and thus it would be a mistake to assume that juror incomprehension of judicial instructions is largely inconsequential.)

That jurors who at best imperfectly understand the judge's instructions nevertheless reliably reach the correct verdict is related to what we know about how juries determine what happened. Much of the structure of a trial and much of the law of evidence is premised on an incremental and Bayesian model of fact finding, in which jurors with prior beliefs about some state of affairs adjust the probability of those beliefs upward or downward as additional pieces of evidence are presented (see Griffiths, Tenenbaum, & Kemp, Chapter 3, for a discussion of Bayesian inference and Hahn & Oaksford, Chapter 15, for applications to the jury decision making). This is a plausible model of how information is received and processed at trial, yet it is not a model that appears to track the reality of juror decision making.

The prevailing psychological model of juror decision making is the Story Model (Pennington & Hastie, 1991), which suggests that juror decision making is more holistic than incremental. The Story Model proposes that jurors evaluate the evidence based on which story (i.e., prosecution, defense, or some other) best explains all or almost all of the evidence they have heard, as opposed to making a preliminary determination on the basis of some evidence and then continually revising that determination as additional pieces of evidence are presented. In seeking the story that best explains the evidence they have heard, therefore, jurors' reasoning is largely devoted to determining which of the two (or more) competing stories at a trial is more coherent and complete. Indeed, another holistic model of reasoning, Explanatory Coherence (Thagard, 1989), has been applied to reasoning about legal cases (Simon et al, 2001; Thagard, 2003), scientific reasoning, and other types of reasoning (Thagard, 2006; Chapter 14). Thus, that these models explain ordinary reasoning as well as jury decision making provides still further support for the view that legal decision making, whether by judge or by jury, is less different

from ordinary decision making than lawyers and judges have long believed.

Note, however, that the aforementioned describes the prevailing model of *juror*, not *jury*, decision making. Often left out of studies of legal decision making is the fact that jurors, always, and judges, often (on appeal but not at trial), make their final decisions as a group. Research on group decision making is thus very relevant to legal decision making (see Salerno & Diamond, 2010).

Fact Finding by Judges

The law of evidence provides an interesting window into the legal system's traditional belief in the superior and distinctive reasoning powers of those with legal training. In countries that do not use juries there is rarely a discrete body of evidence law, and judges are comparatively free to take all relevant information into account. And in the United States, when judges sit without juries, they often tell the lawyers that many of the rules of evidence will be disregarded or interpreted loosely to allow more evidence to be considered than would be allowed were there a jury (Schauer, 2006). Underlying this practice is the belief that only those with legal training can be trusted to evaluate evidence properly (Mitchell, 2003; Robbenolt, 2005), but it turns out that underlying this belief is more unsupported faith than actual data (Spellman, 2006).

Should we expect judges to be better at fact finding than juries? There are many differences between jurors and judges (as we discuss in the next section), but there is certainly nothing about law school training that seems likely to affect this type of reasoning: It is not at all like what Professor Kingsfield had in mind with his version of training in the Socratic method whereby he would press students with question after question about the meaning and implications of the decision in a case. Perhaps, however, either judges' repeated experience listening to cases (versus jurors doing it rarely) or their desire to do the right thing in following the law (where jurors might not take that mandate as seriously) would make judges better. In terms of repeated experience, because there never is real feedback regarding what the true facts of a case were, it is doubtful that practice makes one better. And in terms of wanting to follow the law, there is research supporting the view that judges are barely better than laypeople at ignoring information they are supposed to disregard (Wistrich, Guthrie, & Rachlinski, 2005). Thus, the data that exist about judicial fact finding support the conclusion that, when acting as fact finders and not

as legal interpreters, judges are less different from lay jurors than many people—and many judges—commonly believe (Robinson & Spellman, 2005).

Judges' Expertise and the Authority of Law

There is, as we have emphasized, a running debate between the traditional and Legal Realist accounts of legal reasoning, and one way of framing the question of the distinctiveness of legal reasoning is in terms of the traditional claim that lawyers and judges are experts. That was clearly Kingsfield's claim, for example, but it leaves open the question of what kind of experts lawyers and judges might be. More particularly, is it possible that there are at least some process-based differences between legal and lay reasoning? Consider again the task of analogical reasoning in law. Perhaps lawyers and judges simply become *better* analogical reasoners by virtue of their legal training and experience. Perhaps judges, and to some extent lawyers, are experts at analogical reasoning in ways that laypeople are not.

Judges (and typically lawyers) differ from non-judges and nonlawyers on a variety of dimensions (see Stanovich, Chapter 22). On average, they have higher IQs than, say, jurors. They have more formal schooling. They may differ on some personality variables. They have chosen to go into, and stay in, the legal field. They are repeat players—doing the same thing time after time. And, as a result, they are likely motivated to “get it right,” or at least not to “get it badly wrong,” because their decisions become public and their reputations and even their jobs could be at stake. They also have their years of law school training. There is research showing that judges fall prey to the same standard reasoning biases as other mortals (e.g., anchoring, hindsight bias, etc., even when the problems are framed in a judicial context; Guthrie, Rachlinski, & Wistrich, 2001). But the research has focused on tasks other than those that are characteristically legal tasks. Maybe what Kingsfield was driving at was the notion that law students can be trained to be better at the central reasoning tasks that engage lawyers and judges.

Expertise and Analogy

That lawyers and judges are better at analogical reasoning than laypeople seems like a plausible claim, but it is not borne out by the research. Just as there are no data to support the belief that judges are expert fact finders (Robinson & Spellman, 2005) or experts at weighing evidence (Spellman, 2006), there are no data to support that judges' ability to

use analogies transcends the domains in which they normally operate. And if they are not experts at using analogies outside of the law, then the expertise they have is an expertise that comes from their legal knowledge and not from any increased ability in analogical reasoning itself. Thus, when law students in their first and third years of law school were compared to medical students and graduate students in chemistry and psychology (Lehman, Lempert, & Nisbett, 1988), the law students had initially higher scores on a verbal reasoning test (which included verbal analogies) than the others, presumably partly a function of self-selection and partly of the selection criteria of law schools. After 3 years of schooling, however, the law students showed only a statistically nonsignificant increase in verbal reasoning while the others improved to a greater extent. If these findings are generalizable, they might be thought to provide further support for the view that legal reasoning expertise, if it exists, is a content-based and not process-based expertise.

Expertise and Authority

But as described earlier, particularly in the sections on rules that give the wrong answer and on precedent, there is more to legal reasoning than using analogies. Understanding the traditional view of legal reasoning, and even the nature of law itself, requires appreciating the role that authority plays in legal decision making. Just as citizens are expected to obey the law even when they think it mistaken, so too are lawyers and judges expected to follow the legal rules and legal precedents even when they disagree with them. In this sense the law is genuinely authoritative; its force derives from its source or status rather than from its content (Hart, 1982). Just as the exasperated parent who, having failed to reason successfully with her child, asserts, “Because I said so!” law's force derives from the fact that the law says it rather than the intrinsic value of the content of what the law is saying.

The nature and power of authority has been the subject of psychological research, primarily by social psychologists, but the effect of an authority, even an impersonal authority like the law, also has cognitive dimensions. For example, authoritative sources may provide arguments and reasons that the decision maker would not otherwise have thought valid and relevant. On the other hand, sometimes an authoritative legal source will tell a decision maker to ignore what she thinks is a relevant fact (Raz, 1979), and sometimes it will tell a decision maker to consider

what she thinks is an irrelevant fact. As an example of the former: The relevant Supreme Court free speech cases make irrelevant the fact that a speaker is a member of the American Nazi Party or the Ku Klux Klan and wishes to publicly espouse Nazi or racist sentiments. The law not only demands that these factors be disregarded, but it also demands that they be disregarded even by a decision maker who disagrees with this aspect of the law. As an example of the latter: In determining whether a will is valid, a judge must determine whether the will contains the requisite signatures applied according to various other formalities, absent which the will is invalid even if there is no doubt that it represents the wishes of the deceased. And the judge is obliged to take this into account even if the judge believes it would produce an unjust outcome in this case, and even if the judge believes that the law requiring the formalities is obsolete or otherwise mistaken.

Thus, an important question is the extent to which legal decision makers can suppress their best judgment in favor of an authority with which they disagree. The traditional view of legal reasoning is that decision makers can be trained to do just that, and in fact much of the training in law school is devoted to inculcating just this kind of distinction between obedience to legal authority and taking into account that which otherwise seems morally and decisionally relevant (Schauer, 2009). Indeed, because the inherent authority of law often requires a decision maker to ignore what she thinks relevant, and consider what she believes irrelevant, it may be useful to understand part of legal reasoning as not being *reasoning* at all. It is, to be sure, decision making, but part of legal decision making is the way in which authoritative law makes legal decision makers avoid reasoning and even avoid thinking. For the legal decision maker, just like the legal subject, the authority of law is the mandate to leave the thinking and reasoning to someone else.

Are people willing and able to do that? Research by Schweitzer and colleagues (Schweitzer, Sylvester, & Saks, 2007; Schweitzer et al., 2008) indicates that law students are more willing than laypeople to follow rules even when the result produced by following a rule conflicts with the just result, suggesting that the difference between legal reasoning and ordinary reasoning may involve some process- and not content-based skills. Yet Schweitzer and colleagues also found no differences between first-year and third-year law students, possibly indicating that the process-based dimensions of legal reasoning

are more a matter of self-selection and law school admissions selection than of anything that is actually taught and learned during the study or practice of law. Perhaps, therefore, lawyers and judges are different from laypeople, but those differences may be more a function of knowledge, experience, and self-selection than of actual training in distinctively legal reasoning.

Legal Procedures

In this chapter, and throughout much of the research on legal reasoning, great emphasis has been placed on the legal decision maker. Who makes legal decisions, how might legal decision makers resemble or differ from other decision makers, and what differences, if any, might these similarities and differences make (see LeBoeuf & Shafir, Chapter 16)? But the law is not only a domain of decision makers with unique abilities, training, and experience, it is also a domain in which the procedures and structures for making decisions differ from those commonly found elsewhere. Controlling for differences in decision maker characteristics, therefore, might decision-making procedures by themselves produce important differences in the thinking and reasoning of those who are making the decisions?

The structural and procedural differences of the legal decision are manifested in numerous ways. Consider, for example, the all-or-nothing nature of much of legal decision making. Legal decisions are typically binary, with the parties winning or losing, and with legal rules or precedents being applicable or not. Probabilistic determinations are the exception and not the norm in law. A plaintiff who suffers \$100,000 damages and proves her civil case to a 60% certainty does not recover \$60,000, as expected value decision theory would suggest, but rather the entire \$100,000; and if she established the same case with 48% certainty, she would get nothing at all. A defendant who is charged with first-degree murder (which includes a finding of premeditation) cannot be found guilty of manslaughter (which does not) if he was not charged with manslaughter but the jury thinks he indeed killed the victim without the requisite intent.⁸

Similarly, it is rare for a judge to say that a rule or precedent is almost applicable or partly applicable, and even rarer for an uncertain judge, at least explicitly, to split the difference in a legal argument. There has been little research how the all-or-nothing character of legal decision making might create or explain some of the differences between legal and nonlegal decision making.

The binary character of legal decision making is merely one example of the procedural peculiarity of legal decision making, but there are many others. Judges are typically expected to provide written reasons for their decisions, but how does the requirement of formal reason-giving affect the nature of the decision?⁹ Conversely, juries are typically prohibited from explaining the reasons behind their decisions, and how might this prohibition influence their decisions? The appellate process commonly produces redundancy in decision making, but how is the decision of an appellate court influenced by the knowledge that the judge below has already reached a decision about the same questions? Finally, and perhaps most obviously, legal procedures are especially adversarial, and it would be valuable to know the extent to which decision makers—whether judges or jurors—think differently in the context of adversarial presentations than they would were the same information and arguments presented to them in a less combative or more open-ended manner. In these and other respects, it may well be that considering legal reasoning solely as a matter of content- or process-based differences (or not) is too simple, and that a psychological account of legal reasoning must be conscious of how these distinctively legal procedures and structures affect the decision makers.

Conclusion and Future Directions

We have noted at various places that most of the research on judicial decision making has been based on assumptions rather than data about the similarity between judges and lay decision makers. There are obvious problems with trying to use judges and even experienced lawyers as experimental subjects. Still, insofar as the central questions of legal reasoning from a psychological perspective are the questions of whether people can be selected (or self-select) for a certain kind of legal reasoning ability, or whether they can be trained for a certain kind of legal reasoning ability, further research on the differences between lawyers, law students, and judges, on the one hand, and laypeople, on the other, remains an essential research task.

A related agenda for research is one that would distinguish the task of fact finding from the task of interpreting, applying, and, at times, making law. The traditional claims for legal reasoning are largely about these latter functions, and thus the evaluation of the traditional claims will need to focus more on the application of rules and precedents than has thus far been the case. Only when such research

has been conducted in a systematic way will we will be able to approach an answer to the question of whether Kingsfield was right, or whether he was just the spokesman, as the more extreme of the Legal Realists claimed, for a long-standing but unsupported self-serving ideology of the legal and judicial professions.

Notes

1. In three recent Supreme Court nomination hearings, for example, now-Chief Justice Roberts insisted that Supreme Court Justices were like baseball umpires, simply calling balls and strikes with no interest in the outcome; now-Justice Sotomayor claimed that her past decisions as a judge were based solely on the law and not on her personal views, and that her future decisions would be the same; and now-Justice Kagan, even while acknowledging that Justices must exercise substantial discretion, said that good Supreme Court decisions were still based on “the law all the way down.”

2. The difference between this formulation of the Realist view and the earlier one is, did the judge first consciously decide what she wanted the outcome to be (e.g., Bush has to win in *Bush v. Gore*, 2000) and then try to justify it (strong Realism) or did the decision come unbidden, as a “hunch”? This latter version sounds a bit like the Moral Intuitionist version of moral reasoning (Haidt, 2001; see Chapter 19)—in which people make moral judgments from quick intuitions then strive to justify them—but they are different. The Moral Intuitionist view is vague about what intuitions are and how they arise; we believe that intuitions arise from knowledge, and, thus, an experienced judge’s intuition about a case will reflect her knowledge of other similar cases. She may arrive at the opinion consistent with her values not because she consciously decided which way to rule, but because her previous knowledge and beliefs gave her a justifiable intuition (Spellman 2010; see Kahneman & Klein, 2009).

3. Civil law countries are those whose legal systems emanate, for example, from the Code of Justinian in Roman times or the Napoleonic Code 2,000 years later.

4. Common-law countries include the United States, the United Kingdom, and Australia. The type of legal system tends to vary with whether the country has juries, with common-law countries using them more and civil-law countries using them less, but the covariation is not a necessary one.

5. The key is to argue that these differences make it not the “same” question.

6. Or, perhaps, because the court believed as a policy matter that they *ought* to be treated as similar and decided accordingly. Similarity judgments may be guided by pragmatic relevance (Spellman & Holyoak, 1996).

7. The rule keeping out such evidence seems concerned with people making the Fundamental Attribution Error (Ross, 1977).

8. This all-or-none nature of a probabilistic verdict provides the backdrop for pretrial settlements and plea bargains. It also affects how much money a plaintiff might ask for in a civil case and which criminal charges a prosecuting attorney will bring.

9. It is in vogue to believe that not thinking about a complex decision is best (Dijksterhuis, Bos, Nordgren & van Baaren, 2006), but there is concern about those findings (e.g., Payne, Samper, Bettman & Luce, 2008; see also McMackin & Slovic, 2000).

Medical Reasoning and Thinking

Vimla L. Patel, Jose F. Arocha, and Jiajie Zhang

Abstract

The practice of medicine requires art as well as science. The latter argues for a deeper understanding of the mechanisms underlying disease processes and use of scientific evidence in making patient care decisions. The study of medical reasoning and thinking underlies much of medical cognition and has been the focus of research in cognitive science and artificial intelligence in medicine. Expertise and medical knowledge organization, the directionality of reasoning, and the nature of medical errors are intricately tied to thinking and decision-making processes in medicine. With the recent advancement of technology in medicine, technology-mediated reasoning and reasoning support systems will be a focus for future research. This chapter discusses these issues within historical and current research perspectives.

Key Words: medical reasoning, directionality of reasoning, knowledge organization, expertise, medical error, technology-mediated thinking

What Is Medical Reasoning?

Medical cognition refers to the study of cognitive structure and processes, such as perception and action, comprehension, problem solving, decision making, memory, and knowledge representation in medical practice or in tasks representative of medical practice. Medical reasoning research describes a form of qualitative and quantitative inquiry that examines the cognitive processes underlying medical decisions. Researchers study individuals at various levels of experience and in different roles in medical settings, including medical students, physicians, nurses, and biomedical scientists.

Medical problem solving, diagnostic reasoning, and decision making are all terms used in a growing body of literature that examines how clinicians understand biomedical information, solve clinical problems, and make clinical decisions. The study

of medical reasoning underlies much of medical cognition, and it has been the focus of considerable research in cognitive science and artificial intelligence as applied to medicine.

Medical reasoning involves an inferential process for making diagnostic or therapeutic decisions or understanding the pathology of a disease process. On the one hand, medical reasoning is basic to all higher level cognitive processes in medicine, such as problem solving and medical text comprehension. On the other hand, the structure of medical reasoning is itself the subject of considerable scrutiny. For example, the directionality of reasoning in medicine has been an issue of considerable controversy in medical cognition, medical education, and artificial intelligence in medicine. It is typical to partition medical reasoning into clinical and biomedical or basic science reasoning. These are some of the central themes in this chapter.

Early Research on Medical Problem Solving and Reasoning

Understanding the thought processes involved in clinical reasoning to promote more effective practices has been the subject of inquiry for more than a century (Osler, 1906). However, it was not until the development of medical cognition, a subfield of cognitive science devoted to the study of cognitive processes in medical tasks, that major scientifically based advances were made. Studies of medical cognition include analyses of performance in “real-world” clinical environments as well as in experimental settings.

There have been two primary approaches to medical reasoning: the decision-analytic approach and the information-processing approach. Decision analysis research aims to compare the performance of a physician with a mathematical model that represents the ideal of rationality and focuses on the reasoning “fallacies” and biases inherent in human clinical decision making (Leaper, Horrocks, Staniland, & De Dombal, 1972). In contrast, the information-processing approach focuses on the description of cognitive processes in reasoning tasks and the development of information-processing models of performance, typically relying on protocol analysis (Ericsson & Simon, 1993) and other techniques, such as naturalistic observation. Human information-processing research has typically focused on the individual. A dual focus on in-depth task analysis and on the study of human performance is a central feature of the information-processing approach to medical cognition, which is the focus of this section.

The information-processing view of cognitive processes came into prominence in the early 1970s, spearheaded by the immensely influential work of Newell and Simon (1972) on problem solving (see Bassok & Novick, Chapter 21). Problem solving was conceived of as search in a problem space in which a problem solver was viewed as selecting an option (e.g., a hypothesis or an inference) or performing an operation (from a set of possible operations) in moving toward a problem solution or a goal state (e.g., diagnosis or treatment plan). This conceptualization had an enormous impact in both cognitive psychology and artificial intelligence (AI). It also led to rapid advances in medical reasoning and problem-solving research, as exemplified by

the seminal work of Elstein, Shulman, and Sprafka (1978). These investigators studied the problem-solving processes of physicians, drawing on then contemporary methods and theories of cognition. Their view of problem solving had a substantial influence on both studies of medical reasoning and medical education. They were the first to use experimental methods and theories of cognitive science to investigate clinical competency. Their extensive empirical research led to the development of a model of hypothetico-deductive reasoning, which proposed that physicians reasoned by first generating and then testing a set of hypotheses to account for clinical data (i.e., reasoning from hypothesis to data). This model of problem solving had a substantial influence on studies of both medical cognition and medical education (Elstein, 2009; Elstein, Shulman, & Sprafka, 1978).

At the same time when empirical research in medical cognition was beginning, medical AI (particularly, expert systems technology) began development of methods and implementations of expert systems that mimic the way medical experts reasoned. AI in medicine and medical cognition mutually influenced each other in a number of ways, including (1) providing a basis for developing formal models of competence in problem-solving tasks; (2) elucidating the structure of medical knowledge and providing important epistemological distinctions, and (3) characterizing productive and less-productive lines of reasoning in diagnostic and therapeutic tasks. Gorry (1973) conducted a series of studies comparing a computational model of medical problem solving with the actual problem-solving behavior of physicians. This analysis provided a basis for characterizing a sequential process of medical decision making, one that differs in important respects from early diagnostic computational systems based on Bayes’ theorem (Ledley & Lusted, 1959; see Chater & Oaksford, Chapter 2; Griffiths, Tenenbaum, & Kemp, Chapter 3), which describes the relations between conditional probabilities and provides a normative rule for updating belief in light of evidence. Pauker, Gorry, Kassirer, and Schwartz (1976) capitalized on some of the insights of Gorry’s earlier work to develop the *Present Illness Program* (PIP), a program designed to take the history of a patient with edema. Several of the questions guiding this research, including the nature and organization of expert knowledge, were of central concern to both developers of medical expert systems and researchers in medical cognition. The development and refinement of the program was partially

based on studies of clinical problem solving. Medical expert consultation systems, such as Internist (Miller, Pople, & Myers, 1984) and MYCIN (Shortliffe, 1976), introduced ideas about knowledge-based reasoning strategies across a range of cognitive tasks. MYCIN, in particular, had a substantial influence on cognitive science. It contributed several advances (e.g., representing reasoning under uncertainty) in the use of production systems as a representation scheme in a complex, knowledge-based domain. MYCIN also highlighted the difference between medical problem solving and the cognitive dimensions of medical explanation. Clancey's work (Clancey & Letsinger, 1984; Clancey, 1985) in GUIDON and NEOMYCIN was particularly influential in the evolution of models of medical cognition. Clancey endeavored to reconfigure MYCIN in order to employ the system to teach medical students about meningitis and related disorders. NEOMYCIN was based on a more psychologically plausible model of medical diagnosis. This model differentiated data-directed and hypothesis-directed reasoning and separated control knowledge (rules) from the facts upon which it operated.

Feltovich, Johnson, Moller, and Swanson (1984), drawing on models of knowledge representation from medical AI, characterized fine-grained differences in knowledge organization between subjects with different levels of expertise in the domain of pediatric cardiology. These differences accounted for subjects' inferences about diagnostic cues and their evaluation of competing hypotheses. Patel and Groen (1986), incorporating distinctions introduced by Clancey, studied the knowledge-based solution strategies of expert cardiologists as evidenced by their pathophysiological explanations of a complex clinical problem. The results indicated that subjects, who accurately diagnosed the problem, employed a forward-driven reasoning strategy—using patient data to lead toward a complete diagnosis (i.e., reasoning from data to hypothesis). In contrast, subjects who misdiagnosed or partially diagnosed the patient problem used a backward-driven reasoning strategy. These research findings presented a challenge to the hypothetico-deductive model of reasoning espoused by Elstein, Shulman, and Sprafka (1978), which did not differentiate expert from nonexpert reasoning strategies.

Much of the early research in the study of reasoning in domains such as medicine was carried out in laboratory or experimental settings. More

recently, there has been a shift toward examining cognitive issues in naturalistic settings, such as medical teams in intensive care units (Patel, Kaufman, & Magder, 1996), anesthesiologists working in surgery (Gaba, 1992), nurses providing emergency telephone triage (Leprohon & Patel, 1995), and patients reasoning with the aid of technology in the health care system (Patel, Arocha, & Kushniruk, 2002). This research was informed by work in the area of dynamic decision making (Salas & Klein, 2001), complex problem solving (Frensch & Funke, 1995), human factors (Hoffman & Deffenbacher, 1992; Vicente & Rasmussen, 1990), and cognitive engineering (Rasmussen, Pejtersen, & Goodstein, 1994).

Models of Medical Reasoning

The traditional view of medical reasoning has been to treat diagnosis as similar to the classical view of scientist's task of making a discovery or engaging in scientific experimentation. This classical view of scientific reasoning makes the same assumption that diagnostic inference follows a hypothetico-deductive process of reaching conclusions by testing hypotheses based on clinical evidence. Within a cognitive perspective, as we saw previously, this view of the diagnostic process in medicine was first proposed in the influential work of Elstein, Shulman, and Sprafka (1978). However, the view of medical reasoning as hypothetico-deductive has been challenged, as we will see in this section. Similarly, the classical view of scientific reasoning has been expanded to cover multiple types of reasoning strategies.

Toward a Model of Reasoning in Medicine: Induction, Deduction, and Abduction

It is generally agreed upon that there are two basic forms of reasoning. One is deductive reasoning (see Evans, Chapter 8), which in the context of medicine consists of deriving a particular conclusion (such as a diagnosis) from a hypothesis (such as a diagnostic category or a pathophysiological process). The other form is inductive reasoning, which consists of generating a likely general conclusion (such as a diagnosis) from patient data (see Rips et al., Chapter 11). However, reasoning in the "real world" does not appear to fit neatly into any of these basic types. For this reason, a third form of reasoning has been recognized as best capturing the generation of clinical hypotheses, where deduction and induction are intermixed. This

corresponds to what Peirce (1955; see Lombrozo, Chapter 14) termed “abductive reasoning,” which in the medical context is illustrated by the clinician generating a plausible explanatory hypothesis through a process of heuristic rule utilization (Magnani, 1992, 2001).

There are different uses of the term “abductive reasoning.” In our chapter, we use it to refer to a cyclical process of generating possible explanations (i.e., identification of a set of hypotheses that are able to account for the clinical case on the basis of the available data) from a set of data and testing those explanations (i.e., evaluation of each generated hypothesis on the basis of its expected consequences) for the abnormal state of the patient at hand (Elstein, Shulman, & Sprafka, 1978; Joseph & Patel, 1990; Kassirer, 1989; Ramoni, Stefanelli, Magnani, & Barosi, 1992). Abductive reasoning is a data-driven process and also dependent on domain knowledge.¹ Within this generic framework, various models of diagnostic reasoning may be constructed. Following Patel and Ramoni (1997), we can distinguish between two major models of diagnostic reasoning: *heuristic classification* (Clancey, 1985) and *cover and differentiate* (Eshelman, 1988). However, these models can be seen as special cases of a more general model: the *select and test* model (Ramoni et al., 1992), where the processes of hypothesis generation and testing can be characterized in terms of four types of processes: abstraction, abduction, deduction, and induction. During *abstraction*, pieces of data in the data set are selected according to their relevance for the problem solution and chunked in schemas representing an abstract description of the problem at hand (e.g., abstracting that an adult male with hemoglobin concentration less than 14 g/dL is an anemic patient). Following this, hypotheses that could account for the current situation are related through a process of *abduction*, characterized by a “backward flow” of inferences across a chain of directed relations that identify those initial conditions from which the current abstract representation of the problem originates. This process provides tentative solutions to the problem at hand by way of hypotheses. For example, knowing that disease *A* will cause symptom *b*, by abduction one will try to identify the explanation for *b*, while through deduction one will forecast that a patient affected by disease *A* will manifest symptom *b*; both inferences use the same relation along two different directions. These two types of clinical reasoning in medicine are described by Patel and Ramoni (1997).

In the testing phase, hypotheses are incrementally tested according to their ability to account for the whole problem, where *deduction* serves to build up the possible world described by the consequences of each hypothesis. This kind of reasoning is customarily regarded as a common way of evaluating diagnostic hypotheses (Joseph & Patel, 1990; Kassirer, 1989; Patel, Arocha, & Kaufman, 1994; Patel, Evans, & Kaufman, 1989). As predictions are derived from hypotheses, they are matched to the case through a process of *induction*, where a prediction generated from a hypothesis can be matched with one specific aspect of the patient problem. The major feature of induction is, therefore, the ability to rule out those hypotheses whose expected consequences turn out to be not in agreement with the patient problem. This is because there is no way to logically confirm a hypothesis. We can only disconfirm or refute it in the presence of contrary evidence. This evaluation process closes the testing phase of the diagnostic cycle. Moreover, it determines which information is needed in order to discriminate among hypotheses and hence which information has to be collected.

Hypothesis Testing and Clinical Reasoning: A View From the Empirical Literature

A model such as one presented earlier can be used to explain the medical diagnostic process, while the empirical literature highlights aspects of medical reasoning that led support to the model. First, seasoned clinicians are selective in the data they collect (*abstraction*), focusing only on the data that are relevant to the generated hypotheses, while ignoring other less relevant data, as was found in the work of Patel and Groen (1986) and later supported in other studies. Successful clinicians focus on the fewest pieces of data and are better able to integrate these pieces of data into a coherent explanation for the problems (see Groves, O’Rourke, & Alexander, 2003, for an example). Second, typically physicians generate a small set of hypotheses very early in the case (*abduction*), as soon as the first pieces of data become available, as was first shown by Elstein, Shulman, and Sprafka (1978) and later corroborated by Feltovich et al.’s (1984) logical competitor set. Third, as also originally shown by Elstein, Shulman, and Sprafka (1978), physicians sometimes make use of the hypothetico-deductive process (*deduction*), which involved four stages: cue acquisition, hypothesis generation, cue interpretation, and hypothesis evaluation. Cues in the clinical case lead

to the generation of a few selected hypotheses, and then each hypothesis is evaluated for consistency with the cues (*induction*).

The empirical research has also highlighted other aspects of medical reasoning that are independent of the general model. These include the directionality of diagnostic reasoning, the role of causal and analogical reasoning in clinical problem solving, and the development of medical expertise. A series of articles (Patel, Arocha, & Kaufman, 1994, 2001; Patel, Kaufman, & Arocha, 2002) and other papers in edited volumes (Clancey & Shortliffe, 1984; Szolovits, 1982) provide summaries of the different aspects of medical cognition. To some of these issues, we turn next.

Problem-Solving Strategies: Forward-Driven and Backward-Driven Reasoning

As indicated above, the study that Patel and Groen (1986) conducted on the knowledge-based solution strategies used by expert cardiologists showing that those physicians who accurately diagnosed the problem employed a forward-driven (also called data-driven) reasoning strategy. That is, they used patient data to generate a fully correct diagnosis; whereas those who did not diagnose the problem accurately or failed to provide a correct solution to the patient problem used a backward or hypothesis-driven reasoning strategy. Such results challenged the hypothetico-deductive strategy proposed by Elstein, Shulman, and Sprafka (1978). Given the contrasting results of Patel and Groen with those of Elstein et al., it was necessary to search for an explanation that reconciled such empirical findings.

A hypothesis for reconciling these seemingly contradictory results is that forward-driven reasoning is used in clinical problems in which the physician has ample experience. In contrast, when reasoning through unfamiliar or difficult cases, physicians resort to backward-driven reasoning because their knowledge base does not support a pattern-matching process. To support this explanation, Patel, Groen, and Arocha (1990) looked for the conditions under which forward-driven reasoning breaks down. Cardiologists and endocrinologists were asked to solve diagnostic problems both in cardiology and in endocrinology. They showed that under conditions of case complexity and uncertainty, the pattern of forward-driven reasoning was disrupted. More specifically, the breakdown occurred when nonsalient cues in the case were tested for consistency against

the main hypothesis, even by subjects who had generated the correct diagnosis. The results supported previous studies in that subjects with accurate diagnoses used pure forward-driven reasoning.

If forward-driven reasoning breaks down when case complexity is introduced, then experts and novices should reason differently because what are routine cases for experts would not be so for less-than-expert subjects. Investigating clinical reasoning in a range of contexts of varying complexity (Patel, Arocha, & Kaufman, 1994; Patel & Groen, 1991a), the researchers found that novices and experts have different patterns of data-driven and hypothesis-driven reasoning. The use that experts make of data-driven reasoning, which depends on the physician possessing a highly organized knowledge base about the patient's disease (including sets of signs and symptoms). Furthermore, due to their extensive knowledge base and the high-level inferences they make, experts typically skip steps in their reasoning. In contrast, because of their lack of substantive knowledge or their inability to distinguish relevant from irrelevant knowledge, less-than-expert subjects (novices and intermediates) used more hypothesis-driven reasoning, resulting often in very complex reasoning patterns. Similar patterns of reasoning have been found in other domains (Larkin et al., 1980).

The fact that experts and novices reason differently suggests that they might reach different conclusions (e.g., decisions or understandings) when solving medical problems. Although data-driven reasoning is highly efficient, it is often error prone in the absence of adequate domain knowledge, since there are no built-in checks on the legitimacy of the inferences that a person makes. Pure data-driven reasoning is only successful in constrained situations, where one's knowledge of a problem can result in a complete chain of inferences from the initial problem statement to the problem solution. In contrast, hypothesis-driven reasoning is slower and requires high memory load, because one has to keep track of goals and hypotheses. It is therefore most likely to be used when domain knowledge is inadequate or the problem is complex. Hypothesis-driven reasoning is an example of a *weak method* of problem solving in the sense that it is used in the absence of relevant prior knowledge and when there is uncertainty about problem solutions (see Bassok & Novick, Chapter 21). In problem-solving terms, strong methods engage knowledge, whereas weak methods refer to general, knowledge-independent

strategies. “Weak” does not necessarily imply ineffectual in this context.

Studies also showed that data-driven reasoning could break down due to uncertainty (Patel, Groen, & Arocha, 1990). These conditions include the presence of “loose ends” in explanations, where some particular piece of information remains unaccounted for and isolated from the overall explanation. Loose ends trigger explanatory processes that work by hypothesizing a disease, for instance, and trying to fit the loose ends within it, in a hypothesis-driven reasoning fashion. The presence of loose ends may foster learning, as the “reasoner” searches for an explanation for them. For example, a medical student or a physician may encounter a sign or a symptom in a patient problem and look for information that may account for the finding, by searching for similar cases seen in the past, reading a specialized medical book, or consulting a domain expert.

However, in some circumstances, the use of data-driven reasoning may lead to a heavy cognitive load (see van Merriënboer & Sweller, 2005, for a recent review). For instance, when students are given problems to solve while they are being trained in the use of problem-solving strategies, the situation produces a heavy load on cognitive resources, which may diminish students’ ability to focus on the task. The reason is that students have to share cognitive resources (e.g., attention, memory) between learning the problem-solving method and learning the content of the material. Research by Sweller (1988) suggested that when subjects use a strategy based on data-driven reasoning, they are more able to acquire a schema for the problem. In addition, other characteristics associated with expert performance were observed, such as a reduced number of moves to the solution. However, when subjects used a hypothesis-driven reasoning strategy, their problem-solving performance suffered.

The Role of Similarity of Cases in Diagnostic Reasoning

The fact that physicians make use of forward-driven reasoning in routine cases suggests a type of processing that is fast enough to be able to lead to the recognition of a set of signs and symptoms in a patient and generate a diagnosis based on such recognition. Most often this has been interpreted as a type of specific-to-general reasoning (e.g., reasoning from an individual case to a clinical schema or prototype). However, consistent with the model of abductive reasoning, some philosophers (Schaffner,

1986) and empirical researchers (Norman & Brooks, 1997) have supported an alternative hypothesis, which postulates specific-to-specific reasoning. That is, experts may use knowledge of specific instances (e.g., particular patients with specific disease presentations) to interpret particular cases, rather than relying only on general clinical knowledge (Kassirer & Kopelman, 1990). Similarity-based clinical reasoning has been informed by models of categorization, where the process of interpreting information, such as a clinical case, can be made by matching the case to a general, abstract category (e.g., a schema). However, in similarity-based reasoning a diagnosis may be reached through a process of matching the current case to similar cases seen in the past (Norman, Young, & Brooks, 2007).

Brooks and colleagues (Brooks, Norman, & Allen, 1991; Norman & Brooks, 1997) investigated clinicians’ use of specific instances in order to compare and interpret a current clinical case. In these studies, mostly involving visual diagnosis based on X-rays, dermatological slides, and electrocardiograms, they showed that specific similarity to previous cases accounts for about 30% of diagnoses made. Furthermore, errors made by experts in identifying abnormalities in images were affected by the prior history of the patient. That is, if the prior history of the patient contained a possible abnormality, expert physicians more often identified those abnormalities in the images even when none were there, which was interpreted as the effect of specific past cases on the interpretation of the current case.

Norman and colleagues (Norman & Brooks, 1997; Norman, Young, & Brooks, 2007) have argued against the hypothesis that expert physicians always diagnose clinical cases by “analyzing” signs and symptoms and developing correspondences between those signs, symptoms, and diagnoses, in the manner that traditional cognitive research in medical reasoning suggests. They propose instead that medical diagnosis is often “nonanalytic.” By this, they mean that diagnostic reasoning is driven by the overall similarity between a previous case and the current case: A case previously seen in medical practice is retrieved unanalyzed from memory and compared to the current case (a kind of exemplar-based or case-based reasoning).

This discussion has its counterpart in the psychology of categorization, where two accounts have been proposed: Either categorization works by relying on prototypes or on exemplars (see Rips et al., Chapter 11). Exemplar-based thinking is certainly

an important process in human cognition. There is ample evidence of conditions where reasoning by analogy to previous cases is used (Gentner & Holyoak, 1997; Holyoak & Thagard, 1997; see Holyoak, Chapter 13). Furthermore, given the complexity of natural reasoning in a highly dense knowledge domain such as medicine, it is very likely that more than one type of reasoning is actually employed. Seen in this light, the search for a single manner in which clinicians diagnose clinical problems may not be a reasonable goal. The inherent adaptability of humans to different kinds of knowledge domains, situations, problems, and cases may call for the use of a variety of reasoning modes, which is what, after all, the notion of abductive medical reasoning has tried to describe (Patel & Ramoni, 1997; see Lombrozo, Chapter 14). Similar conclusions appear to have been developed in the dual-process theory of reasoning (Evans, 2008; see Evans, Chapter 8). Thus, it seems that alongside a rule-based, more effortful prototype reasoning, clinical reasoning also allows for exemplar-based reasoning. However, it should be noted that not all reasoning from instances/analogs is nonanalytic. For example, analogical inferences may involve causal analysis of source analog in which similarity between particulars may be the main cognitive mechanism.

Reasoning and the Nature of Medical Knowledge

A reason for the variety of modes of reasoning used in actual diagnostic problems may be found in the inherent organization of medical knowledge. The prevalent view in the philosophy of medicine (Blois, 1988) has been that medical knowledge has an extremely complex organization, requiring the use of different reasoning strategies than those used in other formal scientific disciplines, such as physics. According to Blois, disciplines such as physics, chemistry, and some subfields of biology, are *horizontally* organized, where these domains are characterized by the construction of causal relations among concepts and by the application of general principles to specific instances (Blois, 1988). Furthermore, Blois asserts that such scientific fields are organized in a hypothetico-deductive manner such that particular cases are explained from first principles, where understanding the causal mechanisms plays a major role. In contrast, in medicine, reasoning from first principles does not play such an important role. He argued that reasoning in medicine instead requires

vertical thinking. In this view, in the medical disciplines, notably clinical medicine, reasoning by analogy from case to case plays a more important role than reasoning causally from an understanding of the mechanism of disease. Based on this distinction, Blois argued that reasoning in the physical sciences and reasoning in the biomedical sciences are of different kinds.

Schaffner (1986) has argued that theories in the physical sciences can be conceptualized as a “deductive systematization of a broad class of generalizations under a small number of axioms” (Schaffner, 1986, p. 69), but that such characterization cannot be applied to the biomedical sciences. The latter are characterized by what Schaffner (1986, p. 68) calls “a series of overlapping interlevel temporal models.” Different level of aggregation (e.g., biochemical, cellular, organ), each with its own temporal development (e.g., some deterministic, others probabilistic, others still random) makes it difficult to develop deductive structures to explain biomedical reality. Rather, theories are based on the familiarization with shared exemplars to a much greater degree than is the case in the physical sciences. In biomedical research, an organism such as a *Drosophila*, for instance, is used as an exemplar embodying a given disease mechanism, which by analogy applies to other organisms, including humans. In the clinical sciences, the patient is seen as an exemplar to which generalizations based on multiple overlapping models are applied from disease mechanisms (e.g., physiological, biochemical, pathological) and from the population of similar patients (e.g., typical diagnostic categories described in clinical medicine).

A reason for the peculiar nature of biomedical knowledge may be that the field consists of two very different categories of knowledge: clinical knowledge, including knowledge of disease processes and associated findings; and basic science knowledge, incorporating subject matters such as biochemistry, anatomy, and physiology. Basic science or biomedical knowledge is supposed to provide a scientific foundation for clinical reasoning. The conventional view is that basic science knowledge can be seamlessly integrated into clinical knowledge, analogously to the way that learning the rules of the road can contribute to one's mastery of driving a car. A particular piece of biomedical knowledge could be automatically elicited in a range of clinical contexts and tasks in more or less the same fashion. However, the integration of these two types of knowledge has been difficult to demonstrate in empirical research.

Knowledge Organization and Changes in Directionality

Following Blois (1988) and Schaffner (1986), it can be argued that the way medical knowledge is organized can be a determinant factor explaining why experts do not use the hypothetico-deductive method of reasoning. Maybe the medical domain is too messy to allow neat partitioning and deductive use of reasoning strategies. Although the theory of reasoning in medicine is basically a theory of expert knowledge, reaching the level of efficient reasoning of the expert clinician reflects the extended continuum of training and levels of reasoning performance (Chi, Bassok, Lewis, Reiman, & Glaser, 1989; Dufresne, Gerace, Hardiman, & Mestre, 1992). This continuum is related to the nature of medical knowledge and its acquisition. Changes have been described in this process that serve to characterize the various phases medical trainees go through to become expert clinicians.

An important characteristic of this process is the *intermediate effect*. Although it generally seems reasonable to assume that performance will improve with training or time on task, there appear to be particular transitions in which subjects exhibit a certain drop in performance. This is an example of what is referred to in the developmental literature as non-monotonicity (Strauss & Stavy, 1982), and it has also been observed in skill acquisition (Robertson & Glines, 1985). The result is a learning curve or developmental pattern that is shaped like either a U or an inverted U, as illustrated in Figure 37.1. In the development of medical expertise, the performance

of intermediates reflects the degradation in reasoning that results from the acquisition of knowledge during a period when such knowledge is not well organized and irrelevant associations abound in the learner's knowledge base. In contrast, the novice's knowledge base is sparse, containing very few associations, whereas the expert's knowledge base has been pruned of the irrelevancies that characterize intermediates.

It should be noted that not all intermediate performance is nonmonotonic; for example, on some global criteria such as diagnostic accuracy there appears to be a steady improvement (Patel & Groen, 1991b). However, this increase in accuracy seems to be linked to a change in diagnostic strategy from hypothesis-driven reasoning to data-driven reasoning (Coderre, Mandin, Harasym, & Fick, 2003), and better organized knowledge in memory. Thus, knowledge acquisition results in changes in knowledge organization, which result in changes in the strategies used to solve clinical problems, which in turn lead to greater diagnostic accuracy. What the intermediate effect tells us is that the progression from a novice to an expert does not necessarily follow a linear improvement in performance, but a U-shaped pattern, where performance drops before it gets better. This is illustrated in Figure 37.1, where medical students' recall of a clinical problem (after reading it once) showed an inverted U-shaped pattern with the third-year students recalling case information the most (Patel & Groen, 1991b). Their inability to separate relevant from irrelevant information was consistently validated under various task conditions. This

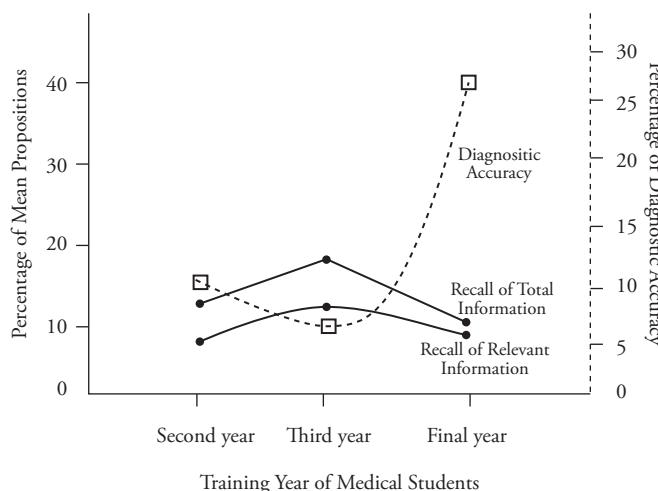

Fig. 37.1 The “intermediate effect.” Recall of total and relevant information as a function of expertise, showing inverted U-shaped pattern, with intermediates recalling more relevant and irrelevant information. The performance level as a function of diagnostic accuracy and expertise shows a U-shaped phenomenon, where performance drops at the intermediate level (third year) before it gets better with training.

inability reflects in a decrease in diagnostic accuracy. Novices do not know enough, while experts know enough and have a well-developed schema for the problem to make accurate diagnoses. Intermediate-level subjects remember the most, but their knowledge is not organized in such a fashion that allows them to generate accurate diagnoses.

Now let us look at some details of the intermediate effect. The intermediate effect occurs with many tasks and at various levels of expertise. The tasks vary from recall of clinical cases (Claessen & Boshuizen, 1985), explanation of clinical problems (Arocha & Patel, 1995), to generating laboratory data (Patel, Groen, & Patel, 1997). For instance, when asked to recall clinical data from case descriptions, intermediates tend to recall more irrelevant information (Schmidt & Boshuizen, 1993) or generate more irrelevant hypotheses to account for a clinical case than novices or experts (Arocha & Patel, 1995). The phenomenon may be due to the fact that intermediates have acquired an extensive body of knowledge but have not yet reorganized this knowledge in a functional manner. Thus, intermediate knowledge has a sort of network structure that results in considerable search, which makes it more difficult for intermediates to set up structures for rapid encoding and selective retrieval of information (Patel & Groen, 1991a). In contrast, expert knowledge is finely tuned to perform various tasks and experts can readily filter out irrelevant information using their hierarchically organized schemata. The difference is reflected both in the structural organization of knowledge and the extent to which it is proceduralized to perform different tasks.

Schmidt and Boshuizen (1993) reported that intermediate nonmonotonicity recall effects disappear by using short exposure times (about 30 seconds), which suggests that under time-restricted conditions, intermediates cannot engage in extraneous search. While a novice's knowledge base is likely to be sparse and an expert's knowledge base is intricately interconnected, the knowledge base of an intermediate possesses many of the pieces of knowledge in place but lacks the extensive connectedness of an expert. Until this knowledge becomes further consolidated, the intermediate is more likely to engage in unnecessary search. Whether this knowledge, painfully acquired during medical training, is really necessary for clinical reasoning has been a focus of intensive research and great debate. If expert clinicians do not explicitly use underlying biomedical knowledge, does that mean that

it is not necessary? Or could it be simply the case that this knowledge remains "dormant" until it is really needed? This raises an important question of whether expert medical knowledge when applied to solving clinical problems is "deep" (e.g., making use of causal pathophysiological or basic science knowledge in clinical problem solving) or "shallow" (e.g., relying on the use of associations between disease categories and clinical manifestations of those categories, without considering the mechanism of the disease).

Causal Reasoning in Medicine

The differential role of basic science knowledge (e.g., physiology and biochemistry) in solving problems of varying complexity and the differences between subjects at different levels of expertise (Patel, Arocha, & Kaufman, 1994) have been a source of controversy in the study of medical cognition (Patel & Kaufman, 1994), as well as in medical education and artificial intelligence. As expertise develops, the disease knowledge of a clinician becomes more dependent on clinical experience, and clinical problem solving is increasingly guided by the use of exemplars and analogy and becomes less dependent on a functional understanding of the system in question. However, an in-depth conceptual understanding of basic science plays a central role in reasoning about complex problems and is also important in generating explanations and justifications for decisions.

Researchers in artificial intelligence were confronted with similar problems in extending the utility of systems beyond their immediate knowledge base. Biomedical knowledge can serve different functional roles depending on the goals of the system. Most models of diagnostic reasoning in medicine can be characterized as being "shallow." For instance, a "shallow" medical expert system (e.g., MYCIN and INTERNIST) reasons by relating observations to intermediate hypotheses that partition the problem space, and further associating intermediate hypotheses with diagnostic hypotheses. This is consistent with the way physicians appear to reason. There are, however, other medical reasoning system models that propose a "deep" mode of reasoning as a main mechanism. Chandrasekeran, Smith, and Sticklen (1989) characterize a deep system as one that embodies a causal mental model of bodily function and malfunction, similar to the models used in qualitative physics (Bobrow, 1985). Systems such as MDX-2 (Chandrasakeran

et al., 1989) or QSIM (Kuipers, 1987) have explicit representations of structural components and their relations, the functions of these components (in essence their purpose), and their relationship to behavioral states.

To become licensed physicians, medical trainees undergo a lengthy training process that includes learning of biomedical sciences, including biochemistry, physiology, and anatomy. There is an apparent contradiction between this type of training and the seeming absence of “deep” biomedical knowledge being used during expert medical reasoning. To account for such apparent inconsistency, Boshuizen and Schmidt (1992) proposed a learning mechanism, *knowledge encapsulation*. Knowledge encapsulation is a learning process that involves the organization of biomedical propositions and their interrelations in associative clusters, under a small number of higher level clinical propositions with the same explanatory power. Through exposure to clinical training, biomedical knowledge presumably becomes integrated with clinical knowledge. Biomedical knowledge can be “unpacked” when needed, but it is not used as a first line of explanation.

Boshuizen and Schmidt (1992) cite a wide range of clinical reasoning and recall studies that support this kind of learning process. Of particular importance is the well-documented finding that with increasing levels of expertise, physicians produce explanations at higher levels of generality, using fewer and fewer biomedical concepts while producing consistently accurate responses. The intermediate effect can also be accounted for as a stage in the encapsulation process in which a trainee’s network of knowledge has not yet become sufficiently differentiated, thus resulting in more extensive processing of information.

Knowledge encapsulation provides an appealing account of a range of developmental phenomena in the course of acquiring medical expertise. However, the integration of basic science in clinical knowledge is a rather complex process, and encapsulation is likely to be only part of the knowledge development process. Basic science knowledge is likely to play a different role in different clinical domains. For example, clinical expertise in perceptual domains, such as dermatology and radiology, necessitates a relatively robust model of anatomical structures that is the primary source of knowledge for diagnostic classification. In other domains, such as cardiology and endocrinology, basic science knowledge has a

more distant relationship with clinical knowledge. The misconceptions evident in physicians’ biomedical explanations would argue against their having well-developed encapsulated knowledge structures in which basic science knowledge could easily be retrieved and applied when necessary.

The results of research into medical problem solving are consistent with the idea that clinical medicine and biomedical sciences constitute two distinct and not completely compatible “worlds,” with distinct modes of reasoning and quite different ways of structuring knowledge (see Patel et al., 1994). Clinical knowledge is based on a complex taxonomy that relates disease symptoms to underlying pathology. In contrast, biomedical sciences are based on general principles defining chains of causal mechanisms. Thus, learning to explain how a set of symptoms is consistent with a diagnosis may be very different from learning how to explain what causes a disease. Although basic science knowledge and clinical knowledge can be seen as worlds apart, this does not mean that basic biomedical knowledge is completely erased from an expert’s disease schemata; rather, as suggested by the hypothesis of encapsulated knowledge, the two types of knowledge are not integrated into a whole (Rikers, Schmidt, & Moulaert, 2005). Thus, when physicians are trying to solve clinical cases at the limits of their expertise, they may resort to using biomedical knowledge to make sense of the clinical information and tie different concepts together, but in normal practice they seem to primarily use either schemata or exemplars that map directly onto clinical cases.

This “two worlds” position, although not incompatible with the notion of encapsulation, is supported in the study of conceptual understanding in biomedicine. The progression of mental models (White & Frederiksen, 1990) has been used as an alternative framework for characterizing the development of conceptual understanding in biomedical contexts. Mental models are dynamic knowledge structures that are composed to make sense of experience and to reason across spatial and/or temporal dimensions. An individual’s mental models provide predictive and explanatory capabilities of the function of a given system. White and Frederiksen employed the progression of mental models to explain the process of understanding increasingly sophisticated electrical circuits. This notion can be used to account for differences between novices and experts in understanding circulatory physiology, describing misconceptions, and explaining the

generation of spontaneous analogies in causal reasoning (Kaufman, Patel, & Magder, 1996).

Running a mental model is a potentially powerful form of reasoning, but it is also cognitively demanding. It may require an extended chain of reasoning and the use of complex representations. It is apparent that skilled individuals learn to circumvent long chains of reasoning and chunk or compile knowledge across intermediate states of inference (Chandrasekaran, 1994; Newell, 1990). This results in shorter, more direct, inferences that are stored in long-term memory and are directly available to be retrieved in the appropriate contexts. Chandrasekaran (1994) refers to this sort of knowledge as *compiled causal knowledge*. This term refers to knowledge of causal expectations that people compile directly from experience and partly by chunking results from previous problem-solving endeavors. The goals of the individual and the demands of recurring situations largely determine which pieces of knowledge get stored and used. When a physician is confronted with a similar situation, she can employ this compiled knowledge in an efficient and effective manner. The development of compiled knowledge is an integral part of the acquisition of expertise.

The idea of compiling declarative knowledge bears a certain resemblance to the idea of knowledge encapsulation. However, the claim differs in two important senses. First, the process of compiling knowledge is not one of subsumption or abstraction, and the original knowledge (uncompiled mental model) may no longer be available in a similar form (Kuijpers & Kassirer, 1984). Second, rather than being prestored unitary structures, mental models are composed dynamically out of constituent pieces of knowledge. The use of mental models is somewhat opportunistic and the learning process is less predictable. The compilation process can work in reverse as well. That is to say, discrete cause-and-effect relationships can be integrated into a mental model as a student reasons about complex physiological processes.

Errors in Medical Reasoning and Decision Making

One critical step toward understanding the cognitive mechanisms of performance problems in medical reasoning is to categorize medical errors along cognitively meaningful dimensions. Reason (1990) defines human error as a failure of achieving the intended outcome in a planned sequence of mental or physical activities. He divides human errors into

two major categories: (1) slips that result from the incorrect execution of a correct action sequence, and (2) mistakes that result from the correct execution of an incorrect action sequence. Norman's theory of action (Norman, 1986) decomposes a human activity into seven stages. Based on Reason's definition of human error and Norman's action theory, Zhang, Patel, Johnson, and Shortliffe (2004) developed a cognitive taxonomy. In this cognitive taxonomy, goal and intention mistakes are mistakes about declarative knowledge (knowledge about factual statements and propositions), such as "Motrin is a pain reliever and fever reducer." Action specification mistakes and action execution mistakes are mistakes about procedural knowledge (knowledge about procedures and rules), such as "give 1 tsp Motrin to a child per dosage up to 4 times a day if the child has fever or toothache and the weight of the child is 24–35 lb."

Goal mistakes and intention mistakes are caused by many complex factors such as incorrect knowledge, incomplete knowledge, misuse of knowledge, biases, faulty heuristics, and information overload. For example, neglect of base rate information could result in incorrect diagnosis of a disease. This is a well-documented finding in human decision making (Tversky & Kahneman, 1974). As another example, the goal of "treating the disease as pneumonia" could be a mistake if it is a misdiagnosis based on incomplete knowledge (e.g., without X-ray images). Intention mistakes can be caused by similar factors. For example, a physician treating a patient with oxygen set the flow control knob between 1 and 2 liters per minute, not realizing that the scale numbers represented discrete rather than continuous settings. As a result, the patient did not receive any oxygen. This is a mistake due to incomplete knowledge.

The use of heuristics is another common source of goal and intention mistakes. A heuristic that is often used is the reliance on disease schemata during clinical diagnosis. Disease schemata are knowledge structures that have been formed from previous experience with diagnosing diseases and contain information about relevant and irrelevant signs and symptoms. When physicians and medical students diagnose patients, they tend to rely on their schemata and base their reasoning on the apparent similarity of patient information with these schemata, instead of a more objective analysis of patient data. The schemata that are used in diagnosis often guide future reasoning about the patient, affecting what

tests are run and how data are interpreted. Arocha and Patel (1995) found that medical students and trainees maintained their initial hypotheses, even if subsequent data were contradictory. Therefore, if the initial hypothesis is wrong, errors in diagnosis and treatment are likely to occur. Preliminary presentation of the patient (e.g., signs and symptoms), then, becomes very important, because it can strongly suggest hypotheses that will be strongly held (i.e., lead to the use of schemata).

Medical Reasoning and Decision Research

Decision making is central to medical activity. Although health care professionals are generally highly proficient decision makers, their erroneous decisions have become the source of considerable public scrutiny, as described in three National Academy Press reports (Institute of Medicine, 1999, 2001, 2004).

Decisions involve the application of reasoning to select some course of action that achieves the desired goal. Hastie (2001) has identified three components of decision making: (a) choice options and courses of actions; (b) beliefs about objective states, processes, and events in the world, including outcomes states and means to achieve them; and (c) desires, values, or utilities that describe the consequences associated with the outcomes of each action-event combination. In this process, reasoning plays a major role. Research on hypothesis testing in the medical domain has shown the pervasiveness of confirmation bias (Patel, Groen, & Norman, 1993), which is evidenced by the generation of a hypothesis and the subsequent search for evidence consistent with the hypothesis, often leading to the failure to adequately consider alternative diagnostic possibilities. This bias may result in a less-than-thorough investigation with possible adverse consequences for the patient. A desire to confirm one's preferred hypothesis may moreover contribute to increased inefficiency and costs by leading to orders for additional laboratory tests that will do little to revise one's opinion, providing largely redundant data (Chapman & Elstein, 2000).

In natural setting of medicine, team decision making is the rule rather than the exception. Naturalistic decision making (NDM) is concerned with the study of cognition in "real-world" work environments that are often dynamic (e.g., rapidly changing; see Klein, Orasanu, Calderwood, & Zsambok, 1993). The majority of this research combines conventional protocol analytic methods with innovative

methods designed to investigate reasoning and behavior in realistic settings (Rasmussen, Pejtersen, & Goodstein, 1994; Woods, 1993). The study of decision making in the work context necessitates an extended cognitive science framework beyond typical characterizations of knowledge structures, processes, and skills, including modulating variables such as stress, time pressure, and fatigue as well as communication patterns that affect team performance.

Among the issues investigated in NDM are understanding how decisions are jointly negotiated and updated by participants differing substantially in their areas of expertise (e.g., pharmacology, respiratory medicine); how the complex communication process in these settings occurs; what role technology plays in mediating decisions and how it affects reasoning; and what the sources of error are in the decision-making process.

Research by Patel, Kaufman, and Magder (1996) studied decision making in a medical intensive care unit (ICU) with the objective of describing jointly negotiated decisions, communication processes, and the development of expertise. Intensive care decision making is characterized by a rapid, serial evaluation of options leading to immediate action, where reasoning is schema driven in a forward direction toward action with minimal inference or justification. However, when patients do not respond in a manner consistent with the original hypothesis, then the original decision comes under scrutiny. This strategy can result in a brainstorming session in which the team retrospectively evaluates and reconsiders the decision and considers possible alternatives. Various patterns of reasoning are used to evaluate alternatives in these brainstorming sessions, including probabilistic reasoning, diagnostic reasoning, and biomedical causal reasoning. Supporting decision making in clinical settings necessitates an understanding of communication patterns.

Another type of decision making that has attracted attention recently in medical cognition research is opportunistic decision making during task transitions. In medical settings (critical care in particular), the environment is stressful, time sensitive, interruption laden, and information rich. Franklin and colleagues (Franklin et al., 2011) studied how decisions are made when clinicians finished one task and transitioned to another task. The authors showed that the clinicians made two kinds of decisions: *planned*, in which they actively selected their next activity, and *opportunistic*, in which their next action in a series of behaviors was not determined

by protocol but rather arose through unanticipated conditions (i.e., time, proximity or resources).

In summary, although traditional approaches to decision making have viewed decisions as choosing among known alternatives, real-world decision making involves reasoning that is constrained by dynamic factors, such as stress, time pressure, risk, and team interactions. Examining medical reasoning in social and collaborative settings is even more important when information technologies are part of the ebb and flow of clinical work.

Reasoning and Medical Education

The failures and successes of reasoning strategies and skills can be traced back to their sources: education. There is evidence suggesting that the way physicians reason results from the way they have been educated. Medical education in North America as well as in the rest of the world has followed a similar path: from practice-based training to an increasingly scientific training.

Motivated by the increasing importance of basic scientific knowledge in the context of clinical practice, problem-based learning (PBL) was developed on the premise that not only should physicians possess the ordered and systematic knowledge of science, but they should also *think* like scientists during their practices. Consistent with this idea, an attempt was made to teach hypothetico-deductive reasoning to medical students, as a way to provide an adequate structure to medical *problem solving*. After all, this was the way scientists were supposed to make discoveries.

However, based on cognitive research in other knowledge domains, some researchers argued that the hypothetico-deductive method might not be the most efficient way of solving clinical problems. To investigate how the kind of training medical students receive affected their reasoning patterns, Patel, Groen, and Norman (1993) looked at the problem-solving processes of students in two medical schools with different modes of instruction: classical and problem-based curricula. They found that students in the problem-based curriculum reasoned in a way that was consistent with their training methods, showing a preponderance of hypothetico-deductive reasoning and extensive elaborations of biomedical information. The PBL students used hypothesis-driven reasoning—from the hypothesis to explain the patient data—while non-PBL students used mainly data-driven reasoning—from data toward the hypothesis. In explaining clinical

cases, PBL students produced extensive elaborations using detailed biomedical information, which was relatively absent from non-PBL students' explanations. It appears that PBL promotes the activation and elaboration of prior knowledge. However, these elaborations resulted in the generation of errors.

Patel, Arocha, and Lecissi (2001) also investigated the effects of non-PBL curricula on the use and integration of basic science and clinical knowledge and its impact on diagnostic explanation. The results showed that biomedical and clinical knowledge are not integrated and that very little biomedical information is used in routine problem-solving situations. There is significant use of expert-like data-driven strategies, however, in non-PBL students' explanations. The use of biomedical information increases when the clinical problems are complex; at the same time, hypothesis-driven strategies replace the data-driven strategies. Similar results were found in other professional domains such as law (Krieger, 2004).

Students from a PBL school integrated the two types of knowledge (biomedical sciences and clinical), and in contrast to the non-PBL students they spontaneously used biomedical information in solving even routine problems. It appeared that for students in the non-PBL curriculum, the clinical components of the problems are treated separately from the biomedical science components. The two components of the problem analysis seem to be viewed as serving different functions. However, when needed, the biomedical knowledge is utilized and seems to act as "glue" that ties the two kinds of information together.

In the PBL curriculum, the integration of basic science and clinical knowledge is so tight that students appear unable to separate the two types of knowledge. As a result, PBL students generate unnecessarily elaborate explanations, leading to errors of reasoning. PBL seems to promote a type of learning in which basic biomedical knowledge becomes so tightly tied to specific clinical problem types that it becomes difficult to decouple this knowledge in context in order to transfer to a new situation (Anderson, Reder, & Simon, 1996; Holyoak, 1985).

This outcome is consistent with how biomedical information is taught in the classroom in PBL schools, namely, by encouraging use of the hypothetico-deductive method, resulting in a predominantly backward-directed mode of reasoning. Elaborations are accompanied by a tendency to generate errors of scientific fact and flawed patterns of explanation,

such as circular reasoning. Even though a student's explanation may be riddled with bugs and misconceptions, their harmful effects may be dependent on the direction of reasoning. If they reason forward, then they are likely to view their existing knowledge as adequate. In this case, misconceptions may be long-lasting and difficult to eradicate. If they reason backward, misconceptions might best be viewed as transient hypotheses which, in the light of experience, are either refuted or else modified to form the kernel of a more adequate explanation. Interestingly, differences in the patterns of reasoning acquired in both PBL and non-PBL medical curricula are found to be quite stable, even after the students have completed medical school and are in residency training programs (Patel, Arocha, & Lecissi, 2001; Patel & Kaufman, 2001).

Instruction that emphasizes decontextualized abstracted models of phenomena has not yielded much success in medicine or in other spheres of science education. It is widely believed that the amount of transfer will be a function of the overlap between the original domain of learning and the target domain (Holyoak, 1985). The PBL's emphasis on real-world problems represents a very good source of transfer to clinical situations. However, it is very challenging to create a problem set that most effectively embodies certain biomedical concepts while maximizing transfer. Knowledge that is overly contextualized can actually reduce transfer.

Technology-Mediated Reasoning and Thinking in Medicine

All technologies mediate human performance. Technologies, whether they be computer-based or in some other form, transform the ways individuals and groups behave. They do not merely augment, enhance, or expedite performance, although a given technology may do all of these things. The difference is not one of quantitative change, but one that is qualitative in nature. Technology, tools, and artifacts not only enhance people's ability to perform tasks but also change the way they perform tasks. In cognitive science, this ubiquitous phenomenon is called the representational effect, which refers to the phenomenon that different representations of a common abstract structure can generate dramatically different representational efficiencies, task complexities, and behavioral outcomes (Zhang & Norman, 1994; see Markman, Chapter 4).

One approach to the study of how technology mediates thinking and reasoning is to consider

technology as external representations (Zhang, 1997; Zhang & Norman, 1994). External representations are the knowledge and structure in the environment, as physical symbols, objects, or dimensions (e.g., written symbols, beads of abacuses, dimensions of a graph), and as external rules, constraints, or relations embedded in physical configurations (e.g., spatial relations of written digits, visual and spatial layouts of diagrams, physical constraints in abacuses). The information in external representations can be picked up, analyzed, and processed by perceptual systems alone, although the top-down participation of conceptual knowledge from internal representations can sometimes facilitate or inhibit the perceptual processes.

The mediating role of technology can be evaluated at several levels of analysis. For example, electronic medical records alter the practice of individual clinicians in significant ways, as discussed later. Changes to an information system substantially impacts organizational and institutional practices from research to billing to quality assurance. Even the introduction of patient-centered medical records early in the 20th century necessitated changes in hospital architecture and considerably effected work practices in clinical settings. Salomon, Perkins, and Globerson (1991) introduced a useful distinction in considering the mediating role of technology on individual performance, the *effects with* technology and the *effects of* technology. The former is concerned with the changes in performance displayed by users while equipped with the technology. For example, when using an effective medical information system, physicians should be able to gather information more systematically and efficiently. In this capacity, medical information technologies may alleviate some of the cognitive load associated with a given task and permit them to focus on higher order thinking skills, such as hypothesis generation and evaluation. The *effects of* technology refer to enduring changes in general cognitive capacities (knowledge and skills) as a consequence of interaction with a technology. For example, frequent use of information technologies may result in lasting changes in medical decision-making practices even in the absence of the system.

In several studies involving the mediating role of technology in clinical practice, Patel and her colleagues (Patel et al., 2000) observed the change of thinking and reasoning patterns caused by a change in methods of writing patient records from paper records to electronic medical records (EMRs). They

found that before using EMRs, physicians focused on exploration and discovery, used complex propositions, and tended to use data-driven reasoning. After using EMRs, which have structured data, physicians focused on problem solving, used simple propositions, and tended to use problem-directed and hypothesis-driven reasoning. The change of behavior caused by the use of EMRs remained when the physicians went back to paper records, showing the enduring effects of technology on human reasoning in medicine.

As the basis for many medical decisions, diagnostic reasoning requires the collection, understanding, and use of many types of patient information, such as history, lab results, symptoms, prescriptions, images, and so on. It is affected by not just the expertise of the clinicians but also by the way the information is acquired, stored, processed, and presented. If we consider clinicians as rational decision makers, the format of a display, as long as it contains the same information, should not affect the outcome of the reasoning and decision-making process. But the formats of displays do affect many aspects of clinicians' task performance. Recently there have been several studies of how different displays of information in EMRs affect clinicians' behavior. Three major types of displays have been studied: source based, time based, and concept based. Source-based displays organize medical data by the sources of the data, such as encounter notes, lab reports, medications, lab results, radiology imaging and report, and physical exams. Time-based displays organize medical data as a temporal history of patient data. Concept-based displays organize medical data by clinically meaningful concepts or problems. In this case all data related to a specific problem are displayed together. For example, if a patient has symptoms such as coughing, chest pain, and fever, the lab results, imaging reports, prescriptions, assessments, and plans are displayed together. Zeng et al. (2002) found that different displays were useful for different tasks. For example, source-based displays aid clinicians in retrieving information for a specific test or procedure from a specific department, whereas concept-based displays aid the search of information related to a specific disease.

Medication management is always a challenging task for patients. How drug information is displayed can affect patients' understanding of the drug information, the way they manage their medication, and ultimately their health outcomes. For example, Day (1988) demonstrated how alternative

representations should be used for different purposes for improving medication scheduling. With the rapid growth of computer-based information systems, people are interacting more and more with computer-generated health information displays. These displays need to be designed to effectively and accurately generate the information that people need for informed reasoning.

Conclusions and Future Directions

Advances in cognitive science have made significant contributions to investigations into the process of medical reasoning. However, there are a number of issues that could benefit from research, especially involving multidisciplinary approaches. At the theoretical level, an important issue for future theoretical and empirical development involves the integration of the diverse modes of medical reasoning. This includes the integration of the expertise and the decision-making approaches to expert cognition (see Kahneman & Klein, 2009), which has direct implications for establishing in more detail the role that intuitive and conscious reasoning play in the different medical tasks and in the commission of errors. Some attempts have been recently made (Croskerry, 2009; Norman, 2009; Norman & Eva, 2010) to clarify their role, particularly through application of the dual-process view of thinking and reasoning (Evans, 2008) to clinical problem solving. As some have pointed out (Glöckner & Witteman, 2010), both types of processes may involve different mechanisms, which remain to be empirically and theoretically established. In this regard, the medical environment may be used as a test bed for investigating these fundamental problems in an applied real-world arena.

As such an applied area, reasoning in a medical context involves complex compositions of various populations, settings, and a high degree of uncertainty (as in critical care environments). Compounded with constraints imposed by resource availability, these factors lead to increased use of heuristic strategies. The utility of heuristics lies in limiting the extent of purposeful search through data sets. By reducing redundancy, such heuristics have substantial practical value, as a significant part of a physician's cognitive effort is based on heuristic thinking. However, the use of heuristics introduces considerable bias in medical reasoning, often resulting in a number of conceptual and procedural errors. These include misconceptions about laws governing probability, instantiation of general

rules to a specific patient at the point of care, incorrect use of prior probabilities and actions, as well as false confirmation of hypotheses.

With the increasing move of cognitive studies toward investigations in real-world settings, complex phenomena can be better studied. The constraints of laboratory-based work make it impossible to fully capture the dynamics of real-world problems. This issue is particularly salient in rapidly changing critical care environments. Studies of thinking and reasoning in medicine, which focus on medical errors and technology-mediated cognition, are increasingly paying attention to dimensions of medical work in clinical settings. The recent concern with understanding and reducing medical errors provides an opportunity for cognitive scientists to use cognitive theories and methodologies to address the pressing, practical problem of managing these errors under conditions of urgency and multitasking. A trend in health care, spurred partly by the advent of information technologies that foster communication, is the development of health care systems that are increasingly multidisciplinary and collaborative, often spanning geographic regions. Increasing costs of health care and rapid knowledge growth have accelerated the trend towards collaboration of health care professionals to share knowledge and skills. Comprehensive patient care necessitates the communication of health care providers in different medical domains, thereby optimizing the use of their expertise. Research on reasoning will need to continue to move toward a distributed model of cognition. This model will include a focus on both socially shared and technology-mediated reasoning. Finally, today medical applications from the domain of artificial intelligence span from molecular medicine to organizational aspects of work domain, the role of modeling human reasoning and cognitive science will need to be reevaluated. Modeling and reasoning will play a significant role as we strive to build successful systems to support reasoning processes (Patel, Shortliffe, Stefanelli, et al., 2009).

Acknowledgment

This chapter is dedicated to the memory of a close friend and a colleague, late Marco F. Ramoni, who was passionate about understanding the nature of reasoning in biomedicine, as he was passionate about life in general.

Note

1. In contrast, early, precognitive, accounts of medical diagnosis (Rimoldi, 1961) described it in a way that was independent of the underlying structure of the domain knowl-

edge, through the application of general reasoning strategies. These accounts simply made the assumption that some domain of knowledge existed and that all the hypotheses needed to explain a problem were available when the diagnostic process starts. For instance, skill in diagnosing patients was assumed to be the result of the application of knowledge-independent strategies to clinical problems (e.g., by following the scientific method).

Thinking in Business

Jeffrey Loewenstein

Abstract

Thinking and reasoning enter into the practice of business in limitless ways. Basic and applied cognition researchers stand to gain by increasing their awareness of each other's work. To foster interaction, this chapter provides an introduction to applied cognitive research in the main areas of business academia, which collectively map out a large range of business practice: consumer behavior within marketing, organizational behavior within management, management science within operations, behavioral finance within finance, and behavioral accounting within accounting.

Key Words: cognition, business, consumer behavior, organizational behavior, management science, behavioral finance, behavioral accounting

The practice of business is enormously variable. The marketer influencing a customer's purchase, the executive negotiating a deal, the manager coordinating the production of goods, the analyst reviewing company performance, and the accountant trying to make the numbers add up are all engaging in aspects of the practice of business. To address the variety, I will provide introductions to research on thinking occurring in the context of marketing, management, operations, finance, and accounting activity. These are arguably the major functional areas of business, and not coincidentally, the major areas of business academia. Accordingly, this chapter organizes research on thinking in business by the domain of business practice, with introductions to each corresponding area of business academia.

Business schools foster a substantial amount and range of applied research on thinking and reasoning. This work, like all applied research, makes two main contributions back to the basic research areas on which it draws: It translates basic research to advance real-world practice, and it provides contexts that raise new questions and phenomena for

basic research. This review aims to foster exchange between applied research on thinking and reasoning in business academia and basic research on thinking and reasoning.

There is important work on all main areas of business practice, but there is more work in some areas than others. I discuss the areas in rough descending order of the amount of current research on thinking in the different academic areas: marketing, management, operations, finance, and accounting. Each academic area operates relatively independently, with its own journals and professional associations, roughly like the fields of psychology, anthropology, economics, sociology, and linguistics operate within social science—there is no single journal or forum in which all areas converge, just numerous overlapping subfields. Each area of business academia has a segment engaged in behavioral research, within which scholars are engaged in research on thinking: consumer behavior (within marketing), organizational behavior (within management), management science (despite the name, it lies within operations), behavioral finance, and behavioral accounting.

Of all cognitive topics studied within business academia, decision-making research is by far the most common. The book based on Herbert Simon's dissertation, *Administrative Behavior* (1947), was particularly influential in making decision making a central behavioral topic in business academia. Because of Simon's (e.g., 1955) persuasive arguments for bounded rationality, meaning that human cognitive processing is limited, Simon also characterized decision making as a behavioral concern. To avoid confusion, I note that it was Simon's work from the 1940s and 1950s that was most influential in business academia; his work from the 1960s and 1970s that had such a large influence on cognitive science, such as *Sciences of the Artificial* (1969) and, with Allan Newell, *Human Problem Solving* (1972), is less widely known in business academia, just as *Administrative Behavior* is less widely known in cognitive science. As behavioral decision-making advanced and gained legitimacy in both psychology and economics due to the work of Kahneman and Tversky and others (Kahneman, Slovic, & Tversky, 1982), and as business schools expanded their hiring of faculty from psychology departments, decision making became an established topic across business school departments. It also has more ties between basic and applied researchers than any other topic in thinking and reasoning research (see LeBoeuf & Shafir, Chapter 16; Camerer & Smith, Chapter 18).

Accordingly, in this review I devote less space to decision-making research than it warrants based on its current volume and more space to other thinking and reasoning research, such as work on learning, categorization, expertise, creativity, and group cognition. These topics are central concerns of thinking and reasoning, and they have particular importance to core business concerns such as innovation—the development and implementation of new products and processes. Broadening the thinking and reasoning topics under discussion is an attempt to help foster new ties and to give a richer view of thinking in business. In addition, I emphasize research published in applied journals published by business academic societies and organizations, rather than the work on thinking and reasoning published in social psychology journals and industrial/organizational psychology journals. That work is no less important or insightful, but because the business outlets and papers are less likely to be familiar to basic researchers studying thinking and reasoning, there is greater potential for novel cross-fertilization.

Marketing: Consumer Behavior

Businesses need to sell their products and services, so a major concern of business is shaping how consumers make purchases, use products, and think about brands. Consumer behavior researchers study these questions and generate more psychological research on individual thinking and reasoning than researchers in any other area of business academia. As a simple indication of the role of cognition research in consumer behavior, the *Handbook of Consumer Psychology* (Haugtvedt, Kerr, & Kardes, 2008) dedicates about half of its 1,200 pages to reviewing information processing and social cognition research (see also, e.g., Loken, 2006). Most consumer behavior research on thinking and reasoning is experimental. There is also mathematical and computational modeling, field survey research, observations of consumer activity, examinations of archival measures of consumer activity, and some qualitative research.

Decision Making

Consumer purchasing is a decision-making activity. For example, one prominent feature of the consumer decision-making context (as any walk through a grocery store or time spent shopping online will make apparent) is a concern for how people make decisions when confronted by large numbers of options (e.g., Broniarczyk, Hoyer, & McAlister, 1998; Hoch, Bradlow, & Wansink, 1999). This work has identified tensions between larger numbers of options providing an opportunity to maximize fit to consumer preferences and making the choice process more difficult and more likely to spur regret (Broniarczyk, 2008; Chernev, forthcoming).

An intriguing development in this area is to consider the relationship among items in the choice set. Drawing on the contrast between alignable and nonalignable differences (Markman & Gentner, 1993; see Holyoak, Chapter 13), it is possible for items in a choice set to differ in ways that are alignable along a single dimension (e.g., increasing power or size) or in ways that are nonalignable (each member possessing a distinct categorical feature). People are more likely to make a choice from a large choice set if its members are all alignable (Gourville & Soman, 2005). Thus, the alignability of the options in a choice set is a moderator of choice set size on people's likelihood of making rather than avoiding making a decision. This work is consistent with research on other means of making large assortments easier to navigate, such as having detailed preferences (Chernev, 2003) due to expertise.

The context of consumer behavior also makes salient, unlike most decision-making research, that the process of deciding can itself offer pleasure and value. Individual preferences for, say, seeking out variety (McAlister & Pessemier, 1982) can guide the construction of choice sets even for purchases that are for others (Chowdhury, Ratneshwar, & Desai, 2009). Thus, one's own pleasure or annoyance at the decision-making process, in addition to considerations of the outcome, guides decision making.

More generally, decision making is an activity, and the many goals decision makers have as they engage in that activity guide the choices that result. For example, reviewing an array of research, Bettman, Luce, and Payne (2008) argue that four broad goals recur across a wide array of consumer decisions, if not decisions more broadly: concerns for accuracy (or decision quality), minimizing effort, minimizing negative emotion, and increasing the justification for the decision. Any of these broad goals can dominate decision making, and people can trade off value across goals.

People also have goals related to specific products that influence how they evaluate options. For example, in one series of experiments, people were asked to imagine wanting to buy a fast computer, and then read about a series of computers with features that strongly or weakly supported that product-related goal or were irrelevant to the goal (Meyvis & Janiszewski, 2002). It appears that people note whether features support the goal they have in mind when evaluating the product's features, and because irrelevant features do not support the goal, they temper judgments (a dilution effect). For instance, participants' explicitly noting whether the features were relevant or irrelevant did not eliminate the dilution effect, but having participants read the features before learning the goal did eliminate the effect. Thus, goals guide how people frame or encode information, which in turn guides their evaluations.

One real-world implication of the presence of multiple goals is that people sometimes exhibit inaccurate judgments of key features of choice options, such as price. For example, one study found that about half of the customers stopped and questioned in grocery stores could not name the price of the item they had just put in their shopping carts (Dickson & Sawyer, 1990). Strikingly, their price estimates deviated from the true prices by an amount that was, on average, as large as the range of prices in the product category.

Learning and Expertise

Another important concern is how consumers learn about products, services, and brands. Accordingly, there is a long-standing interest in consumer expertise (Alba & Hutchinson, 1987). This means that in addition to a concern for explaining a particular choice, another reason to examine consumers' goals is to examine the effect of goals on what consumers learn about products. For example, one study examined exemplar learning by low and high domain knowledge participants, varying whether they were given a goal at initial encoding (e.g., you will be traveling and need a camera that is easy to use), and whether they had a similar or different goal at each of two rounds of retrieval (Cowley & Mitchell, 2003). Learning by participants with low domain knowledge was guided by their initial goals and the fit between those goals and their first goal at recall, whereas high domain knowledge participants' learning was not influenced by the assigned goals at either encoding or recall.

The basic context of thinking about purchasing products is useful for studying learning. For example, consistent with work integrating research on categorical and quantitative inference learning (Juslin, Olsson & Olsson, 2003) and work discussing the importance of how categories are used in category learning (Markman & Ross, 2003), Eisenstein and Hutchinson (2006) examined inference learning tasks in a consumer behavior context. They provided participants with product features and asked them to make either a categorical or numeric judgment. Some estimated whether the product's price was above or below a specific price, and others estimated the product's price. Consistent with the importance of use, asking for categorical responses led to greater levels of learning for examples near the cutoff point (Eisenstein & Hutchinson, 2006). The implication from this work is that well-designed cutoffs can make learning efficient, but poor cutoffs can distort learning and undermine later category use.

Categories

Inference learning is just one instance of a much broader interest in categories within consumer behavior research. Consumers and marketers rely on categories to organize types of products and services (e.g., televisions, minivans, banking). They also rely on brand categories (e.g., McDonalds, Wal-Mart, Sony) to organize judgments of quality, availability, desirability, and other concerns. They also use social

categories to identify kinds of consumers (e.g., early adopters, coffee drinkers, penny-pinchers) that then guide how, for example, people design products, generate marketing campaigns, and choose retail outlets. This work points out intriguing possibilities for research on categories and concepts (see Rips et al., Chapter 11).

As an example, research on brand extensions raises interesting possibilities about category membership: If you have a choice of including an item in a category, forming a subordinate category or forming an independent category, what should you do? If Crest has a strong brand based on its toothpaste products, what might happen if the brand Crest was applied to other products, such as mouthwash, toothbrushes, sinks, dishwashing detergent, or glue? Would this generate better or worse appraisals of the other products, and does it matter what kinds of other products? Would the extension help or hurt the Crest brand as a whole, and would it help or hurt the main Crest toothpaste product on which the brand was built? These are pragmatic questions of interest to marketers, of course, but they are also interesting questions for the study of categories. They highlight the role of people's ability to generate and change categories and the effects of those changes on people's perceptions of the category and new and old category members. These questions generally do not arise when considering categories like robins or chairs. The consumer behavior context makes the roles of people's attitudes and social interaction more central to the study of categories.

There has now been at least 20 years of active experimental research on brand extensions in consumer behavior. This work has established that if the new product will be atypical of the category and not clearly understandable as a category member, then it is more likely to lower people's perceptions of the category as a whole (i.e., the brand; see Keller & Lehmann, 2006, for a review). In some cases, including the new product in the brand can even lower people's perceptions of the flagship product (i.e., central category member; John, Loken, & Joiner, 1998). The variety of products already included in the brand category is also an influence on people's willingness to accept a further product as an instance of the brand (Meyvis & Janiszewski, 2004).

Consumer behavior research on categories also highlights that categories can change over time. For example, the development of the minivan product category shows influence of both consumers and

producers (Rosa, Porac, Runser-Spanjol, & Saxon, 1999). Most basic research on categories, category membership, and category typicality has focused on stable properties of category members, rather than histories of the frequency of instantiation of items as category members (Barsalou, 1985). Examining magazine articles for frequency of instantiation—the proportion of product mentions that were made in reference to a product category, such as “the Honda Odyssey is a minivan that...”—provides a measure of typicality derived from real-world aggregate behavior (Rosa et al., 1999; see also Rosa, Judson, & Porac, 2005). This frequency of category instantiation measure predicted a product's longevity in the market—that is, the more often products were mentioned as being category members, the more likely they were to persist in the market. Frequency of instantiation may in practice be confounded with feature-based criteria for typicality. However, if categories themselves can change over time, and consequently what is central or ideal can change over time, then frequency of instantiation may be critical for establishing category typicality in practice. Given that people rely on a division of cognitive labor so that they do not need to become experts in all domains (e.g., Keil, Stein, Webb, Billings, & Rozenblit, 2008), and given that people are capable statistical learners (e.g., Saffran, Johnson, Aslin, & Newport, 1999), it is plausible that frequency of instantiation is a far greater influence on category learning than current psychological models imply.

Consumer behavior research on categories of services, such as cruises or massages, also extends basic research on event categories. For example, one of the key features of events is that they unfold over time. This allows event duration to be causally important. For example, people use a service's stated length as a heuristic guide to its value (Yeung & Soman, 2007). Furthermore, experiencing greater variety within an event led people to report immediately afterward that the event had a shorter duration than did those experiencing less variety (Ahn, Liu, & Soman, 2009). One to three days later, however, the people who experienced greater variety reported that the event had lasted longer. Thus, event duration can be a central feature of event categories.

Underlying much of this discussion of product and service categories is a close connection between category typicality and preferences. An examination of brands (e.g., Taco Bell, American Airlines) in eight product and service categories (e.g., types of restaurants, types of transportation) found strong

correlations (about .6) between a particular brand's typicality within a product category and positive attitudes toward that brand (Loiken & Ward, 1990). People's attitudes toward category members tend not to be discussed in basic research on concepts and categories. But consistent and strong relationships between typicality and attitudes are important to integrate theoretically and are certainly important practically for thinking about category effects.

Similarity and Analogy

Similarity and analogy research has also considered the joint action of cognition and affect (e.g., Thagard & Shelley, 2001), and consumer research offers new insights here as well. People use experiences as analogical bases that they extend by analogy to understand and develop emotional responses to new products or services serving as targets (Goode, Dahl, & Moreau, 2010). The strength of people's preferences for the base experiences together with the number of inferences drawn from base to target influence people's emotional responses to targets (Goode et al., 2010).

This work is part of a larger stream of research on analogy and similarity in consumer behavior. For example, companies use similarity and analogy to make their products comprehensible and appealing to consumers. Providing analogies appears to promote more focused knowledge transfer and inferences than assigning a product to a category, as categories license generating inferences about both surface features and underlying structure or relations, whereas analogies preferentially focus people on underlying structure (Gregan-Paxton & Moreau, 2003). Analogies are particularly useful for helping consumers understand very new products, rather than incrementally new products (Moreau, Markman, & Lehmann, 2001). Companies can also manipulate surface similarity by designing products to look like something with the same underlying function (Rindova & Petkova, 2007). For example, digital video recorders, such as TiVo, were designed to look like VCRs so that consumers spontaneously made appropriate comparisons. The broad implication, and one that will recur in other areas of business research on thinking and reasoning, is that an understanding of how people think can guide businesses to design more effective products, processes, and policies.

Creativity

Consumer behavior also provides useful contexts for examining creativity (see Smith & Ward,

Chapter 23). Creativity is important for understanding advertising. Some advertising is mainly concerned with raising consumer awareness of a product or brand, whereas other advertising is aimed at engaging consumers and increasing their attitudes toward and involvement with brands (Vakratsas & Ambler, 1999). It is for this latter group that creativity is consequential, because it can draw consumers' attention and consideration. One of the interesting outcomes of research on advertising is that it demonstrates that there are reliable ways to structure advertisements such that people will find them creative and effective (Goldenberg, Mazursky, & Solomon, 1999; Loewenstein, Raghunathan, & Heath, 2011; McQuarrie & Mick, 1996). An avenue for future cognitive research would be to unpack why these structures are effective and to identify additional structures (e.g., Loewenstein & Heath, 2009).

Creativity is also important in understanding how consumers use products. For example, one concern is what leads consumers to generate creative uses for consumer products, such as how one might generate one of those 1,001 uses for duct tape (Burroughs & Mick, 2004). Consumer research also provides novel contexts in which people can be asked to generate new and potentially creative kinds of category members, similar to Ward's (1994; Ward, Patterson, & Sifonis, 2004) drawing tasks. For example, online shopping allows consumers to design their own products (Dellaert & Stremersch, 2005), such as Nike enabling customers to design shoes.

This brief survey shows that thinking and reasoning research has important applications for understanding consumers and those who market to them. It also shows that the context of marketing to consumers spurs insights and reveals new phenomena to integrate back into basic research on decision making, learning, categories, similarity, and creativity, among other topics.

Management: Organizational Behavior

To have a product or service to sell takes work, of course. The field of organizational behavior aims to explain and facilitate employee, manager, and executive work, including, for example, decision making, conflict management, the generation and production of innovations, and group performance. Organizational behavior research generally relies on field surveys and experiments, but there is also qualitative research, research using archival sources, and a small amount of computational modeling work.

Ethics and Decision Making

Organizational behavior is the only behavioral research area in business in which decision-making research is not the dominant stream of work on thinking and reasoning (Moore & Flynn, 2008). Still, decision making has not been neglected. For example, decision making has been influential in organizational behavior research on negotiation (Bazerman, Curhan, Moore, & Valley, 2000). A distinctive contribution of organizational behavior research on decision making has been its examination of ethics (see Waldmann et al., Chapter 19). Ethics is related to practical concerns but also to a fundamental cognitive claim, which is that how people represent or frame a problem or decision influences the solution or choice people generate. An important consequence, as Tenbrunsel and Smith-Crowe (2008) note, is that if decision frames do not take ethics into consideration, then the resulting decisions may be unethical without people realizing it.

For example, one study engaged participants in a hypothetical dilemma: They could either cooperate with a group agreement at a high known cost to themselves or defect from the group agreement with a low known cost (Tenbrunsel & Messick, 1999). In a baseline condition, overall 55% stated they thought they were making an ethical decision, with the remainder framing it as a business (i.e., a narrowly framed cost/benefit) decision. In a second condition, in addition to the low known cost of defection, there was a chance of being caught for defecting and having to pay a small penalty. In this case just 18% used an ethical decision frame—the threat of a penalty shifted people's decision frames. The decision frame was consequential, as 91% of those with an ethical decision frame cooperated, whereas just 39% of those with a business decision frame cooperated. It is plausible that the habitual use of many representations relevant to the business domain, as well as other domains in life, implicitly encourages people to make choices that are, unintentionally, unethical. Therefore, a useful project for thinking and reasoning research would be to examine factors that foster flexibility in how people represent information—the cognitive skills behind ethical behavior could overlap considerably with those for creativity.

A further concern over ethical implications of behavioral decision making is that risk-seeking behavior can involve unethical behavior. For example, in one study, people were asked to complete an

anagram task, with an opportunity to score and pay themselves for their own performance (Schweitzer, Ordoñez, & Duouma, 2004). Participants were assigned different goals: challenging goals, readily achievable goals, or simply a request to do their best. They found that relative to the two easy goal conditions, participants with the challenging goals—who likely thought that their performance would not be sufficient to allow them to reach their goals—were twice as likely to cheat. Related work found that participants who had already completed a goal were more likely to take a risky gamble than accept a sure payoff, and the more they had surpassed their goal the more likely they were to take the risky gamble (Jeffrey, Onay, & Larrick, 2010). It is an open question whether in the aftermath of achieving a goal people will be not only more risk seeking but also more willing to be unethical.

To address individual-level biases toward unethical decision making, or more broadly, towards poor decision making, research need not look solely to individual-level solutions. Social and organizational contexts can mitigate some individual shortcomings (Heath, Larrick, & Klayman, 1998). For example, the guidelines for total quality management, a collection of practices aimed at improving the reliability of work processes, encourage people to gather complete information about problems, in contrast to individual tendencies to gather information selectively. A broad implication is that examining organizational routines and jobs can reveal specialized controls and tasks that cover for what people otherwise fail to consider or do. Another implication is that there are likely other cognitive limits that organizations are failing to address, awaiting people to draw attention to them and propose repairs.

Learning

Another central cognitive concern in organizational behavior is learning from experience, with a particular concern for learning from events that are often complex, ambiguous, and far from randomly sampled (Loewenstein & Thompson, 2006; March, 1994; Wood, 1986). For example, Denrell (2003; Denrell, Fang, & Levinthal, 2004; Denrell & March, 2001) used computational modeling to show that organizational settings produced a host of biased samples as successful managers and organizations tend to stay and grow in prominence, whereas unsuccessful ones tend to leave or fold. The result is effectively learning based on sampling on the dependent measure.

Another approach to learning from experience is to examine counterfactual reasoning. For example, one study examined airplane accidents (Morris & Moore, 2000). The National Transportation and Safety Board maintains records of airplane accidents and near-accidents. These include narrative descriptions of accidents, which can be coded for the presence of counterfactuals and the presence of specific lessons for the future. Pilots' narratives with upward, self-directed counterfactuals (e.g., If only I had done X, the accident would not have happened) were most likely to exhibit lessons for the future, in contrast to narratives with downward counterfactuals (e.g., If I had not done X...), narratives with other-directed counterfactuals (e.g., If only air traffic control had said...), and narratives with no counterfactuals (Morris & Moore, 2000). Two follow-up experiments tested the effects of counterfactual reasoning on learning from experience used a flight simulator game. Replicating the archival study of actual pilots, participants who spontaneously generated upward, self-directed counterfactuals were most likely to write specific lessons learned. Participants asked to generate upward or downward self-directed counterfactuals after an initial flight simulator session revealed that those asked to make upward counterfactuals showed greater improvement on a subsequent flight simulator session than those asked to make downward counterfactuals (Morris & Moore, 2000). These studies also found that people generated more counterfactuals the more severe the accident, and the more personally accountable (as opposed to organizationally accountable) the pilot. The implication is that counterfactual reasoning is a form of self-explanation that people generate spontaneously in response to events that can yield learning.

Categories

Organizational behavior has a long-standing interest in the products of learning. For example, there is research on novice and experienced entrepreneurs' understandings of worthwhile and non-worthwhile opportunities to start a new business (Baron & Ensley, 2006), managers' understandings of threats and opportunities (Jackson & Dutton, 1988), and participants' reactions to tasks framed as work and play (Glynn, 1994). In a characteristic early study along these lines, Lord, Foti, and De Vader (1984) examined the category "leader," using feature listing and ratings tasks to assess what features indicate the category. They showed that

participants rated a feature's prototypicality faster the more typical it was. They also showed that a vignette about a leader managing a project that used typical features for the leader, compared to one using atypical features, yielded ratings indicating that participants expected the leader to behave in more typical ways, and considered the leader more responsible and accountable for the project.

In a series of studies on firm competitors, Porac and colleagues (Porac & Thomas, 1994; Porac, Thomas, & Badenfuller, 1989; Porac, Thomas, Wilson, Paton, & Kanfer, 1995; Porac, Wade, & Pollock, 1999) examined managers' category taxonomies as an influence on which firms a manager at a given company would say were competitors. Rather than assuming managers are rational agents examining every firm's resources and dependencies to determine their competitors, this work suggests that managers use categories of firms to simplify and guide their attention. For example, one study examined a category taxonomy derived from the superordinate category "retailer" (Porac & Thomas, 1994). Store managers noted typical subordinates such as groceries and drug stores and atypical subordinates such as travel agencies and animal grooming shops. Store managers rated stores from the same subordinate categories as their own stores as far more likely to be competitive threats than those from different subordinate categories. Store managers also tended to perceive typical retailers to be more of a competitive threat than atypical retailers. Thus, category membership and typicality influenced managers' perceptions of the firms with whom they were competing.

A further study surveyed managers from the Scottish knitwear industry (Porac et al., 1995). They found that five prominent dimensions (firm size, location, knitting method, construction method, and product style) accounted for how managers categorized firms in the industry. Managers largely perceived their competitors to be other firms within the same category as their own firm. Furthermore, the more typical a firm was of its category, the more likely it was to be rated a competitor by others in its category. These studies indicate that category taxonomies and category typicality are tools managers use to simplify the task of who to monitor and compete against. They also suggest that there is social consensus about categories.

Organizational research, due to concerns over power and ethics, also highlights that people sometimes manipulate category membership. For

example, public companies have to report which firms they used as a basis for comparison when deciding on the compensation package for their CEOs. Usually the reports cite other firms from the same industry. However, managers include comparison firms from outside their industry in greater numbers when, for example, firm performance is low or when their industry performs well (Porac, Wade, & Pollock, 1999). The implication is that managers are changing category membership when it serves the purpose of rationalizing higher compensation for their CEOs. Thus, firm categories are useful and cannot simply be ignored, but they can be manipulated.

Another area of research examines culture's influence on categories. For example, Keller and Loewenstein (2011) used a cultural consensus model analysis, following Atran, Medin, and Ross (2005), to examine how people think about a complex category: cooperation. The study examined similarities and differences in how people in the United States and China understand 17 dimensions related to the category of cooperation. Overall, there was substantial consensus across both nations about what does and does not indicate cooperation. Importantly, there were high levels of consensus both for settings that indicate cooperation (e.g., having aligned goals, being friends with the people in one's group) and for actions that indicate cooperation (e.g., putting in effort on group tasks, sharing knowledge with others). This makes the category of cooperation complex and not easily defined, but it also makes the category of cooperation highly useful. Because the category spans settings and actions, it performs a valuable function by linking perception and action. A broad implication might be that internal category structure might be complex so as to increase the efficiency of category use.

The study of cooperation also found a striking cultural difference in category membership. About two-thirds of the Chinese participants (and a third of U.S. participants) felt that competing with others within one's group and trying to outperform them was considered cooperative, and that not trying to compete within one's group was considered noncooperative. Additional research (Keller, Loewenstein, & Yan, 2010) shows that people in both cultures believe that cooperation and competition are opposites. The difference seems to be that people in China are more likely to show a predilection for dialectics (Peng, Spencer-Rodgers, & Nian, 2006),

or an interest in integrating opposites rather than keeping them separate. Dialecticism mediates the link between culture and the categorization of competitive behaviors within a group as cooperation. Broad cultural tendencies in how to reason about categories can influence category content and the relationship among categories.

The cultural differences and uses of categories highlight social bases for category formation that are generally not considered by basic psychological research. Most such research assumes that what makes something a member of a category is the intrinsic properties of the category members themselves (e.g., what features it has). Additional research examines the particular goals people have in using the categories (Ratneshwar, Barsalou, Pechmann, & Moore, 2001), and the role of the category member in a larger event or system of relations (relational and role-based categories; Gentner & Kurtz, 2005; Markman & Stilwell, 2001). Yet although it is only rarely described this way, category membership in most basic research is dictated by experimenter fiat, and participants usually manage to learn the categories. Categorization research needs a means for separating out the role of categorization based on features from categorization based on social or cultural forces.

Creativity

Research on creativity is also an important organizational behavior topic, as innovation is a common reason for the creation for new businesses and the success of existing businesses. A central finding from this work is that bringing knowledge from a variety of domains or contexts together is important for creativity (George, 2007). For example, a case study found that designers at IDEO are effective because they bring together people with experience working on different kinds of products, enabling them to draw effective analogies (Hargadon & Sutton, 1997). This is similar to Dunbar's (1995) case study research on microbiology lab groups (see Dunbar & Klahr, Chapter 35). An archival study of comic book prices found that on average, the more genres in which a comic book's authors had experience, the higher the market value of the comic book (Taylor & Greve, 2006). There was value for both individuals and teams of authors to have had varied domain experience, and signs that individuals who themselves had a variety of prior experience had the strongest relationship between variety and creativity.

A further study of creativity examined the researchers at an applied research institute, their working relationships, and the creativity of their work. The greater the variety of work experience represented in a researcher's relationships, the more likely they were to have their work rated as creative (Perry-Smith, 2006). For these researchers, the variety of work experience that was important was not those with whom one worked closely (strong ties, in social network parlance), but those with whom one was acquainted (weak ties). These illustrative studies of creativity using a variety of methods rarely used in basic research suggest that there is robust support for the claim that the variety of knowledge one can bring to bear is important for producing creative work. It also suggests there is still unexplained variation as to when it is most beneficial for that variety of knowledge to be mastered by one person, held within a tight working group, or accessed through brief interactions.

Group Cognition

The field of organizational behavior also has a strong interest in how groups and organizations learn, remember, innovate, and perform. Thus, cognition research in organizations is frequently at the level of social aggregates (e.g., Walsh & Ungson, 1991). These are not claims about group minds. Rather, the interest is in how people work together, socially distributing information-processing tasks and coordinating problem-solving activity. For example, people working closely together learn to generate divisions of cognitive labor, allocating different kinds of information about their tasks to different members to encode, remember, and retrieve from each other when needed (Faraj & Sproull, 2000; Lewis, Lange, & Gillis, 2005). At the level of the organization, research on learning curves, for example, has demonstrated that manufacturing error rates decrease and efficiency increases with production experience, echoing individual-level learning curve research (see Argote, 1999, for a review). Thus, there are literatures within organizational behavior on how large-scale cognitive tasks are socially distributed and the cognitive challenges and opportunities involved. The implication for research on thinking and reasoning is that analyzing individual thinking and reasoning may be misleading if the activities under study are collaborative, and that to understand the collaborative cognitive work that consumes so many people's working lives, studies of individual thinking and reasoning can offer only a partial account.

Taken together, organizational behavior research on thinking and reasoning highlights the value of studying cognition in context. For example, the categories research shows why categories may be so complex: social and cultural influences can dictate whether something is or is not a member of a category regardless of what a given individual might believe, and category membership can be complex if it serves to simplify category use. Furthermore, because people are using categories, making decisions, learning, and being creative in the context of working with others, then the thinking and reasoning they do may be qualitatively different due to those interactions and due to the distribution of thinking and reasoning across members of a team or organization.

Operations: Management Science

Business activity often now involves considerable technical complexity in buying, developing, manufacturing, and selling products. It also involves gathering, generating, processing, and distributing large quantities of data. Management science emphasizes the role of analytic and information technology support for guiding organizational action and decision making. It has something of an engineering culture and emphasizes mathematical and computational modeling to guide potentially complex, practical and large-scale concerns, such as scheduling transportation, maximizing factory production yields, and minimizing risk. Management science research links to thinking and reasoning research mainly in considering the use and flow of information, but there is also a stream that considers the pragmatic, robust implementation of routines for effective performance despite the involvement of fallible human performers. Management science research often involves formal and computational modeling but also includes field research, archival research, and experimental research.

Cognitive Support Systems

One concern in management science is to design support systems to process information in the service of improving decision making. Consistent with Payne and others' research on multiple goals in decision making noted earlier, Todd and Benbasat (1992) found that people tend to use decision support systems to reduce the effort involved in decision making rather than to improve the quality of their decision making. Furthermore, if people perceive that decision systems will require effort to use

or will function in a rigid way, they are less likely to want to use them (Wang & Benbasat, 2009). Novices seem particularly strongly guided by concerns about ease of use, whereas experienced users are more evenly guided by ease of use and ability to control the functioning of the decision support system (Taylor & Todd, 1995). Why and how people choose to use decision support systems appear to be consistent with research on unaided decision making, and the interaction between the two areas should lead to more effective support systems.

The conclusions from decision support systems are consistent with broader examinations of why people choose to use any kind of information technology (Venkatesh, Morris, Davis & Davis, 2003). There are thus more areas to learn about by examining information technology use than decision making alone. For example, different communication media serve different communication needs, so examining which media fit which kinds of tasks could lead to improved performance (Te'eni, 2001). New information technologies provide new opportunities for creating fits, and how people choose among available communication media can therefore be informative (Watson-Manheim & Bélanger, 2007). As a further example, information systems frequently generate classification systems, and research on human categorization is beginning to guide the design of such systems (Parsons & Wand, 2008). The general point is that analyzing the features of artifacts designed to support cognition provides avenues for understanding unaided cognitive processing, and management science research has yielded a wealth of data on this issue.

Information Search

Management science also contributes to thinking and reasoning research by addressing neglected topics. For example, most basic research provides information to participants rather than examining how people search for information or examining when people decide to stop searching for information. The widespread use of information technology, company databases, and the Internet makes the search for information salient, and satisficing (Simon, 1955) provides a reason to think about people's rules for stopping their search for information. One study examined five stopping rules: finding information about a single issue; finding all the information on one's initial list; noting that one's representation is no longer changing; noting that the incremental gain of each new piece of

information is consistently small; and noting that the amount of information gathered reached a threshold (Browne, Pitts, & Wetherbe, 2007). Different stopping rules seemed to fit with different kinds of tasks. For example, the list stopping rule was commonly used by people engaged in product and job search tasks, whereas the threshold stopping rule was commonly used by people engaged in a map search task. This line of research could be broadly expanded and doing so could contribute substantially to understanding real-world problem solving and decision making.

Learning

Management science research also has an interest in how people learn to act in complex and dynamic systems. For example, Sterman (1989a) examined people's performance on a dynamic inventory distribution task, the classic "beer game." In the task, four people play roles in a typical supply chain: A beer manufacturer supplies a beer distributor, who supplies a beer wholesaler, who supplies a beer retailer. As customers purchase beer from retailers, retailers need to request new supplies, and those requests ripple up the supply chain, with lags at each step. People learn poorly from the delayed feedback built into the task (Sterman, 1989a). Dynamic systems modeling of the tasks facilitated pinpointing the locus of participants' errors. Tracings of the data implied that participants were using an anchoring and adjustment strategy in their largely futile attempts to keep their supplies constant. Open-ended participant responses afterward confirmed that the impression from the model parameters fit people's subjective impressions. In additional research (Sterman, 1989b), participants in a single-player dynamic game showed similar patterns.

Interaction with a dynamically changing environment and delayed feedback is a common and often unavoidable aspect of action in the world, and it clearly presents strong challenges for learning (Rahmandad, Repenning, & Sterman, 2009). It is less often a feature of cognitive psychological research, but it is tractable. For example, part of people's difficulty with learning from delayed feedback is a failure to keep track of prior actions (Gibson, 2000). Modeling and experimentation showed that people's learning from delayed feedback improved if the system displayed their history of prior actions. Similar issues regarding delayed feedback arise in computer-based tutoring systems (e.g., Anderson, Corbett, Koedinger, & Pelletier, 1995), but with an added

concern with task dynamics. Delayed feedback is not the only aspect of dynamic systems that is challenging conceptually. Even in very simple situations, people have difficulty understanding accumulation (Cronin, Gonzalez, & Sterman, 2009).

Groups

A final feature of management science research to note is that there is a concern for how groups and organizations work together using information technology to accomplish tasks. For example, large-scale projects, such as building an airplane or writing and revising the Linux operating system, raise the issue of how to design the project so that multiple people can work on the project. If working on one part of the project depends on what happens on another part of the project, this makes doing the work more complicated, error prone, and costly. MacCormack, Rusnak, and Baldwin (2006) analyzed open source software design projects, using design structure matrices to capture the interdependencies in the source code. This method allowed them to analyze and track changes in the overall pattern of dependencies among parts of the project, providing useful insights into quantifying the design of projects to estimate the likelihood of effectively distributing the work, or what they call the “architecture for participation.” It is plausible that reducing dependencies among parts of a problem would also ease individual problem solving.

Management science research, by highlighting roles for technology in thinking and reasoning and distributing thinking across individuals working together, raises similar issues to discussions of situated cognition in the 1990s. Most real-world thinking and reasoning involves groups of people generating and using artifacts to accomplish tasks, and hence studying individuals in isolation is likely insufficient to explain the thinking and reasoning of people at work. With the proliferation of information technology, its ready accessibility in the form of mobile phones and tablets, and the geographic dispersion of work, the work in management science to understand how groups of people work and use technology to assist their work provides further support for the practical value of that research agenda and provides new reasons to extend it.

Finance: Behavioral Finance

Part of the practice of business—and to some, perhaps too much of the practice of business—is concerned with financial markets. Behavioral

finance aims to explain actors’ decisions in financial markets, providing an alternative to financial economics models that assume markets are aggregates of the behaviors of rational agents. As psychological research has called into question the assumption that individual agents act rationally, behavioral finance researchers have begun to test for effects of biased actors on financial activity, and to formulate new models for understanding individual investor behavior and aggregate market performance (Barberis & Thaler, 2003; Subrahmanyam, 2007). This research involves core issues in finance, such as whether stock prices are accurate representations of the aggregate information about the prices of firms. Behavioral finance research consists primarily of experimental research, archival research to examine individual and aggregate performance of financial actors, and mathematical modeling.

Judgment and Decision Making

The most proximal cognitive concern in behavioral finance research is work examining the behavior of individual investors. This is a decision-making context about which one can sometimes obtain excellent real-world behavioral data, such as transaction data from individual retirement accounts. It is also an important practical area to study. For many reasons, including the shift in retirement plans away from providing a defined benefit or pension to providing a defined contribution to an investment portfolio that individuals themselves manage, more people than ever are making investment decisions.

Unfortunately, people often appear to make poor financial investment decisions. There is both experimental evidence and evidence from investment records that employees tend to allocate their own retirement investment funds based on the choice sets provided by their company retirement plans (Benartzi & Thaler, 2001). The array of funds offered by companies play an important signaling role for what investments people perceive to be normative. For example, in one experiment, participants tended to allocate money evenly between two mutual funds, regardless of whether the two funds’ holdings were stocks and bonds, stocks and a mixture of stocks and bonds, or bonds and a mixture of stocks and bonds (Benartzi & Thaler, 2001). This pattern matches a tendency to seek variety from options that are presented simultaneously that is also found in consumer behavior decision-making research (e.g., people’s selections from arrays of snack foods; Simonson, 1990). Choices

made serially show less variety-seeking behavior, as people repeatedly choose a favored item. Accordingly, Benartzi and Thaler's (2001) conclusion was that people make major financial decisions based on the same heuristic that guides their selection of candy bars. Behavioral decision-making tendencies appear robust, for good and ill.

A further general point is that people seem to make decisions as if each decision was separate from others (choice bracketing; Read, Loewenstein, & Rabin, 1999). Standard finance models assume that people's choices regarding an investment decision should be linked to one's other investments, one's home mortgage, and so forth. Instead, it appears that people tend to treat these decisions as if they were independent. This tendency relates to the notion that people make choices with respect to a reference point, and hence people are sensitive to changes in utility, not absolute or total utility (Tversky & Kahneman, 1974). The reference point is often used to highlight the difference between how people perceive gains and losses, and the loss aversion effect, or the tendency to avoid losses more strongly than to seek comparably sized gains. But just as important as loss aversion is the notion that the reference point is generated separately for each decision—decisions are narrowly framed or bracketed (Barberis, Huang, & Thaler, 2006). Without this assumption, prospect theory and related models could not predict the basic loss aversion effect. Furthermore, if people think about financial decisions separately rather than in terms of their influence on their total financial portfolio and are risk averse, this could help explain the historical reluctance of individuals to invest in the stock market—in 1984, half the households with \$100,000 in liquid assets did not own stock (Barberis et al., 2006).

Vivid information appears to have large-scale effects due to its influence on decision making. Following Griffin and Tversky's (1992) suggestion that people overemphasize vivid evidence and underemphasize the credibility of the source of that evidence, Sorescu and Subrahmanyam (2006) tested the implications of buying or selling stocks based on large or small changes in recommendations (e.g., strong sell, sell, hold, buy, strong buy) by high- and low-credibility analysts. Examining stock prices over several days, all recommendations, on average, yielded gains (positive abnormal returns). However, if the evidence was vivid (i.e., a large change in recommendation) and made by a less credible source (analysts with little experience or who work for

lower prestige firms), then over the longer term, the recommendations led to losses. In contrast, if the evidence was not vivid (small change in recommendation) or was made by a higher credibility source (analysts with years of professional experience or who work for the highest prestige firms), then the recommendations yielded gains over the longer term (Sorescu & Subrahmanyam, 2006). The implication is that stock investors appear to overreact to low quality, vivid evidence, consistent with claims from lab research.

Behavioral finance generates some striking evidence that irrelevant or transient information can be consequential. For example, stock market returns tend to be positive on sunny days and mixed on cloudy days (Hirshleifer & Shumway, 2003; Saunders, 1993). Similarly, the outcomes of national sporting events predict national stock market performance (Edmans, Garcia, & Norli, 2007). Even simple association effects matter. Company names that capitalize on cultural trends show stock market advantages. Companies adding dot-com names during the technology boom of the 1990s generated sharp gains after the announcement of their name change (Cooper, Dimitrov, & Rau, 2001). The gains did not fade immediately afterward but appeared to persist. Furthermore, companies dropping dot-com names during the technology crash also generated sharp gains (Cooper, Khorana, Osobov, Patel, & Rau, 2005). Some clever companies both added and removed dot-com names, and they tended to generate stock price gains both times. Similarly, mutual fund name changes attract investors (and hence money), but have no influence on fund performance (Cooper, Gulen, & Rao, 2005). The emotion-cognition link (e.g., Clore & Huntsinger, 2007) has broad social consequences.

Prediction markets show another interaction between individual-level thinking and macro behavior. In prediction markets, people wager real or virtual money on the outcomes of future events, such as the revenue of Hollywood movie openings, the level of U.S. unemployment, the winners of political elections, and the outcomes of geopolitical events (Wolfers & Zitzewitz, 2004). The logic is that the opportunity to make money provides an incentive to find, aggregate, and weigh information to form judgments. However, lab studies show that because people sometimes make optimistic bets, other market participants observing the bets tend to change their beliefs to believe the optimistic outcome is more likely (Seybert & Bloomfield, 2009).

Thus, individual beliefs interacting with collective behavior can make beliefs more and less accurate, and work on prediction markets is aimed at understanding when each occurs.

Learning and Expertise

Another main finding in behavioral finance is that investors who are confident in their own abilities make more trades (Graham, Harvey, & Huang, 2009). This suggests the importance not only of examining how people make a given decision but also the reasons why they are likely to make a decision or take an action in the first place (Heath & Tversky, 1991). For example, in a series of studies of archival records of individual brokerage accounts, Odean (1998, 1999; Barber & Odean, 2000) generated evidence consistent with the possibility that overconfidence leads investors to buy and sell stocks. Odean and colleagues found that those who trade more earn less, and that the stocks they sold perform better in the coming year than the stocks they purchased.

Investment experience does not necessarily alter cognitive tendencies. For example, records of bond futures traders' personal trading accounts show that those who lost money during the first half of the trading day made more and riskier trades during the second half of the trading day, consistent with loss-aversion-induced, risk-seeking behavior (Coval & Shumway, 2005). It is as if professional traders tally their accounts at the end of each day and wish to avoid finishing the day with a loss. Of interest, the assumptions that traders are loss averse and tally their accounts at the end of each day are key to a model of investor behavior to explain why stocks have, historically, yielded higher returns than bonds (the equity premium puzzle; Benartzi & Thaler, 1995). Thus, research on decision making appears to be a useful guide to at least some forms of important investment activity by both novices and experts; furthermore, cognitive research may provide useful components for models of aggregate behavior (cf., Goldstone, Roberts, & Gureckis, 2008).

Overall, behavioral finance research shows that numerous individual-level cognitive tendencies have large personal consequences and are useful predictors of aggregate behavior. It is heartening to see basic research hold up in real-world settings under high stakes. It is also a spur to search for more comprehensive models that incorporate additional aspects of thinking and reasoning, and to craft interventions to support people's thinking

and reasoning when they are making large financial decisions.

Accounting: Behavioral Accounting

Businesses aim to make money, which sounds simple but can be extremely complex to assess, let alone bring about. Behavioral accounting research examines how people generate, use, audit, and regulate an organization's quantitative economic information (Libby, Bloomfield, & Nelson, 2002; Sprinkle & Williamson, 2006). Accounting research is concerned with how such quantitative information is used within organizations (the domain of managerial accounting), such as for budgeting or compensation systems to pay employees. Accounting research is also concerned with how quantitative economic information is used by organizations to communicate to lenders, investors, and regulators (the domain of financial accounting), such as for financial statements the Securities and Exchange Commission requires of public companies. In all cases, there is a concern with generating accurate quantitative information for guiding decision making and behavior.

Expertise

A major tenet of how financial markets function is that markets accurately integrate information into prices. The accounting literature shows that the analysts whose judgments guide the buying and selling of stocks and other concerns traded in financial markets form systematically inaccurate assessments. One reason is that they rely too heavily on domain categories. For example, companies can use accounting categories to frame their actions in ways that influence financial analysts' stock price judgments (Hopkins, 1996). To establish baselines, Hopkins showed that an announcement that a firm acquired financing through a loan led analysts to predict no change in stock prices, whereas announcing financing through the use of additional stock led analysts to predict a 4% drop in stock prices. Hopkins (1996) provided other participants with an announcement of mandatorily redeemable preferred stock that was framed as either being like a loan or like additional stock, which yielded predictions comparable to the effects to the unambiguous frames. Thus, rather than generating the same predictions from identical financial terms, analysts with an average of 10 years of professional experience instead appeared to rely on category-based induction to guide their judgments.

As a further example, another study contrasted two forms of presenting information about firm actions on analyst forecasts (Sedor, 2002). One form was a list of facts. The other form was a narrative linking the facts into a coherent explanation. Analysts with an average of 8 years of professional experience forecasted higher earnings from the narrative form, consistent with a range of research on the value of information in story form (e.g., Pennington & Hastie, 1986) and making relations explicit (e.g., Gentner & Toupin, 1986). The implication from this work and other behavioral accounting research (Bonner, 2008) is that cognitive information-processing models make predictions that fit the judgment and decision-making performance of professional accountants and analysts. Furthermore, the research suggests that companies are taking advantage of these information-processing tendencies to generate favorable market reactions.

Another issue raised in behavioral accounting research is predicting effective knowledge transfer. Most cognitive science research examines learning and knowledge transfer in settled domains of math and science, such as probability judgments (e.g., Ross, 1987). In this way, researchers can establish correct answers. In domains such as accounting (and many other areas of business, and, for that matter, life), it is far more challenging to establish that knowledge transfer is useful rather than misleading. Cognitive science research on knowledge transfer (e.g., Gick & Holyoak, 1980; Loewenstein, Thompson, & Gentner, 1999; Singley & Anderson, 1989), combined with domain task analysis (e.g., Bonner & Pennington, 1991, provided a general task analysis for the auditing process) could therefore help to identify opportunities for effective knowledge transfer. The result could produce substantial savings in training and benefits for task performance.

For example, auditors with experience in the financial services industry performed as well at assessing the potential for a manufacturing firm to go bankrupt as auditors from the manufacturing industry (Thibodeau, 2003). They were also better than analysts in the manufacturing industry at assessing bankruptcy potential for firms in the gambling industry. Thibodeau (2003) measured auditors' knowledge of the core accounting tasks for assessing firm financial conditions, future cash flows, and payment histories, and showed that this knowledge mediated auditors' assessments. Thus, cognitive research can facilitate understanding the skills involved in task performance, which in turn

can guide the search for opportunities for effective knowledge transfer.

Numerical Cognition

Given the strong focus on handling quantitative information in accounting, behavioral accounting research has examined managers' and accountants' memory and recall of numeric accounting data (Kida & Smith, 1995; Libby, Tan, & Hunton, 2006). For example, in one study, researchers presented managers with accounting information for a specific firm as well as prior year figures and industry averages and then, an hour later, gave the managers a recall test (Kida et al., 1998). Managers remembered the affective tone of the accounting information most often, less frequently remembered the relative standing of the information (e.g., higher or lower than the prior year), and still less frequently remembered the approximate (let alone the exact) numbers.

In a further study, researchers presented managers with information about two sets of companies, separated by an hour's delay. After a further hour, they asked for the firm in which managers would be most interested in investing, and they found that a firm from the first set, which clearly dominated the set, was chosen more than a firm from the second set that did not clearly dominate its set but was clearly objectively superior (Kida et al., 1998). The implication is that managers' memory for numbers may preserve affective and qualitative aspects more robustly than the exact quantities, and that as a result making decisions from one's memory of numeric data can readily become distorted. This finding relates to consumer behavior research discussed earlier (Dickson & Sawyer, 1990) that showed consumers poorly recall exact prices.

This very brief review of behavioral accounting research provides an indication of the degree to which limitations to human thinking and reasoning, over and above decision biases, has important practical consequences for the practice of business. Behavioral accounting research might be very useful to link to research on thinking and reasoning in the law (see Spellman & Schauer, Chapter 36), which, despite having less of a numerical component, is also heavily concerned with understanding people's thinking when it is guided by a complex system of socially generated rules.

Conclusions and Future Directions

The practice of business has wide scope, making many aspects of thinking and reasoning important

for understanding this important applied area. Each area of business research examines thinking and reasoning involved in tasks in a major aspect of the practice of business. These are important practical concerns, so it is noteworthy for basic researchers to know that their work is being used to understand and improve behavior in these domains, and that there are applications of their work that they may not have realized.

There are many opportunities for exchange between basic and applied business researchers studying thinking and reasoning. Translating and applying basic research to understand a particular context raises questions, and studying particular applied contexts generates new phenomena and ideas. One goal of this chapter has been to highlight examples and so foster such work, in part by helping to develop mutual understanding despite differences in vocabularies (Clark, 1996). Thus, perhaps the simplest use of this overview is to provide starting points for scholars, journals, and topic keywords to examine for relevant research. It is easy enough to miss the fact, for example, that consumer behavior research on brands, organizational behavior research on competitors or organizational identities, and behavioral finance research on portfolio allocations, is all research on categories. These and other lines of business research highlight aspects of cognition that are less often considered in standard psychological research, such as (to stick with the topic of categorization) the potential for categories to change (e.g., membership changes, typicality changes), the potential for category membership to be a choice, or the influence of social and cultural factors on category membership.

An overarching theme from most areas of business academia is linking individual- and social-level cognition and behavior, whether by social one means groups, organizations, industries, or societies. Research on thinking and reasoning has the potential to help understand large-scale patterns of behavior (e.g., Goldstone et al., 2008; Koonce & Mercer, 2005; Loewenstein & Heath, 2009). Furthermore, effects at those social levels in turn influence individual cognition, such as what people attend to, learn, and think about (e.g., DiMaggio, 1997; Douglas, 1986; Ocasio, 1997). For example, due to the limitations of human memory, record-keeping was arguably critical for the development of advanced economies (Basu, Kirk, & Waymire, 2009). Archival research shows associations between the use of writing systems and the size of communities, the use of credit, and the

frequency of interactions between strangers (Basu et al., 2009). Whether it is to study culture, markets, organizations, industries, professions, or other macro concerns, research on thinking and reasoning can offer key insights.

A linked theme is that business academia makes far more use of survey and archival research methods than does basic research on thinking and reasoning. These methodological approaches offer the potential to examine sophisticated questions outside of the lab and thereby provide evidence of real-world consequences and open up possibilities for guiding organizational action and public policy. The broader implication is that a better understanding of cognition across levels of analysis would serve to enrich research on both individual cognition and the practice of business. It might also be profitable.

Acknowledgments

I wish to thank Andres Almazan, Susan Broniarczyk, Keith Holyoak, Steve Kachelmier, Lisa Koonce, Bobbie Spellman, and Michael Williamson for guidance and insights, and support from the Kelleher Center and IC², both of The University of Texas at Austin.

Abstract

Listening to music entails processes in which auditory input is automatically analyzed and classified, and conscious processes in which listeners interpret and evaluate the music. Performing music involves engaging in rehearsed movements that reflect procedural (embodied) knowledge of music, along with conscious efforts to guide and refine these movements through online monitoring of the sounded output. Composing music balances the use of intuition that reflects implicit knowledge of music with conscious and deliberate efforts to invent musical textures and devices that are innovative and consistent with individual aesthetic goals. Listeners and musicians also interact with one another in ways that blur the boundary between them: Listeners tap or clap in time with music, monitor the facial expressions and gestures of performers, and empathize emotionally with musicians; musicians, in turn, attend to their audience and perform differently depending on the perceived energy and attitude of their listeners. Musicians and listeners are roped together through shared cognitive, emotional, and motor experiences, exhibiting remarkable synchrony in behavior and thought. In this chapter, we describe the forms of musical thought for musicians and listeners, and we discuss the implications of implicit and explicit thought processes for musical understanding and emotional experience.

Key Words: music, performance, composition, improvisation, emotion, listening, mood, arousal, rhythm, expression, timing, melody, harmony

Introduction

Music is a puzzling phenomenon because its manifestations, uses, and social functions are highly variable. Like language, music unfolds in time and varies in pitch, timing, timbre, and intensity, and music performance, as with speaking, is accompanied by meaningful gestures and facial expressions that contribute to its intelligibility. Unlike language, musical behavior often seems discretionary. If language were to disappear, there would be profound and catastrophic consequences for virtually every facet of our lives. The disappearance of music would be an unwelcome change, but the world could continue roughly in the same manner as before.

Perhaps because music has no one function that is essential to human survival, it is free to take many

different forms within and across cultural groups. Among its varied uses are aesthetic enjoyment, emotional communication, symbolic representation, social conformity, and group bonding. It is also often used to accompany or encourage synchronous group movement (e.g., dancing, marching) or as symbolic validation of social institutions and religious rituals. Many musicologists are reluctant to assume that there are essential structural or functional properties of all music, and music is often defined broadly. For example, the *American Heritage Dictionary* defines music as the “arranging of sounds in time.” Such a definition is highly inclusive but seems unsatisfactory in ignoring the aesthetic, emotional, and motional properties of music. Ian Cross (2003a, 2003b) carefully considered the problems

of defining music and argued that it always involves the creation of sounds and movements that have the potential to carry meaning across a range of contexts. This latter characteristic, what Cross calls *floating intentionality*, allows music to be exploited for a range of purposes.

If music has no essential function, then why is musical behavior observed in every known culture, and why is it so important to us? In Western industrialized cultures, people spontaneously sing while engaged in activities such as house cleaning, driving, or showering. Live or recorded music is played at social gatherings such as funerals, graduation ceremonies, birthday parties, and weddings. Young adults often form passionate attachments with specific musical styles and may nurture a sense of identity that is deeply connected with specific groups of musicians (whether followers of The Grateful Dead or Lady Gaga). The cognitive and educational costs involved in music appreciation and production are high. Music is taught at home and all levels of education, and society places enormous value on the craft of music making—the performers and composers of music. Acquiring expertise as a performer or composer can take 10 or more years of intensive training (roughly 10,000 hours of effortful practice) and elite musicians are among the most esteemed members of a society.

In this chapter, we review current knowledge of the psychological basis of music, focusing on cognitive processes involved in the activities of music listening, performing, and composing. These processes are best described as music relevant rather than music specific. That is, they handle input from any domain, but a breakdown in that process is more likely to affect music perception than the perception of speech or environmental sounds because music entails fine-grained changes in acoustic attributes (Peretz & Hyde, 2003). Indeed, the severe musical deficits observed in individuals with tone deafness or “amusia” may arise from processes that are not specialized for musical input (Douglas and Bilkey, 2007; Nan, Sun, & Peretz, 2010; Patel, Wong, Foxton, Lochy, & Peretz, 2008). We also explore the relevance of cognitive constraints, involuntary processes, and focused attention for musical activities, addressing the following questions: To what extent does music behavior rely on conscious, explicit processes? To what extent does it rely on early predispositions, unconscious biases, and other involuntary processes? Can people acquire knowledge of musical structure in the absence of formal training? Why

does music give rise to such powerful aesthetic and emotional experiences? To what extent do perceptual and cognitive processes constrain our capacity to perceive, perform, and compose music?

A central theme of the chapter is that listeners, performers, and composers are “roped together” by shared cognitive and motor processes. The distinctions made between these three activities are not always clear cut. Listeners are most often active participants in music making (singing along, tapping to the beat). Performers and composers are almost invariably listeners (a notable exception is the deaf percussionist Evelyn Glennie). As such, the sections on performing and composing in this chapter make frequent reference to music listening, illustrating, for example, how the mechanism of auditory scene analysis called auditory streaming can shape performance and compositional choices. Other well-studied mechanisms that may have served the same illustrative purpose, such as listener sensitivity to consonance and dissonance between tones, are exhaustively reviewed elsewhere (Bregman, 1990; Handel, 1989). Approaches to cognition in music performance and composition that are less directly related to the listener are also covered elsewhere and include musical expertise (Lehmann & Gruber, 2006; Sloboda, 2000; Sloboda, Davidson, Howe, & Moore, 1996), improvisation (Pressing, 1984, 1988) and composition (McAdams, 2004; Sloboda, 2004) synchronization in ensemble playing (Goebl & Palmer, 2009; Rasch, 1988), and sensorimotor integration in music performance (Goebl & Palmer, 2008; Palmer, Koopmans, Loehr, & Carter, 2009).

Listening to Music

The specific arrangements of sound that we perceive and characterize as music are referred to here as *structures*. In Western music, these include individual sequences of tones perceived as *melodies* (melodic structure), simultaneous combinations of tones perceived as *chords* (harmonic structure), and distinctive temporal patterns of events perceived as *rhythms* (rhythmic structure). Structures can be remarkably complex, especially in the domains of pitch and rhythm. Yet with no formal music training or vocabulary to describe musical structure, listeners readily appreciate and respond to music, often without knowing why. Sequences of pitches may be perceived as a *melody*, but not all pitch sequences are heard as such. Indeed, the term “melody” is a *psychological* construct rather

than a physical description of a sonic event. Melody perception is dependent on perceptual mechanisms that group sequences of tones into a coherent stream and segregate them from sounds that occur before, after, or concurrently with those tones. Auditory stream segregation is important for music perception because melodies are often accompanied by other textures in the music, forming simultaneous combinations of pitches that are perceived as the *harmony* of the music. Not all tone combinations are perceived as harmonious and pleasing: Like melody, harmony is a psychological construct that depends on a perceptual interpretation of sound waves impinging on the eardrum.

Melody and harmony unfold rhythmically and often suggest a regular cycle of strong and weak accents or “beats,” collectively called the meter. Rhythm and meter, like melody and harmony, are psychological constructs because their appreciation depends on the operation of perceptual and cognitive processes. Because of these processes, one can perceive a strong metric accent at a time in the music when there is no sound. Once a metric framework is established, the brain “infers” subsequent cycles of strong and weak accents through expectancy mechanisms. Important musical events tend to coincide with metrically strong beats, so listeners anticipate points of metric stress and allocate greater attentional resources to them. As such, our attention to music occurs not in an evenly distributed manner over time but exhibits cyclical characteristics described as *dynamic attending* (Jones, 1989; Large & Jones, 1999). The cyclical nature of attention means that some musical elements (coinciding with strong accents) are more salient and better remembered than others (coinciding with weak accents). Dynamic attending need not be limited to meter. For example, by spanning a regular number of metrical cycles, melody (e.g., four-bar phrasing) and harmonic progression (e.g., twelve-bar blues) may generate further expectancies at longer cycles. Multiple cyclical boundaries give music a nested or hierarchical quality (Lerdahl & Jackendoff, 1983). Other attributes of sound also vary systematically in music, such as event density, intensity, timbre, and pace or tempo. These attributes also influence the dynamic nature of auditory attention and the perceived hierarchical structure of music. Musicians manipulate almost all perceivable attributes of sound, and all perceivable attributes contribute to a listener’s perception and appreciation of music.

Perceiving Musical Structure

For music to acquire meaning, listeners must perceive its structure and organization. Musical meaning can arise from relationships between adjacent and nonadjacent events (formalist meaning) and from the feelings or emotions that these relationships evoke (expressionist meaning; Meyer, 1956). A first step in this process is to differentiate musical sound from meaningless noise and other nonmusical sounds. Performers and composers—the producers of music—intuitively take steps to facilitate the process of perceiving musical structure. Performers introduce expressive actions that highlight or enhance structural features, slowing down at the end of phrases, accenting musically significant notes, and introducing timing asynchronies so that melodic lines stand out from the accompanying musical material. Most composers create music with structures that can be easily perceived and remembered. They often introduce a metric framework so that listeners can keep track of strong and weak accents, and they manipulate the musical materials so that some events are strongly associated with closure and stability while others connote instability and tension. Once established, these associations provide listeners with a means of understanding the musical narrative: the increases and decreases in tension, momentary points of repose, unexpected outcomes, and a sense that the music has come to an end (Cuddy & Lunney, 1995; Lerdahl & Jackendoff, 1983; Meyer, 1956; Narmour, 1992; Schellenberg, 1997). Of course, some composers intentionally avoid such conventions (e.g., Schoenberg, Webern), but such music does not enjoy widespread appreciation.

The attributes and structures that comprise music are influenced by the architecture of human cognition, providing a source of commonality in the forms of music that are most readily perceived and remembered across cultures, historical periods, and genres. For example, the limits of working memory exert an impact on optimal phrase lengths in melodies across cultures. This constraint does not mean that long phrases are impossible to appreciate, but most people across cultures prefer melodic phrases that can be readily perceived and remembered as a coherent musical package. Music can be appreciated on multiple levels of analysis, including local structure (tones, intervals), higher order structure (phrases, movements), and abstract structure (scales, keys).

Our ability to perceive musical structure is partly driven by general mechanisms such as pitch perception and auditory scene analysis, and partly shaped

by long-term knowledge of abiding regularities in music. This knowledge can be gained through formal training in music, but it arises involuntarily following long-term exposure to music by a process of implicit learning. It is through implicit learning that most Western listeners acquire their knowledge of Western tonal music (such as the music of Mozart and Bach, but including contemporary popular and folk genres). The same processes allow non-Western listeners to acquire implicit knowledge of the music of their culture, whether the Carnatic music of South India, the Sami music of Northern Finland, or Indonesian Gamelan music.

Following passive exposure to music, listeners acquire extensive knowledge of the music of their culture, allowing them to anticipate, evaluate, and respond to its characteristic features. In most cultures, music is highly structured and requires complex mental representations for its appreciation. Western tonal music is a system based on a relatively small number of elements that exhibit high regularity in their occurrence and co-occurrence. It is based on a set of 12 pitch classes, from which a subset of seven notes typically dominates the music (for example, the seven notes of the major scale: doh-re-mi-fa-sol-la-ti). Sequences of notes from this subset form the melodies of music. In turn, chords are defined by sets of notes played simultaneously. For example, the notes of C, E, and G played simultaneously define a C major chord. Sequences of chords are the basis of musical harmony. Through persistent exposure to the music in one's environment, listeners internalize regularities in the melodic and harmonic materials to which they are exposed. These regularities include typical levels of musical stability or tension associated with different scale notes and chords, and customary transitions between the notes and chords that make up melodic and harmonic sequences.

Acquiring Sensitivity to Musical Structure

Because musical regularities vary across cultures, infants and young children must abstract the specific properties of the systems in their environments. This process takes many years. Its development can be traced in preverbal infants as an emerging sensitivity to subtle changes in a repeated melody, as reflected in measures such as head-turn responses, looking times, and differential sucking rates. Stimuli that are perceived to be novel elicit changes in these measures. Thus, by varying the degree of novelty or familiarity of a stimulus, and then observing

changes in these behaviors, researchers can evaluate sensitivity to various aspects of musical structure. Before 1 year of age infants show little sensitivity to the features of Western tonal conventions, having insufficient time to abstract the relevant features. For example, they detect changes to a melody equally regardless of whether the new note conforms to the implied harmony or scale of the original melody (Schellenberg & Trehub, 1999; Trainor & Trehub, 1992). By the age of 4 years, they more easily detect changes to a diatonic melody (i.e., made up of conventional scale notes) than changes to a nondiatonic melody (Trehub, Cohen, Thorpe, & Morrongiello, 1986). By the age of 7 years, children exhibit sensitivity to Western harmony (Trainor & Trehub, 1994). How do infants and children acquire this knowledge of Western tonal conventions?

Saffran, Johnson, Aslin, and Newport (1999) provided evidence that listeners acquire sensitivity to statistical properties of music through passive listening. They constructed a small artificial musical "vocabulary" consisting of six, three-note sequences or "tone-words." They then constructed a 7-minute sequence by chaining together these tone-words and repeating them at varying temporal locations. The result was a continuous stream of tones in which certain tone transitions occurred more often than others. Tone transitions that occurred in the tone-words occurred repeatedly and were therefore associated with high transitional probabilities (average $p = .64$), just as the probabilities of phoneme transitions that occur in linguistic words are high. In turn, tone transitions that did not occur in any of the tone-words had low transitional probabilities (they could occur between the end of one figure and the start of another, average $p = 0.14$).

Twenty-four nonmusicians heard the 7-minute sequence three times, unaware that the sequence was constructed from a vocabulary of three-note tone-words. After the exposure phase they were presented pairs of three-note stimuli in the test phase. For each pair, one stimulus was a tone-word and the other was a novel (nonword) tone sequence. Listeners indicated which of the two figures was most familiar. As expected, figures that were part of the vocabulary of the 7-minute sequence were judged as significantly more familiar to listeners than were the novel figures. All six tone-words were learned at a level significantly better than chance. Although none of the tone-words were heard in isolation prior to the test phase, listeners internalized the high predictability of note transitions in the tone-words and

perceived them as familiar. Further analyses suggested that the impression of familiarity was based on sensitivity to the conditional probabilities of tone transitions in the tone-words.

MUSICAL PREFERENCES

The aforementioned results indicate that sensitivity to transitional probabilities can lead to an impression of familiarity. Research on the “mere exposure effect” illustrates that statistical learning also affects our preferences for music. Wilson (1979, Experiment 2) repeatedly exposed participants to melodic sequences in one ear while presenting spoken material to the other ear (exposure phase). Participants were required to shadow the verbal material (say each word aloud as they heard it) while proofreading written text of the verbal material. In a subsequent (test) phase, they rated the exposed and novel melodic sequences for preference and indicated whether they remembered hearing each sequence in the proofreading phase. Recognition of the exposed sequences was not above chance but preference was significantly higher for exposed than for novel sequences.

Peretz, Gaudreau, and Bonnel (1998) provided further evidence for this effect. Listeners were exposed to a set of familiar and unfamiliar melodies (exposure phase). They were then presented with exposed and novel melodies (test phase). Half of the listeners rated their preference for the test melodies (implicit test) and half identified the melodies that they remembered hearing in the exposure phase (explicit test). Both preference for and recognition of exposed melodies were above chance, but when the investigators varied the time interval between exposure and test phases (between-task interval), they observed a different temporal gradient of memory loss for preference and recognition judgments, suggesting that recognition and preference arise from independent memory systems. Changes in timbre between exposure and test phases (piano vs. flute tones) did not affect preference judgments but negatively impacted recognition, which further implies independence between recognition and preference, and illustrates the robustness of exposure effects on preference.

In short, statistical learning leads to impressions of familiarity and preference, effects that are arguably forms of implicit memory (see Evans, Chapter 8; Zajonc, 1968). Thompson, Balkwill, and Vernescu (2000) found evidence that recently heard melodic patterns also shape the expectations that listeners

form about notes to follow, beyond what can be explained by explicit memory for those patterns. Listeners were presented with 30 short tone sequences (target sequences) three times each (exposure phase) and reported the number of notes in each. They were then presented target and novel sequences and rated how well the final note continued the pattern of notes that preceded it. Novel sequences were identical to target sequences except for the final note. Ratings were significantly higher for target sequences than for novel sequences, indicating that mere exposure to melodic sequences influences expectations about future events in music. These effects could not be explained by explicit memory for the target sequences or by anything inherently predictable about the target sequences.

Emotional Responses to Music

Research on statistical learning illustrates how general cognitive processes can shape music experiences, giving rise to feelings of familiarity, preference, and expectation as music unfolds. The effects of passive listening on expectation are particularly significant because violations and fulfillments of expectancies are responsible for some of the most powerful effects of music. Meyer (1956) was among the first to discuss the role of expectancies in emotional responses to music. When we listen to music that is culturally familiar, we continuously form expectations about what will occur, and when (Huron, 2006; Thompson, Cuddy, & Plaus, 1997). Composers and performers toy with our expectations, fulfilling our expectations in some cases but also delaying or thwarting expected events at other moments. Composers manipulate expectancies primarily through the attributes of pitch and temporal structure (Thompson & Stainton, 1998). Performers use expressive devices to manipulate expectancies, such as crescendo (a gradual increase in loudness), tempo (the overall pace of the music), and ritardando (a gradual slowing down).

Violations to expectations are charged emotionally because the mechanisms for predicting events are central to all behavior and indeed to human survival. To function, people must continuously anticipate the future, whether in the simple act of walking (knowing when your feet will contact the ground), planning a meal, avoiding danger, or interacting socially. The feeling of surprise at an unexpected outcome is a biological signal that current strategies of prediction have gone awry and need refinement (Mandler, 1984).

Responses to violations and fulfillments of expectations in music can account for a wide range of emotional experiences, not just surprise. Huron (2006) outlined some of the ways that expectancies generate complex emotional responses. He pointed out that expectations occur on different levels of analysis, from physiological preparation for an imminent event, to longer term expectations of future states. He also posited different types of reactions to expected outcomes. The *prediction response* is a transient state of reward or punishment that arises in response to the accuracy of prediction. Accurate expectations are encouraged by positively valenced emotional responses; inaccurate expectations are discouraged by negatively valenced emotional responses. The *reaction response* is a rapid, automatic bodily or visceral reaction based on an immediate assessment of an event, independent of whether it has been accurately predicted. The *appraisal response* is a more reflective and conscious evaluation of an outcome, and it need not be compatible with the reaction response.

Expectancies for music, formed primarily by statistical learning, generate powerful emotional responses to music (e.g., happiness, sadness). Other attributes of music, including overall intensity, pitch height, and tempo, also have emotional connotations independently of expectancy mechanisms, possibly because of the association between these attributes and emotion in human speech (Ilie & Thompson, 2006; Juslin & Laukka, 2003). Ilie and Thompson (2011) presented eight groups of listeners with 7 minutes of music by Mozart. All groups received the same composition, but the music was manipulated in tempo (slow, fast), pitch height (low, high) and intensity (soft, loud). Manipulations influenced three dimensions of affective experience: energetic arousal, tension arousal, and valence. For example, tension arousal was higher after listening to loud music than soft music; energetic arousal was higher after listening to fast music than slow music; and valence was higher after listening to high-pitched music than low-pitched music. When these manipulations were applied to a narrated documentary, they gave rise to the same affective consequences, illustrating that music and speech may share a common emotional code.

The same manipulations also affected cognitive function. Exposure to fast music not only led to the experience of high energetic arousal; it enhanced speed of processing (as measured by reaction time in a routine task). Exposure to high-pitched music

not only led to a positively valenced experience, it also enhanced creative problem solving, as measured by success on Dunker's (1945) candle problem and Maier's (1931) two-string problem (see van Steenburgh et al., Chapter 24). In short, listening to music has multiple effects on thought and experience. Listeners internalize statistical properties of the music and develop preferences, feeling of familiarity, and expectancies for common tone transitions. They also perceive and experience strong emotions, and their cognitive functioning may be significantly affected.

Performing Music

With decades of intensive training, practicing musicians perform highly complex passages of music with apparent ease. Elite singers, for example, exercise precise vocal control so as to manipulate sounded attributes such as pitch, intensity, vibrato, timing, and timbre. To what extent do music performers rely on implicit and explicit processes in order to execute a performance? Performers effortlessly produce highly practiced movement sequences that reflect embodied or procedural knowledge of music. At the same time, they monitor the sounded output of their actions, consciously reflecting on the music that they are producing and making online adjustments to optimize their communicative intentions.

To illustrate the delicacy of this balance, imagine an established singer performing an aria from Mozart's *The Marriage of Figaro*. She has performed the aria innumerable times and typically receives standing ovations for her performances. In one performance at the prestigious *Lyric Opera* in Chicago, she is approaching a particularly complex and beautiful vocal passage in which the sung melody mirrors the accompanying violins. Unexpectedly, her online reflections on the performance begin to intrude excessively into her consciousness, disrupting the delicate balance between implicit and explicit processes required for an optimal performance. Although potentially disastrous, the singer cannot help but worry about the difficulty of an upcoming passage, and she entertains the possibility of a lapse in memory. Suddenly, a performance that has been delivered effortlessly in hundreds of previous performances ceases to be fluent and automatic, and the singer is filled with self-doubt and anxiety. To flounder in front of thousands would be catastrophic, and her conscious awareness of this possibility makes matters worse. From that moment

onward, each sung note feels effortful and tenuous, and there is a very real possibility that her performance will break down.

The musician in question was Renée Fleming, arguably one of the most successful opera singers today (Fleming, 2005; see also Lehrer, 2009, p. 132). Such instances of music performance anxiety are remarkably common in both experienced and inexperienced musicians (Kenny, 2010). The widespread prevalence of music performance anxiety illustrates that all musicians are vulnerable to disruption of the balance between the use of procedural memory and conscious processes that musicians must rely on to guide a performance.

Why is procedural memory important for performers? One reason is that working memory has insufficient capacity to process the amount of information involved in a musical performance. Performing long pieces of music places enormous demands on memory (Aiello & Williamon, 2002) and in the absence of external cues (sheet music) this load is best handled in procedural memory. Procedural memory can be used to generate rapid pitch (or chord) sequences that are implemented with precise timing and expressive actions such as the *ritardando* (a gradual slowing down), *accelerando* (a gradual speeding up), *crescendo* (a gradual increase in loudness), and *diminuendo* (a gradual decrease in loudness). That is, procedural memory not only can be used to store the motor commands needed to perform a sequence of carefully timed notes; it can also be used to store the various changes in timing, pitch, and loudness that are collectively known as *performance expression*.

Understanding Performance Expression

Performance expression refers to those qualities of an individual performance that distinguish it from a strict or mechanical rendering of the set of pitches and durations that are (or could be) indicated in a written or “notated” representation of that music (called a score), and that permit different expressive interpretations of the same piece of music. In Western classical genres, a score provides a reduced or idealized representation of the music. It outlines the basic sequence of notes to be played (pitches and durations), a structural framework in the form of a key signature and a time signature, and selected guidelines for the performer at specific points in the music. Such expressive markings include desired loudness of notes or phrases using abbreviations such as *f* for the Italian *forte*

(loud), *ff* or *fff* to indicate greater intensity levels, *pp* to indicate *pianissimo* (soft), and so forth. Performance expression can be understood as those qualities of the music that go beyond the set of pitches and durations (the notes) as indicated in the score. It includes variations in timing (e.g., rubato, accelerando, ritardando), intensity (e.g., accent, crescendo, diminuendo), timbre, and articulation (e.g., legato, staccato). If music were played without performance expression, it would sound mechanical and regular, and it would likely sound less expressive and emotional.

The expressive actions of performers are deliberate and systematic, and they help listeners to perceive structural features in the music, anticipate climactic moments, grasp emotional connotations, and appreciate points of tension and relaxation. Expressive devices highlight phrase boundaries, harmonic changes, points of accent, and other structural attributes (Ashley, 2002). For example, performers may use intensity and timing to accent notes that have a significant musical function, and they may insert pauses at phrase boundaries to enhance perceptual grouping. Timbre and pitch can also be manipulated in expressive ways. By increasing force to the bow, a violinist can increase the amount of noise at the onset of a note. Similarly, guitar distortion is often used in rock music to suggest friction and instability. When music is performed well, listeners are in a better position to form a stable representation of the structural and emotional properties of that music (Clarke, 1988; Palmer, 1997, 1989; Thompson & Cuddy, 1997).

For elite performers, expressive actions are stored in procedural memory and can be implemented with little or no conscious effort. Conscious efforts to play with no expression do not eliminate them entirely, suggesting that expressive actions become automatized after extensive practice (Bengtsson & Gabrielsson, 1983; Palmer, 1989; Seashore, 1938). Consistent with such results, some researchers surmise that conscious processes are most relevant only for beginners, or when one is learning something new; experts are capable of drawing upon implicit knowledge with no need for conscious thought (Ericsson, 2006). This reliance on implicit processing and skirting of explicit cognition is a hallmark of expertise. As a case in point, when musicians are practicing a new piece they need to make many conscious decisions about technical issues such as fingering and body position, as well as issues of interpretation, such as how to implement expressive actions

such as phrasing, crescendi, rubati, and pedaling at various points in the music. The implementation of such conscious decisions becomes largely automatic with extensive practice, reducing demands on conscious processes during a performance (Lehmann & Gruber, 2006).

Others, however, point out that the flexibility that elite performers exhibit cannot be explained by the exclusive use of procedural memory, and that performers must draw upon a declarative “mental road map” held in long-term working memory (Chaffin & Imreh, 2002; Chaffin, Imreh, & Crawford, 2002; for a discussion of this view, see Geeves, Christensen, Sutton, & McIlwain, 2008). This mental road map is particularly important when something goes wrong in a performance: Under such circumstances a performer “must know where he or she is in the piece, and be prepared to put the performance back on track” (Chaffin & Imreh, 2002, p. 342). Conceptual memory is vital for restarting a motor sequence, and for monitoring the pace, precision, and expressive quality of one’s performance. In turn, performers pay particular attention to their technical and aesthetic goals during difficult or climactic moments in a piece.

The difficulty of separating deliberate and automatic processes is exemplified in the many perceptual interactions that occur between attributes of music. Such interactions are largely outside of the awareness of musicians and listeners but exert a significant influence on music performance, experience, and memory. Conscious attention may be directed toward one attribute, but responses and evaluations to that attribute are often biased by many other attributes. Our experience of a change in pitch (called an *interval* when the change is between successive discrete tones) is influenced by a range of ostensibly irrelevant attributes such as overall pitch height, intensity, and timbre (Russo & Thompson, 2005a; 2005b). The facial expressions of singers also affect how listeners perceive the music (Thompson, Graham, & Russo, 2005) even when they are instructed to focus exclusively on the acoustic information (Quinto, Thompson, Russo, & Trehub, 2010; Thompson, Russo, & Quinto, 2008). Performers, in turn, preattentively implement a range of facial movements in live performances to clarify or enhance emotional messages in the music (Livingstone, Thompson, & Russo, 2009) and to highlight musical structure (Thompson & Russo, 2007; Thompson, Russo, & Livingstone, 2010).

Pitch and Timing

The timing of musical events is biased by the pitches of those events, an interaction that affects performers and listeners (Ammirante, Thompson, & Russo, 2011; Prince, Schmuckler, & Thompson, 2009). One explanation for this bias is that it reflects an implicit awareness of the spatiotemporal correlations in moving bodies in the natural environment (Helmholtz, 1962/1867; Jones & Huang, 1982). To change directions, moving bodies must slow down. When a melody changes direction (e.g., from upward to downward pitch motion), does the music itself seem to slow down? Boltz (1998) found that tempo judgment negatively covaried with the number of changes in pitch direction in isochronous melodies, implying that, just as with moving bodies that change direction, a musical sequence seems to lose momentum at changes in pitch direction.

Ammirante and colleagues predicted that tonal motion implied by pitch structure is mirrored in concurrent motor activity (Ammirante & Thompson, 2010; Ammirante, Thompson, & Russo, 2011). Participants maintained a steady beat by tapping on a single key of a MIDI keyboard. Each tap triggered a discrete tone in a sequence varying in pitch. Although participants were instructed to focus on tapping and ignore the tones that were triggered by their taps, the tonal information significantly affected performance on the tapping task. Where pitch structure implied faster tonal motion (e.g., unidirectional pitch motion, larger pitch intervals “traversed” between tones), the intertap interval (ITI) initiated by the just-triggered tone and the velocity of the tap that followed (TV) were faster; where pitch structure implied slower tonal motion (e.g., a change in pitch direction, smaller pitch intervals), slower ITI and TV followed. These findings suggested that participants failed to disambiguate velocity implied by tonal motion from the velocity of their finger trajectory.

Ammirante et al. argued that the perceived relation between pitch movement and speed (tempo) unconsciously induced local deviations in timing and loudness (a louder sound is produced when a key is struck with faster TV). Interestingly, such temporal and dynamic deviations are also found in expressive music performance, suggesting that certain expressive actions by musical performers reflect sensitivity to spatiotemporal correlations in the natural environment. In effect, music is unconsciously perceived to have “life-like” qualities that give rise to perceptual interactions between musical features. These

interactions are evident in perceptual judgments and timed movements, blurring the distinction between performers and listeners. Its external manifestation may be unconsciously or deliberately communicated in expressive music performance (Truslit in Repp 1993/1938) or “corporeally articulated” in the unconscious actions of an engaged listener, such as swaying with the music (Leman, 2009).

Composing Music

Elite music performance demands flexibility and balance between implicit and explicit processes in real time; composition entails a comparable flexibility and balance applied over a longer time scale. Unlike music performance, where a performer often takes considerable guidance from a musical score, there are few boundaries on the process of music composition. How do composers narrow down the set of decisions involved in such an ill-defined task? One approach is to compose music within the boundaries of a standard musical form such as sonata, 12-bar blues, musical theater, or opera. Composers are also conscious of the biophysical constraints on what can be physically realized by a performer, and the acoustic effects of combining sounds.

For the most part, music is composed with listeners in mind. As such, compositional choices are influenced by an awareness of *musical accessibility*. This includes culturally acceptable ways that the conventions of a stylistic idiom may vary. Music creators may attempt to strike a balance between producing music that is familiar but not trite, and that expands a stylistic idiom without being opaque. One approach is to manipulate expected features. For example, the rhyming style of the “new school” of rap that emerged in the late 1980s replaced simple, monosyllabic end rhymes that coincided with the fourth beat of a four-beat metric cycle with low-probability multisyllabic rhymes and an expressive dodging of the onset of the fourth beat (Bradley, 2010).

Tonal Structure

In the evolution of the Western classical composition, tonality is a distinguishing feature. Western listeners are highly sensitive to tonality, and they expect it. Indeed, most listeners find music that does not have a tonal center confronting or disturbing (e.g., the atonal music of Schoenberg, the free jazz of Ornette Coleman). What accounts for this rigid expectation for tonality? Two mental representations,

both implicit forms of knowledge, may underlie it. The first maps relationships between tones within a musical framework called the *key*. The second maps relationships between keys. Listeners acquire these representations through passive exposure to tonal music (e.g., by listening to music such as Mozart, Bach, Haydn, and most Western popular genres). Once these representations are established, a sense of tonality rapidly emerges while listening to music, as long as the music implies a collection of tones that have a hierarchical organization (Cohen, 1991). The most common tone collection in Western music is the major scale—doh-re-mi-fa-sol-la-ti. Within that scale, the first note (called the tonic) is the most stable pitch and often occurs at points of stability, such as phrase endings or down beats. Other pitches have subordinate levels of stability. Guided by the second representation, listeners are also sensitive to relationships among keys. For example, the key of C is strongly related to the key of G but weakly related to the key of F#. Movement between related keys sounds natural and may even go unnoticed; movement between distantly related keys can sound unnatural or abrupt.

Stylistic changes between the 18th and 20th centuries are characterized by a conscious destabilization of a central recurring tone or “tonic” around which compositions are organized. Composers were troubled by their unconscious adherence to tonal compositions and worried that they would repeatedly “reinvent the wheel” unless they consciously attempted to avoid clear tonal centers. Thus, they began to compose music with an increased emphasis on tones that were distantly related to the tonic, and they shifted the tonic within and between musical movements. These strategies culminated in the works of the late 19-century Romantics such as Wagner and Mahler. In the early 20th century, serialism employed compositional procedures that more rigorously avoided the establishment of any tonal centre or hierarchical organization. One form of serial composition—12-tone music—uses a “tone row” as a musical theme. As a rule, each member of the set of discrete pitch classes contained in the tone row (the 12 tones of the chromatic scale) must be presented before a member can be repeated. Even stricter forms of serialism extend this rule for pitch classes to tone duration and timbre.

Cognitive Constraints on Composition

Listeners, who had internalized an expectation for unambiguous tonal centers following repeated

exposure to tonal music did not respond well to these experiments. Lerdahl (1988) argued that the widespread rejection of serial composition by listeners is not only a question of familiarity but is understandable from a cognitive perspective. To perceive and remember music, listeners need hierarchical structure. When all events are perceived on the same structural level with no one musical event subordinate to another, the music will sound “like beads on a string” with little basis to perceive, remember, and appreciate it (1988, pp. 341–342; see Dienes and Longuet-Higgins, 2004). On the other hand, listeners’ sensitivity to hierarchical structure may be limited, so its requirement as a musical property may be overstated. Listeners do not even appear to notice when music starts and ends in a different key (Cook, 1987), suggesting that short-term memory limits the extent to which hierarchical structure can be extracted. Cook (1987) proposed that theories of music that emphasize hierarchical structure are “better seen as a means of understanding the practice of tonal composers than as a means of predicting the effects of their compositions upon listeners” (p. 204).

According to Lerdahl’s (1988) view, the capacity of listeners to perceive and appreciate music is not just a question of experience and enculturation but is also driven by hard-wired perceptual and cognitive constraints. These include psychophysical limits, such as the range of perceivable frequencies, which precludes the appreciation of melodies composed with extremely high or low pitches, as well as constraints on memory. Not surprisingly, listeners find it easy to remember melodies composed with seven discrete pitches (e.g., the major scale) but difficult to remember melodies composed of 26 discrete pitch categories (as might occur in microtonal tuning). They also find it easiest to track rhythms that consist of durational contrasts that form small integer ratios (Clarke, 1999). Lerdahl (1988) proposed that qualities such as memorability and simplicity are fundamental requirements for music to be understood and appreciated. For the most part, such cognitive constraints exert an unconscious influence on composers and listeners, but composers can work consciously against such constraints in an attempt to break new ground, and listeners in search of innovative forms may actively seek out music that challenges their musical expectations.

Huron (2001a) identified several basic principles of auditory perception that are culturally encoded in the traditional pedagogy for composing with

multiple voices, known as the *rules of voice-leading*. Dating back hundreds of years and commonly taught today, these rules describe the arrangement of individual voices (e.g., soprano, alto, tenor, and bass) with respect to other voices sounding simultaneously (harmony). They include guidelines for optimal movement between successive tones within a single voice (melody), and for optimal *concurrent* motion in voices that are occurring simultaneously (counterpoint). In general, adherence to the rules of voice-leading promotes the perceptual independence of each voice. Composers such as Palestrina in the Renaissance period and J. S. Bach in the Baroque period, whose works stress differences between voices (polyphony), are remarkably consistent in their adherence to the rules of voice-leading. In contrast, for homophonic traditions such as barbershop quartet, which stress the harmonic blending of multiple voices, voice-leading rules may be deliberately disregarded.

Three selected examples illustrate the type of connections identified by Huron. First, both the dictates of harmonic writing and the distribution of pitches found in Western and non-Western music correspond to the region of frequencies associated with highest pitch *clarity*, also called the dominant pitch region (extending from F2 to C5 and centered at 300 Hz, which is approximately two semitones above middle C). This correspondence implies a tacit goal of using tones with a clear sense of pitch. Second, voice-leading rules that encourage stepwise melodic motion to a neighboring scale tone (e.g., from *mi* to *re*) reflect the mechanisms of auditory scene analysis that connect acoustic events over time into a single perceptual stream. A sequence of discrete tones varying in pitch is more likely to be perceived as a coherent whole or stream when the pitch interval between successive tones is small. Conversely, pitches that are distant from each other tend to be perceptually segregated into separate streams. Thus, to ensure the perceptual independence of voices, the pitches of successive tones within a single voice must be more proximate than the pitches of successive tones between voices. Otherwise, confusions in voice attribution may occur, particularly if voices “cross” in pitch register; a voice-leading practice that, not surprisingly, is discouraged.

Third, the spacing of tones between voices sounding simultaneously is influenced by *harmonicity*. Frequencies that fall along the harmonic series (unison, octave, perfect fifth, etc.) tend to be perceptually fused, giving rise to a single pitch sensation.

Huron (1991) found that in the polyphonic writing of Bach, these intervals are actually avoided between voices in direct proportion to the strength with which each interval promotes tonal fusion. That is, even though such intervals are consonant, they are avoided when the goal of polyphonic writing is to emphasize the independence of different voices. Tonal fusion is also promoted by positively correlated pitch motion between voices. Voice-leading rules, in turn, encourage the use of *contrary* melodic motion among voices where possible, and they discourage similar movement among voices especially if those voices are separated by a consonant interval. Indeed, parallel movement of unisons, octaves, and fifths is strictly discouraged. In short, when a composer wants the different voices of a polyphonic composition to make independent contributions to the overall musical texture, detailed steps are taken to avoid the perceptual process of tonal fusion.

Conclusions

Figure 39.1 illustrates an overview of some of the processes that underlie the acts of listening to and making music. Processes that operate automatically are differentiated from processes that rely on working memory and executive function. The two types of processes operate simultaneously. However, whereas automatic processes operate continuously, those that rely on working memory and executive function are coupled with the musical structure and influenced by the salience of unfolding events. Metric stress provides a source of salience that operates cyclically; other attributes of music (e.g., harmonically important events) also affect salience and,

hence, the amount of attention allocated. The time-varying allocation of attentional energy that arises from meter and other sources of salience is known as *rhythmic attention*.

This waxing and waning of attention accompanies many automatic processes that operate continuously and without conscious control. For example, listeners automatically internalize regularities in music, such as the frequency of occurrence of pitches (Saffran et al., 1999). In Western and non-Western music, the frequency of occurrence of pitches is correlated with the relative prominence of that pitch within a key, with the most prominent or stable tone occurring more frequently than other pitches. Composers do not consciously manipulate the frequency of occurrence of pitches. Rather, composition in Western tonal music is characterized by a set of rules for moving toward and away from the tonic. Only listeners with formal music training are aware of these rules but all listeners acquire implicit knowledge of tonality through an automatic process of statistical learning.

Listeners also respond emotionally to music using both implicit and explicit processes. Listeners automatically decode acoustic attributes associated with emotional responses, such as increases in loudness (as in a crescendo), rapid tempo, and high pitch (Ilie & Thompson, 2006, 2011). Automatic decoding of acoustic attributes is manifested in emotional interpretations of music, and it can also lead to changes in mood and arousal states. At the same time, music may trigger conscious associations: with a difficult period in one's life, a cherished memory, or an imaginary event such as an arduous journey. Such

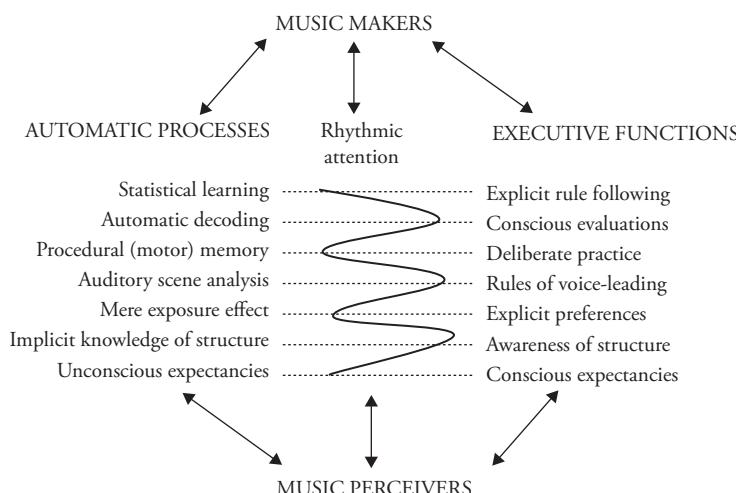

Fig. 39.1 A framework for understanding the automatic and explicit processes involved in musical thought.

associations are often part of conscious awareness and can significantly affect evaluations and experiences of music.

Such experiences are powerful, and many individuals pursue them through the craft of musicianship. After years of deliberate practice—practice that is initially effortful and consciously goal directed—elite musicians eventually encode the technical skills required for a music performance in *procedural* (motor) memory. Once encoded, performances are guided by procedural memory with little need for conscious monitoring of each motor action. The use of procedural memory to assist music performance frees up cognitive resources that can then be applied to other aspects of musical behavior, such as refining one's expressive performance or monitoring listeners' responses.

Others seek out musical experiences through the art of composition. Students of composition are initially taught *rules of voice-leading* and their compositions are initially crafted using explicit knowledge of these rules. Underlying these rules are unconscious perceptual processes that function to analyze the acoustic environment (Huron, 2001a). As musicians develop their expertise at composition, their application of the rules of voice-leading itself becomes automatized, a form of procedural memory.

Most listeners are conscious of their musical preferences, but not for how these preferences arise. Preferences can emerge automatically following passive exposure to music, reflecting implicit memory for music (the *mere exposure effect*). They may also arise through explicit routes, however, such as direct peer influence or validation of one's sense of identity.

Passive exposure to music not only leads to musical preferences; it enables listeners to build sophisticated internal representations of melodic, harmonic, tonal, and rhythmic structure. For example, the brain reliably registers subtle violations to harmony even in listeners with no musical training (reflected in EEG recordings as an early right anterior negativity or ERAN). With training, musicians acquire explicit knowledge of this structure that they can label, analyze, and critique. They may even experience musical events in terms of explicit labels such as “perfect fourth” or “dominant seventh” and their awareness of structure can affect their aesthetic experiences of music.

Knowledge of musical structure, whether implicit or explicit, provides a basis for anticipating events. Music that is conventional can be readily anticipated; music that is unconventional may violate

our expectations. Expectations provide a powerful source of emotion because they are basic to human behavior. When expectations are fulfilled, we feel a sense of stability and reward; when expectations are thwarted, we feel a sense of instability and surprise. Music makers consciously and unconsciously manipulate the expectations of listeners, creating complex and dynamic aesthetic and emotional effects as music unfolds. In most cases, listeners are unaware that violations and fulfillments of expectations are taking place, but they are usually well aware of the emotional effects of the music.

Music makers and perceivers share most of the processes that support musical thought, in spite of differences in overt behavior and expertise. In this context, it is worth noting that the distinction between listeners and musicians is a relatively recent phenomenon, promoted by the rise of the concert hall in the 19th century and escalated by the invention of the gramophone and phonograph—technologies that enabled a physical separation between music makers and music consumers. Prior to such technologies, musical behavior was mostly a group activity with no clear separation between music makers and listeners. Research into the mirror neuron system further supports a connection between musicians and listeners, in that the same neural centers may be active when perceiving or executing an action (Rizzolatti & Craighero, 2004). In particular, musical signals that arise through the actions of performers may be transformed into motor representations by perceivers (Colling & Thompson, in press; Overy & Molnar-Szakacs, 2009; Thompson & Quinto, 2011). Musically trained listeners may form detailed motor representations of these signals, but untrained listeners may also exhibit a motor response. In the absence of specialized knowledge of music production, untrained listeners can still tap to music, dance to music, perform “air guitar,” or otherwise synchronize with the music, reestablishing the shared experience between music makers and perceivers that has characterized musical behavior for much of human history.

Future Directions

The recent surge of interest in selected issues will undoubtedly lead to significant advances in the study of music and thought. First, there has been a renewed interest in evolutionary perspectives on music, following a neo-Darwinian movement across numerous disciplines (Vitouch & Ladinig, 2009; Wallin, Merker, & Brown, 2000). Adaptationist

arguments hold that the mind is specifically shaped by evolution to support musical behavior. They include the hypothesis that music originated as a sexually selected trait, like birdsong (Darwin, 2006; Miller, 2000), or from lullabies that promoted parent–infant bonds, which were crucial for infant survival (Dissanayake, 2008; Falk, 2004), or as a means of promoting group bonding and cooperation, which was essential for survival for early hominids (Huron, 2001b). Nonadaptationist accounts suggest that musical behavior is an evolutionary byproduct—a human “invention” that draws upon existing brain functions but has no survival or reproductive function in itself (Pinker, 1997). However, because musical activities can lead to various benefits for individuals during their lifetime (e.g., social bonds, cognitive benefits, parent–infant bonds, mood regulation), it has been characterized as a “transformative technology of the mind” (Patel, 2010).

A second area of renewed interest is the connection between music and emotions, which draws on data in psychology and neuroscience on the role of emotion in memory, reasoning, and problem solving (for a review, see chapters in Juslin & Sloboda, 2009). Music has a powerful capacity to communicate and induce emotions (Huron, 2006; Juslin & Västfjäll, 2008), and it appears to draw from emotional signals that are evident in speech prosody or “tone of voice” (Ilie & Thompson, 2006, 2011; Juslin & Laukka, 2003).

Finally, there has been intense scientific interest in the neuroscience of music following the rapid advances in neuroimaging techniques and other methods of understanding the brain (Patel, 2008; Peretz & Coltheart, 2003; Peretz & Zatorre, 2005). It was once believed that music was primarily the domain of the right hemisphere (Joseph, 1988). We now know that musical behaviors engage a wide range of activity across both hemispheres, and that training in music can promote structural enhancements and greater brain plasticity (Schlaug, 2001; Wan & Schlaug, 2010). Such findings highlight the enormous potential for music to be used as treatment or intervention for neurological and developmental disorders, or for cognitive impairments associated with normal aging.

Learning to Think: Cognitive Mechanisms of Knowledge Transfer

Kenneth R. Koedinger and Ido Roll

Abstract

Learning to think is about transfer. The scope of transfer is essentially a knowledge representation question. Experiences during learning can lead to alternative latent representations of the acquired knowledge, not all of which are equally useful. Productive learning facilitates a general representation that yields accurate behavior in a large variety of new situations, thus enabling transfer. This chapter explores two hypotheses. First, learning to think happens in pieces and these pieces, or knowledge components, are the basis of a mechanistic explanation of transfer. This hypothesis yields an instructional engineering prescription: that scientific methods of cognitive task analysis can be used to discover these knowledge components, and the resulting cognitive models can be used to redesign instruction so as to foster better transfer. The second hypothesis is that symbolic languages act as agents of transfer by focusing learning on abstract knowledge components that can enhance thinking across a wide variety of situations. The language of algebra is a prime example and we use it to illustrate (1) that cognitive task analysis can reveal knowledge components hidden to educators; (2) that such components may be acquired, like first language grammar rules, implicitly through practice; (3) that these components may be “big ideas” not in their complexity but in terms of their usefulness as they produce transfer across contexts; and (4) that domain-specific knowledge analysis is critical to effective application of domain-general instructional strategies.

Key Words: computational modeling, language and math learning, educational technology, transfer, cognitive tutors, cognitive task analysis, *in vivo* experiments

“Learning to think” is different from “learning” in that it implies that a learner achieves an increase in more general intellectual capability, rather than just in more specific domain content. Learning to think implies more than learning English, learning math, learning history, or learning science. In other words, learning to think implies transfer (Barnett & Ceci, 2002; Gick & Holyoak, 1983; Singley & Anderson, 1989). Is it possible to “learn to think”; that is, is general transfer possible? A simple “yes or no” answer is not to be expected. A substantial amount of transfer can be achieved, especially with scientifically designed instruction, but full general

transfer is a tempting dream, not a practical reality. It is not possible to teach children how to be generally intelligent, experts in all domains, without specific instruction in some domains. But dreams can help inspire action, and the action we need is research and development to understand human learning capacities and constraints and to design and evaluate instruction that achieves *as-general-as-possible* transfer. Progress is required not only in domain-general cognitive and learning science but also in domain-specific analysis of the content domains across and within which we hope to see general transfer.

Components of Learning to Think and How Symbolic Languages Help

One way to learn to think is learning languages with which to think more powerfully. The obvious case is learning a natural language, like English. It seems uncontroversial that a good part of what makes human thinking so powerful is our capability for language (cf. Tomasello, 2000; see Gleitman & Papafragou, Chapter 28). The spoken form of natural language not only facilitates communication and collaborative thinking but also provides a medium for reasoning and logical thinking (Polk & Newell, 1995). The written form further facilitates collaborative endeavors over wide stretches of time and space and is also arguably a vehicle for improving thought. Anyone who has written a manuscript, like this one, is likely to have had the experience that the writing process changes one's thinking and yields a better product than spontaneous speech would have. Clearly, language-learning activities are a huge part of learning to think and a major responsibility of our educational systems.

But natural languages like English are not the only languages we use to enhance our thinking. By "language," in a more general sense, we mean a culturally transmitted symbolic system including any commonly used form of external representation. Examples include symbolic algebra and other mathematical notation systems (e.g., calculus notation, probability and statistics notation), Cartesian graphing and other scientific visualization techniques, and computer programming languages, including the huge and growing number of end-user programming languages (e.g., functions in Excel or html). We create external symbols (including pictures and diagrams; see Hegarty & Stull, Chapter 31) to make abstract ideas more available to our brains' powerful perceptual processing and learning mechanisms (e.g., Goldstone, Landy, & Son, 2010; Koedinger & Anderson, 1990). These forms make the abstract concrete and leverage thinking by allowing easier processing of the abstract ideas (e.g., Larkin & Simon, 1987).

In this chapter we explore two themes. The first theme is the idea that external symbol systems (languages in the broad sense) greatly enhance the power of our thinking and learning. They organize the changes internal to the mind that are necessary to implement learning and transfer (cf. Goldstone et al., 2010; Novick, 1990).

The second theme is that learning grows in "pieces" and thinking involves using those pieces in

new combinations. The amazing flexibility humans can exhibit in thinking and learning would not be possible if it were not for their extendable and reusable base of knowledge. Many pieces of knowledge have analogs or near analogs in external symbol systems, such as knowledge of English letters and words, but many do not. Such "knowledge components" (Koedinger, Corbett, & Perfetti, 2010) can include categories for which there is no word (e.g., a category of objects my 2-year-old calls "phones" but which includes remote controls and small blocks of wood). They can be "pragmatic reasoning schemas" (Cheng & Holyoak, 1985; see Evans, Chapter 8) that support correct reasoning about certain kinds of social rules, but not about abstract logical rules. They can be the "intuitions," heuristics, or abstract plans that guide our search, decision making, and discoveries. They can be metacognitive or learning strategies, like knowing to try to "self-explain" a worked example (Chi, Bassok, Lewis, Reimann, & Glaser, 1989) or to cover up one's notes and try to recall what's there while studying (cf. Pashler et al., 2007).

This knowledge component view is supported by researchers who have done detailed cognitive analysis of complex real-world learning domains, such as learning physics (diSessa, 1993; Minstrell, 2001; VanLehn, 1999), mathematics (Koedinger & Corbett, 2006), legal argumentation (Aleven, 2006), or programming (e.g., Pirolli & Anderson, 1985). The view is also supported by attempts to create large-scale computational models of complex human reasoning and problem solving (e.g., Anderson & Lebiere, 1998; Newell, 1990). With respect to transfer, this view echoes the classic "identical elements" conception of transfer (Thorndike & Woodworth, 1901) but is enhanced by advances in cognitive theory and computational modeling (cf. Singley & Anderson, 1989). The identical elements, or units of transfer, are no longer stimulus-response links but are latent representations of components of tasks or their underlying structure. It is not sufficient to provide behavioral task (stimulus-response) descriptions of such elements; rather, we need a language of abstraction for specifying cognitive representations that will often generalize over, or be applicable across, many situations. In computational modeling terms, there need to be "variables" (or some functional equivalent) in the formalism or language used (by cognitive scientists) to represent general cognitive elements (see Doumas & Hummel, Chapter 5).

In this chapter, we begin by elaborating the knowledge component view on transfer. We then provide examples of identifying and modeling knowledge components in algebra and show how these models can be tested in classroom studies. These studies have also identified the missing components—missing both in terms of students lacking the relevant knowledge, as well as cognitive scientists overlooking these pieces in their puzzle of the domain. We then argue that these missing components are intimately tied with the symbolic forms of the language itself. Next, we demonstrate how supporting language acquisition helps students achieve better transfer. Last, we discuss various aspects of applying laboratory-derived instructional principles in the classroom, and we review methods for knowledge component (or cognitive model) discovery from data. The conclusion raises open questions about the insufficiently understood interplay between language-mediated and non-language-mediated processes in transfer and learning to think.

Knowledge Components as Carriers of Transfer

Questions of transfer of learning have been addressed by a number of contemporary cognitive scientists (e.g., Barnett & Ceci, 2002; Singley & Anderson, 1989; see Bassok and Novick, Chapter 21). Much discussion has been around issues of what is “far” transfer, how much transfer instructional improvements can achieve, and what kind of instruction does so. A key observation is that when transfer occurs some change in the mind of the student is carrying that transfer from the instructional setting to the transfer setting. It might be a new skill, a general schema, a new mental model, better metacognition (see McGillivray et al., Chapter 33), better learning strategies, a change in epistemological stance, new motivation or disposition toward learning, or a change in self-beliefs about learning or social roles.¹ In the Knowledge-Learning-Instruction (KLI) Framework, Koedinger et al. (2010) use the term “knowledge component” to include all these possible variations and provide a taxonomy of kinds of knowledge components. Knowledge components are the carriers of transfer.

To better understand how knowledge components act as agents of transfer, one should identify the breadth or scope of applicability of those knowledge components in tasks, problems, or situations of interest. In other words, in how many different kinds of situations does the acquired knowledge

apply, and what are its boundaries? Understanding the answer to this question allows us to design instruction that better supports transfer. For example, instruction on computer programming might yield knowledge that applies (*a*) only to programming tasks that are quite similar to those used in instruction, (*b*) to any programming task involving the same programming language, (*c*) to programming in other languages (e.g., Singley & Anderson, 1989), or (*d*) to reasoning tasks outside of programming, like trouble-shooting or “debugging” a set of directions (e.g., Klahr & Carver, 1988).²

These two questions suggest a scientific path toward achieving more general transfer or learning to think. A key step along that path is identifying those knowledge components that are as broad or as general as possible in their scope of application. Take, for example, the algebraic task of combining like terms (e.g., $3x + 4x$). Students may learn this skill as a mental equivalent of something like “combine each number before each x.” This encoding produces correct results in some situations, but not all. It is overly specific in that it does not apply to the cases like $x + 5x$ where the coefficient of x (1) is not visually apparent. It might also yield $-3x + 4x$ as $-7x$, if the mental skill encodes “number before” too specifically as a positive number rather than more generally as a signed number (e.g., Li et al., 2010). Acquired knowledge may also produce incorrect responses by being overly general. For example, if students have encoded “number before each x” too generally, they may convert $3(x + 2) + 4x$ to $7x + 2$.

Big Ideas and Useful Ideas

In the search for transfer-enabling knowledge components, special attention has been given to the notion of “big ideas,” which has been a rallying cry in much educational reform, particularly in mathematics. It is worth reflecting on what the “big” in big idea means. It is often used in contrast with facts, procedures, or skills and associated with concepts, conceptual structures, or mental models. For instance, Schoenfeld (2007, p. 548) makes a contrast between “long lists of skills” and “big ideas,” and Papert (2000, p. 721) characterizes school as “a bias against ideas in favor of skills and facts.”

A particularly tempting example of this is the general problem-solving strategies of the sort mathematician George Polya (1957) identified in his reflections on his own mathematics thinking and teaching. Experimental efforts to investigate the effect of instruction designed to teach such general

problem-solving strategies have met with limited success. Post and Brennan (1976), for instance, found no improvement from teaching general problem-solving heuristics such as “determine what is given” and “check your results.” Schoenfeld (1985) developed more specific versions of Polya’s heuristics, and Singley and Anderson’s (1989, p. 231) analysis of that study suggests an important reason for caution in pursuing the “big idea” approach. They noted that Schoenfeld’s heuristics that led to transfer were ones that indicated when the heuristic should be applied, such as “If there is an integer parameter, look for an inductive argument.” Other heuristics, such as “Draw a diagram if at all possible,” did not indicate conditions of applicability and did not lead to transfer. Students can learn such heuristics, in the sense that they can repeat them back, but they do not get any use out of them because it is not clear when they apply. So a first caution is that sometimes an apparently as-general-as-possible knowledge component may not lead to broad transfer because it is *too vague to be useful*.

Just because a student knows general strategies for working backward, or problem decomposition, does not mean that he or she can successfully execute those strategies in a specific context. Haverty, Koedinger, Klahr, and Alibali (2000) provide an informative example. They investigated college students’ ability to induce functions, like $y = x^*(x - 1)/2$, from tables of x-y pairs, like {(2, 1) (3, 3) (4, 6) (5, 10)}. They found that all students engaged in working backward by performing operations on the y values, such as dividing each by the corresponding x value to produce {.5 1 3/2 2}. However, those who succeeded were differentiated from those that did not by recognizing that this pattern is linear (increasing by $\frac{1}{2}$). In other words, it was specific fluency in number sense that distinguished students, not general problem-solving skills that all students manifest. Thus, a second caution regarding the search for big ideas to yield far transfer is that many general concepts or strategies require the learner to obtain domain-specific knowledge in order to apply those general strategies effectively.

A third caution is that some general problem-solving or critical-thinking skills may be relatively easy to learn, in the sense that they are generally acquired without any formal schooling. Lehrer, Guckenber, and Sancilio (1988) taught third graders a general “problem decomposition heuristic” as part of an intensive 12-week curriculum surrounding the LOGO programming language. Although

they found evidence of transfer of some big ideas, they found no evidence of improvement in general problem decomposition as measured by puzzle tasks. It may be that many children acquire the relevant problem decomposition skills through prior experiences. Another example can be found in the self-explanation literature. One consistent and surprising result is that merely prompting students to self-explain improves learning, even without teaching students how to self-explain productively (Chi et al., 1989; Siegler, 2002). While improving the dispositions toward self-explanation is an important goal, it seems that the skill of knowing how to self-explain does not need much support.

The temptation to seek really big ideas is strong and these cautions are nuanced. Statements like the following are indicative: A recent National Academy of Education paper (2009) called for better assessment of “skills such as adapting one’s knowledge to answer new and unfamiliar questions.” This statement and the surrounding text, which is a call for assessments to measure “higher order, problem-solving skills,” implies that there is a general skill of “adapting one’s knowledge” that can be acquired, measured, and applied generally. It is quite unlikely, however, that there is a single, general skill of adapting knowledge. Adapting one’s knowledge is not a single skill, but, more likely, a complex set of skills that have domain-specific ties—some adaptations come easily, when the domain knowledge is in place, and others do not. There *may* be general skills that students can acquire for better adapting knowledge, but until we have identified assessments that can measure them, we should not assume that they exist.

The search for big ideas assumes that some ideas are sophisticated enough to be applied across a wide range of domains and tasks. But focusing on the complexity or sophistication of the idea itself is not sufficient if we are aiming for more effective transfer and learning to think. The issue is not the size of the idea itself, but rather the size of what the idea opens up for a learner. More precisely, it is about the size of the productive *reuse* of the idea. Some sophisticated concepts indeed get a lot of reuse, but so do some simpler facts, associations, or procedural knowledge components. For instance, knowing the phoneme associated with the letter “s” is not big in the sense of the idea being big—this fact is a small and simple one. However, it is big in the sense of its reuse. As children acquire it and the 36 or so phonemes associated with the 26 letters,³ a whole new world opens

up for them. They can use and reuse this relatively small set of knowledge components to identify (decode and pronounce) a much larger set of words in text. They can thus read words that they have not read before. Many will be words they already know from spoken language and some will be new words, which they can begin to acquire in context. Furthermore, this decoding capability (made possible by this small set of grapheme->phoneme knowledge components) greatly increases the learning capabilities of the child—he or she can now learn by reading in addition to listening, watching, and doing.⁴ Thus, rather than simply search for *big* ideas, we should be searching for *useful* ideas.

Small-big ideas are knowledge components that may be quite specific but are big in the scope of their use—they get reused in many contexts. The notion is similar to Gagné's “vertical transfer” in its emphasis on components that can combine with others to produce broader competency. However, unlike vertical transfer, small-big ideas are not limited to within-domain transfer. Small-big ideas may extend beyond their nominal domain to improve performance or learning in other domains. Phonemes are nominally in the reading domain, but acquisition of them improves learning in history, science, math, and so on—all domains in which reading is part of learning. Similarly, the distributive property is nominally in the algebra domain, but acquisition of it (and the cluster of skills associated with it) supports performance and learning in physics, chemistry, engineering, statistics, computer science, and so on—in the STEM disciplines generally.

Testing Knowledge Component Models in Instructional Contexts

Beginning in the 1980s, John Anderson and colleagues have put the series of ACT theories of cognition (e.g., Anderson, 1983) to test through the development of a brand of intelligent tutoring systems, called Cognitive Tutors (Anderson, Corbett, Koedinger, & Pelletier, 1995). Since then the work has greatly expanded in its dissemination—over 500,000 students a year use the Cognitive Tutor Algebra course (e.g., Ritter, Anderson, Koedinger, & Corbett, 2007)—and in its scope—Cognitive Tutors and variations thereof have been created for a wide variety of content, including intercultural competence (Ogan, Aleven, & Jones, 2010), statistics (Lovett, Meyer, & Thille, 2008), chemistry (Yaron et al., 2010), and genetics (Corbett, Kauffman, MacLaren, Wagner, & Jones, 2010). Many large-scale evaluations of these

courses have demonstrated their effectiveness (Ritter, Kulikowich, Lei, McGuire, & Morgan, 2007). More important for this chapter, tutoring systems (and online courses more generally) have become platforms for advancing research on thinking and learning in the field and in the context of substantial knowledge-based academic content. This makes it possible to test and advance theories of learning that may be overgeneralized or otherwise inaccurate given their origins in laboratory settings and typically knowledge-lean content. Such technology allows us to carry out well-controlled studies in the classroom environment and to collect detailed moment-by-moment data. Many of the research findings of such research can be found in the open research wiki of the Pittsburgh Science of Learning Center at <http://www.learnlab.org/research/wiki>.

A key tenet of the ACT-R theory is that human knowledge is modular—it is acquired and employed in relatively small pieces (Anderson & Lebiere, 1998). Although such pieces can be recombined in many different ways, they are not completely abstracted from context. Indeed, a second key tenet is that knowledge is context specific. A procedural form of knowledge (implicit knowledge for doing) is characterized by an if-then production rule notation (see Doumas & Hummel, Chapter 5), whereby the context in which the production applies is specified in the if-part and an associated physical action, subgoal, or knowledge retrieval request is specified in the then-part. Similarly, a declarative form of knowledge (explicit or directly accessible knowledge that can be visualized or verbalized) has retrieval characteristics that depend, in part, on the *context* of other active knowledge (the more that related knowledge is active, the more likely to retrieve the target knowledge).

These tenets lead to two important ideas for instructional design. First, it is possible to create specifically targeted instruction that isolates the learning of a particular knowledge component. Second, it is critical to design instruction so that knowledge components are acquired with appropriate context cues or features so that they generalize or transfer broadly, but accurately. Thus, isolated practice cannot be too decontextualized, otherwise inert or shallow knowledge acquisition may result.

In the process of applying the ACT intelligent tutoring systems to support learning of programming and mathematics, eight principles of instructional design were formulated to be consistent with ACT and with experience in developing, deploying,

and evaluating these systems (Anderson, Corbett, Koedinger, & Pelletier, 1995). One of these principles is that tutor design should be based on a knowledge component analysis of the target domain.⁵ This principle emphasizes the importance of the modular nature of human knowledge and the great value of domain-specific cognitive task analysis for producing effective instruction. Clark et al. (2007) describe a meta-analysis of seven studies comparing existing instruction with redesigned instruction based on a cognitive task analysis, which yielded an average effect size of 1.7 (i.e., students who received the redesigned instruction scored 1.7 standard deviations better on posttests than did students who received normal instruction).

The theory of transfer, as briefly outlined earlier, makes specific predictions about students' learning. For example, one prediction is that knowledge of a specific component can manifest itself in many different contexts. Students who acquire multiplication knowledge (with general and accurate retrieval features) can apply it to different numbers (e.g., $2 \times 3 = ?$; $6 \times 5 = ?$), to more complex symbolic problems (e.g., $2 \times 3 + 5 = ?$), and to problems presented as or emerging in a broader situation (Danny bought two pens for \$3 each). Another useful hypothesis is that performance on each component improves with practice. Cognitive Tutors and paper-based assessments allow us to put these hypotheses and analysis of the domain to test. By analyzing students' behavior on problems that share knowledge components, we can evaluate whether our analysis of knowledge components is accurate.

This idea can be illustrated with a story about algebra story problems. The cognitive science literature includes statements about how students "find word problems...more difficult to solve than problems presented in symbolic format (e.g., algebraic equations)" (Cummins et al., 1988, p. 405). When asked to predict student performance, teachers and educators indicate that algebra story problems are harder for students to solve than matched symbolic equations, since students need to first translate these word problems into symbolic notation (Nathan & Koedinger, 2000).

Koedinger and Nathan (2004) compared students' performance on story problems and matched equations, and discovered that the assumed knowledge component analysis (e.g., that equations are needed to solve story problems) was incorrect. They found that beginning algebra students are actually better able to solve introductory

story and word problems than matched equations. For instance, students were 62% correct on word problems such as, "Starting with some number, if I multiply it by 6 and then add 66, I get 81.9. What number did I start with?" but only 43% were correct on matched equations, such as " $x \times 6 + 66 = 81.90$."

One striking fact regarding these studies is the contrast between beliefs of researchers and educators on the one hand and actual student performance on the other. In this example, students' actual performance is at odds with the predictions of scientists and teachers alike. Koedinger and Nathan's (2004) domain analysis revealed previously unrecognized knowledge demands in acquiring symbolic skills. This analysis pinpoints knowledge components for symbolic language comprehension.

Learning to Think by Learning Languages to Think With

The fact that students are better at solving word problems than solving equations may sound counter to our point that learning symbolic languages, symbolic algebra in this case, facilitates thinking. However, our point is not that being "given" a symbolic language suddenly makes one a better thinker, but that the payoff for *learning* a symbolic language is more powerful thinking. That students are still struggling with the language of algebra many months into a course is surprising to many and, ironically, more so to those who have succeeded in doing so. For instance, high school algebra teachers are more likely to make the wrong prediction (equations are easier) than elementary or middle school teachers (Nathan & Koedinger, 2000). It seems that many successful algebra learners do not have good explicit memory for, and perhaps did not have much explicit awareness of, all the work they did (or their brains did) while learning algebra. This observation is consistent with the hypothesis that much (not all!) of algebra learning is done with little awareness of many of the mental changes that are taking place. Although algebra textbooks and classes include lots of verbal instruction, much of the process of learning appears to occur while students are studying examples and practicing on problems (cf. Matsuda et al., 2008; Zhu & Simon, 1987), and neither examples nor problems contain verbal descriptions of the to-be-learned patterns or rules. Many of the pattern, rule, or schema induction processes that carry out this learning are implicit (see Evans, Chapter 8), that is, are not mediated by (nor

involve the subvocalization of) the verbal rules read in the text or heard in class.⁶

Although our empirical and theoretical support for this claim comes largely from research in the algebra domain, this substantial nonverbal character of learning may extend beyond algebra. That is, much of our learning even in the academic context may be implicit (nonverbally mediated), particularly so in the STEM disciplines where symbolic notations are so common (e.g., chemical symbols, genetics notations, process diagrams). This claim is less surprising when you consider that the human brain has an amazing capability for learning language (without already having language available). Does this capability stop working once we have learned our first language, so that subsequently we only learn through language and through conscious awareness? That seems unlikely. It seems more likely that the ability to learn languages without language continues to operate even after students begin using language-mediated learning strategies. The hypothesis that nonverbal learning mechanisms are critical to learning formal symbolic “languages,” like algebra, is at least worth pursuing.

Learning a symbolic language is hard, not in the sense that it feels hard (though it might), but in the sense that it takes a long time, many months or years, to reach proficiency. Children are acquiring their first spoken language, like English, during the first 4 or 5 years of life. It typically takes a few more years to learn the written form of English, that is, reading and writing. It takes at least a year for most students to (begin to) learn algebra, and most only become fluent as they continue to use (and improve) their algebra skills in downstream STEM courses, such as Algebra II, Calculus, Chemistry, Physics, Statistics, and Programming.

Through work on Cognitive Tutor math projects, it became increasingly apparent to the first author that students’ struggles were as or more often with the specifics of the math content than with general strategies for employing it effectively in problem solving. Some targeted instruction on strategies for general problem solving may be effective, but a major challenge for students is learning specific symbolic material (e.g., vocabulary, notational tools, principles) and specific symbolic processing machinery (interpretive procedures) to fuel those general problem-solving strategies.

The Koedinger and McLaughlin (2010) study summarized later in this chapter provides evidence of grammar learning being important to progress

in algebra. Computational modeling by Li, Cohen, and Koedinger (2010) indicates that probabilistic grammar learning mechanisms are not only capable of acquiring key aspects of algebra but appear to provide a candidate answer to a mystery in expertise development. Such mechanisms provide an explanation for how learners achieve representational (or “conceptual”) changes along the path from novice to expert, accounting not only for their improved performance (accuracy and speed) but also for acquisition of deep features (e.g., Chi, Feltovich, & Glaser, 1981) and perceptual chunks (e.g., Gobet, 2005; Koedinger & Anderson, 1990). Similar learning mechanisms (Bannard, Lieven, & Tomasello, 2009) have been demonstrated to characterize children’s language acquisition.

Non-language-mediated learning mechanisms may also be a key part of learning in other STEM domains, which involve specialized symbol systems (e.g., chemistry equations, physics principles, genetics notations) and associated semantics, new vocabulary, and problem-solving processes. These *physical symbol systems*⁷ allow our powerful perceptual pattern-finding and structure-inducing learning mechanisms to operate in new abstract worlds that are designed as *visible* metaphors of hidden scientific phenomenon. Learning to see complex scientific ideas in symbolic forms allows experts to off-load long chains of abstract reasoning into physical space (on paper or computer screens). Such chains of reasoning are difficult to do in one’s head, without the external memory and perceptual processing support of symbol systems (cf. Goldstone et al., 2010). Experts are certainly capable of chains of mental reasoning without external symbolic support. This reasoning may often be done through subvocalization or subvisualization (in our “mind’s eye”), whereby (with experience) we can simulate in our minds what we might have previously done with the external support of a symbolic language (cf. Stigler, 1984).

Improving Transfer With Domain-General and Domain-Specific Approaches

So far we have focused on the role of *domain-specific* symbols and modular knowledge acquisition in facilitating transfer. However, differences in *domain-general* instructional and learning strategies (e.g., spacing practice, comparison, self-explanation) also influence transfer (cf., Koedinger et al., 2010; Pashler et al., 2007). Can such strategies be effectively and straightforwardly applied across domains?

We first illustrate how applying domain-general instructional strategies necessitates addressing the domain-specific question of what are the as-general-as-possible knowledge components. Next, we illustrate how the nature of knowledge components in a domain may change regardless of whether one instructional strategy produces more learning and transfer than another.

Finding the Right Level of Generality to Apply an Instructional Strategy

Consider the Gick and Holyoak (1983) studies that compared the effects on an analogical transfer task of different instructional strategies (see Holyoak, Chapter 13). The domain involves “convergence” tasks whereby a story lays out a problem (e.g., about the need for radiation treatment of high intensity that reaches a brain area, but without damaging the skull and tissue surrounding it), to which the solution involves a dividing of forces along multiple paths that then converge together on a target. Gick and Hoyer found that the best transfer was achieved by instruction that asked students to compare two examples (or analogs) of a general solution schema in the context of a symbolic abstraction (a diagram) representing the general solution schema. Other studies have also demonstrated the effectiveness of prompting for example comparisons (Gentner et al., 2009; Rittle-Johnson & Star, 2009), or for providing an abstraction of a general rule, pattern, or theory behind solutions (e.g., Judd, 1908; Holland, Holyoak, Nisbett, & Thagard, 1986).

How might we best map laboratory results like these onto educational practice? One challenge is determining the general schema that is the target of instruction or, to put it in more concrete terms, the scope of tasks, examples, or analogs from which to draw for use in instruction and in assessing transfer. It is necessary to have a clear definition of the target knowledge, or, in other words, the as-general-as-possible knowledge components.

Consider the goal of applying these results to the teaching of algebra symbolization, that is, translating story problems to algebraic expressions.⁸ Figure 40.1 illustrates the potential complexity of this question (data from Koedinger & McLaughlin, 2010). Is there a general schema that covers all algebra problems (or even broader, covering all math problems or all problems including convergence problems)? Or is the schema something more narrow, like all problems whose solution is a linear expression of the

form $mx + b$? Gick and Holyoak (1983) observed that the level of similarity or dissimilarity of the analogs may play an important role in how much learning and transfer occurs. Analogs with higher similarity have the advantage that students may be more likely to make a reasonable mapping between them and induce a general schema. They have the disadvantage that the schema that is induced may not be as general as it could be.

Here are two symbolization problems that are quite close analogs:

1) Sue is a plumber and gets \$30 for showing up to a job plus \$60 per hour she works. Write an expression for how much Sue makes if she works for x hours. Answer: $60x + 30$

2) Rob is an electrician. He gets paid \$50 per hour and also gets \$35 for every job. Write an expression for how much Rob makes if he works for h hours on a job. Answer: $50h + 35$

They are both in the form $Mx + N$, where M and N are small positive integers. They have some different features, including the different numbers (values for M and N) and different cover story features (e.g., “plumber” in one but “electrician” in the other). Analogs that are even closer in similarity are possible, for example, where the cover story is the same, but only the numbers change; or where the cover story changes, but the numbers do not. Analogs that are more dissimilar can also be produced, for example, by changing the type of quantities from money to distances. Structural changes are also possible, for example, introducing problems of the $Mx - N$ form (i.e., story problems with solutions like $5x - 10$). Student performance on $Mx + N$ and $Mx - N$ forms is quite similar, which suggests that such variation is not too much—does not cross into the disadvantage side of dissimilarity—and thus transfer between such problems may well be achieved. But what about more dissimilar problems?

Would it be better to include an analog with a negative slope, that is, story problems with a solution like $800 - 40x$ (31% correct)? Might that foster more generalization such that students would be more likely to transfer their learning experience not only to other positive slope problems but also to all problems of the form $mx + b$, where m and b can be positive or negative? Might we go even further to foster even greater generalization and transfer? The generalization hierarchy of problem types (potential general schemas) in Figure 40.1 illustrates

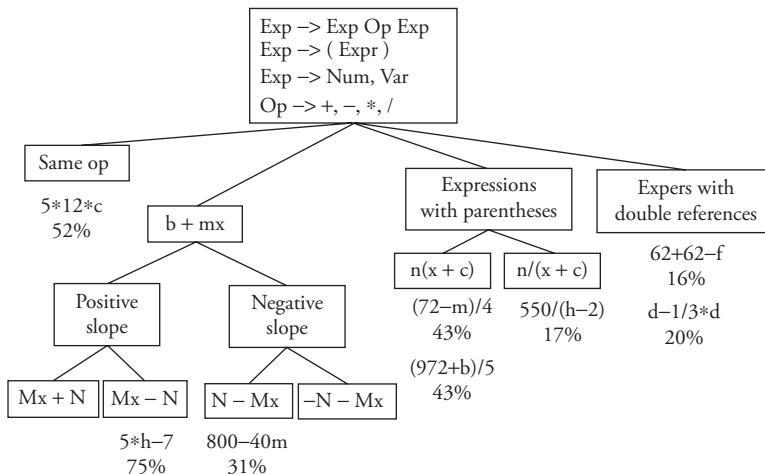

Fig. 40.1 What is (are) the general schema(s) for algebra symbolization? More broadly defined schemas (at the top) increase the potential for transfer, but more narrowly defined schemas (at the bottom) increase the probability that a general schema is induced and some transfer is achieved.

a challenge for instructional designers: Even if the instructional principle is clear and well documented, applying it to a domain of interest is not obvious. As shown next, the challenge is greater in cases where different instructional principles suggest competing paths to learning.

Knowledge-Based Dependencies in Applying Instructional Principles

Two competing instructional principles are *learning by doing* and *learning from worked-out examples*. Learning by doing (e.g., Dewey, 1916) essentially suggests that ideas or skills that we are told or shown do not stick, are not robustly learned, unless we use them. A version of this principle is another one of the Cognitive Tutor principles: Provide instruction in a problem-solving context (Anderson et al., 1995). It is related to the “testing effect” (e.g., Roediger & Karpicke, 2006), in that problem solving requires or “tests” recall in targeted contexts and so strengthens the mental link between context and appropriate action.

However, cognitive load theory (e.g., Sweller, 1988; Van Merriënboer & Sweller, 2005) suggests that premature problem-solving practice (e.g., before enough study of worked examples) produces *extraneous* cognitive load. One unfortunate outcome of intuitive instructional design is that it often introduces activities requiring more cognitive processing than necessary, which distracts students from processes relevant to learning (cf. Clark & Mayer, 2003). Indeed, many studies in science, math, and technical domains have demonstrated the “worked example effect,” whereby replacing many

problems with worked examples enhances learning (see reviews by Renkl & Atkinson, 2010; Pashler et al., 2007). In an apparent contrast with the “testing effect,” the worked example principle implies more study (of examples) and less testing (fewer problems to solve). Both principles reject the extremes of all learn by being told or all learn by doing. However, it is unclear whether the greater student assistance recommended by the worked example principle is actually, or just apparently, contradictory to the greater student challenge recommended by the testing effect.

One possible account of the apparent contradiction focuses on differences in the knowledge content involved in the corresponding instructional experiments. Experiments on the testing effect have targeted specific facts (e.g., in language learning), simpler knowledge components, and the corresponding learning theory emphasizes memory processes. In contrast, experiments on the worked example effect have targeted general schemas (e.g., in math and science learning), more complex knowledge components, and the corresponding learning theory emphasizes the induction of schemas (see Holyoak, Chapter 13). Koedinger et al.’s (2010) KLI Framework provides a principled distinction between simpler and more complex knowledge components. Schema induction may be more optimally supported by increased study of examples before turning to practice (e.g., Gentner et al., 2009; Gick & Holyoak, 1983), whereas fact memory may benefit from a faster transition from study to recall practice. However, as far as we know, no one has attempted to test this content-by-principle

interaction hypothesis, namely, that a higher ratio of study/examples to test/problems is appropriate for more complex knowledge (schema induction), whereas a lower ratio is appropriate for simpler knowledge (fact memory).

Translating general instructional approaches, such as comparison of examples, to real instructional problems may seem relatively straightforward, but this discussion suggests that it requires the answer to what can be a difficult question: What is the target schema that should guide which analogs are selected, how general should it be, and, correspondingly, how much transfer can be achieved? Typically, instructional designers make a decision based on intuition, but a more scientific approach is possible. The next section provides an example of such an approach.

Discovering a Small-Big Idea: Algebra as Language Learning

Koedinger and McLaughlin (2010) performed an experiment targeting the highest level in Figure 40.1. They identified a general schema (or knowledge component) common to all problems in this broad category. Prior empirical cognitive task analysis (Heffernan & Koedinger, 1998) had demonstrated that students' difficulties in translating story problems to algebra were not so much in understanding the English of the story but primarily in producing algebraic expressions. We hypothesized that a general knowledge component that many students were missing was (probably implicit) knowledge of the grammar of algebraic expressions involving more than one operator (see the top box in Fig. 40.1). Such students can accurately produce algebraic expressions of the form "number operator number" (e.g., $800 - y$ or $40x$), but have trouble producing expressions involving a subexpression like "number operator expression" (e.g., $800 - 40x$), that is, learning recursive grammatical patterns. We hypothesized that we could support students in learning of such recursive grammar patterns through exercises isolating the production of two-operator expressions, namely, substitution problems like "Substitute $40x$ for y in $800 - y$." We found that tutored practice on such substitution problems led to greater transfer to performance on translating two-operator stories than did tutored practice on translating one-operator stories (Koedinger & McLaughlin, 2010).

We did not provide any direct instruction on the algebraic grammar, but nevertheless students

improved in their algebraic language production. The transfer observed is consistent with the hypothesis that implicit (non-language-based) symbolic language-learning mechanisms are operative even for algebra students.

While the difference in transfer was statistically reliable, it was not large. The large differences in error rates for problems in Figure 40.1 suggest that learning recursive grammar rules is not be the only challenge for students. Problems whose solutions include parentheses are likely harder than otherwise similar problems. In fact, producing the associated expressions requires new grammar rules. It also appears that additional knowledge is needed to address problems in which a quantity serves in multiple roles, like the " d " in " $d - 1/3d$." These observations about problem difficulty suggest hypotheses for alternative instructional design. Students may benefit, for instance, from more focused instruction on the use of parentheses in algebraic expressions.

The earlier example is illustrative of using student performance data to drive cognitive task analysis, search for as-general-as-possible knowledge components, and correspondingly improve instructional design. The next section describes some strategies for fostering the process of discovering such general knowledge components.

Methods for Discovering As-General-As-Possible Elements of Transfer

We review a number of empirical methodologies for discovering transfer-enabling knowledge components or, in different terms, to perform cognitive task analysis to aid designing effective instruction for transfer. Because so much of learning is not language based and not available to our intuitions, we need techniques that bring theory and data to bear on questions of what constitute ideal instructional objectives, what are the big ideas instruction should target, and how general instructional principles can be best applied in specific content domains to produce transfer.

THINK ALOUD: EMPIRICAL ANALYSIS OF EXPERTS AND NOVICES

Having experts or novices think aloud as they solve tasks in a target domain (Ericsson & Simon, 1984) is a powerful tool for aiding in identifying the knowledge they employ. Chi et al. (1989) used think-aloud methods with physics learners to identify a potential "big-big" idea, *self-explanation*. Designing instruction that prompts students to self-

explain has been demonstrated to greatly enhance student learning in a variety of domains (see recommendation #7 in Pashler et al., 2007). As mentioned earlier, Haverty et al. (2000) performed a think-aloud procedure with students engaged in inductive pattern discovery and were surprised to find that success was differentiated not by big-big ideas like general problem-solving strategies, but by small-big ideas that produce fluency with number patterns.

One too-rarely-employed strategy for identifying as-general-as-possible elements of transfer is to use the think-aloud method on tasks for which experts lack domain-specific knowledge. For example, Schunn and Anderson (1999) asked *social* psychologists to design experiments to address a *cognitive* psychology question so as to isolate domain-general scientific inquiry skills from domain-specific experience.

DIFFICULTY FACTORS ASSESSMENT: EXPERIMENTAL ANALYSIS OF TASK FACTORS THAT REDUCE LEARNERS' PERFORMANCE

Wanting to preserve the value of getting empirical data on student task performance yet reduce the costs of think-aloud data collection and analysis, the first author began a strategy of placing item-based experimental designs into classroom quizzes. We have called this approach Difficulty Factors Assessment (DFA), and the Koedinger and Nathan (2004) story problem data described earlier is an example of this approach. A DFA is a factorial design of matched tasks or problems that vary in a multidimensional matrix of factors, for instance, whether the problem is presented in a story, in words, or in an equation, whether the unknown is in the result ($4 * 25 + 10 = x$) or start ($x * 25 + 10 = 110$) position, or whether the numbers involved are whole numbers or rational numbers. These items are distributed on multiple forms and administered to students as a quiz. We have run DFA studies in many domains, including algebra problem solving, algebra symbolization, negative numbers, fractions, data display interpretation and production, and finding areas (e.g., Heffernan & Koedinger, 1998; Koedinger & Nathan, 2004). Baker, Corbett, and Koedinger (2007) discuss how DFA studies can be used in instructional design. The idea, described earlier, of using algebraic expression substitution exercises to improve transfer in algebra symbolization, was discovered from DFA studies. In general, identifying the task factors that cause students the most

difficulty supports the instructional designer both in focusing their effort on the greatest need, and in testing whether purported forms of instructional assistance actually improve student performance.

EDUCATIONAL DATA MINING: DISCOVERING COGNITIVE MODELS FROM STUDENT PERFORMANCE AND LEARNING DATA

As we have fielded more interactive tutoring systems, they have increasingly become valuable sources of data to understand student learning (Cen, Koedinger, & Junker, 2006; Koedinger et al., 2010). In these tutoring systems, students typically solve a series of problems and the system evaluates student performance on a step-by-step basis such that error rate (did they get that step right on their own on the first try) can be logged for each task (each step in each problem). As with DFA studies, such student error data can be used to develop better cognitive models of the factors of problems or tasks that cause students difficulty. One current disadvantage of using tutor data relative to DFAs is that the set of problems given to students in the former type of study are typically not as systematically designed and administered, with matched sets of problems in a Latin square design, as they are in DFA studies.

However, there are also multiple advantages of tutor data over DFA data. First, fielded tutors allow for much more data to be naturally collected as a part of normal system use, that is, without the need to administer a special-purpose paper-based quiz. Second, student performance is automatically graded. Third, the data are more fine grained: whether the student got each step right, rather than just whether the student got the whole problem right. Even if students show their work on paper, if an error is made on an early step in a problem, the rest of the steps are typically absent or suspect. Tutoring systems, on the other hand, provide data on every step because they give students assistance so that early steps are eventually performed correctly and thus the student can attempt every step on his or her own. The fourth, and most important, advantage of tutoring systems over DFAs is that tutor data are longitudinal, providing an indication of changes in student performance over time. Seeing change in performance over time (sequence data) is of critical importance for understanding transfer.

Let us illustrate this point by contrasting how a question of knowledge decomposition (what are the elements of transfer) can sometimes be better

addressed using sequence data (from tutor log data) rather than factorial design data (from a DFA). The question in the abstract is whether there is transfer between two tasks that have some core similarity, that is, they share a deep structure (or key aspects of a deep structure) but have some significant dissimilarity, which may be either or both substantial (but solution-irrelevant) surface differences or nonshared aspects of the deep structure. Call these tasks “dissimilar analogs.” The knowledge component question concerns the components that are in common in these dissimilar analogs and what components, if any, are specific to each analog.

Consider task A and task B as dissimilar analogs where the average success rate on A is 43% and B is 27%. Table 40.1 shows an example of two such tasks.

One of the simplest knowledge component models to characterize this situation is that the harder task B requires two knowledge components, say K1 and K2, whereas the easier task A, requires just K1. This “overlap” knowledge component model predicts transfer between instruction on one of these tasks and performance on another. This situation is illustrated in Table 40.1 where task A (in the first row) is modeled by a single knowledge component representing algebra grammar knowledge for producing a recursive expression (an expression, like “ $72 - m$,” inside another expression, like “ $(72 - m)/4$ ”). Task B is represented by two knowledge components, one for comprehending English sentences and translating them to math operations, like $72 - m$ and $x/4$, and the other is the overlap, the knowledge for producing a recursive expression.

A competing *nonoverlap* model corresponds to the idea that these dissimilar analogs are not (functionally) analogs at all, but they are different topics and draw on different skills or concepts. Each task involves a separate knowledge component, say Ka for task A and Kb for task B. This model predicts no transfer. How can we use data to determine which is the correct model?

According to the “identical knowledge components” theory of transfer, the overlap knowledge component model predicts that successful instruction (e.g., tutored practice) on task A will improve performance on task B, whereas the nonoverlap knowledge component model predicts no improvement. We can distinguish these models if we have sequence data that provide performance on task B after task A for some students and before task A for others. If performance on task B is better after task A than before it, then the overlap knowledge component model is the better model. For the tasks shown in Table 40.1, students who saw Task B after seeing two substitution problems (isomorphic to Task A) indeed achieved reliably greater success, 38% correct, as compared to 27% for students who had not seen substitution problems.⁹

More generally, computer-collected student performance and learning data have been used to evaluate cognitive models and to select among alternative models (e.g., Anderson, 1993; Ohlsson & Mitrovic, 2007). Automated methods have been developed to search for a best-fitting cognitive model either purely from performance data, collected at a single time (e.g., Falmagne, Koppen, Villano, Doignon, & Johannessen, 1990), or from learning data, collected across multiple times (e.g., Cen et al., 2006).

Table 40.1 Two Dissimilar “Analogs” With Different Problems but Similar Solutions

Problem	Solution	% Correct	Knowledge Components Needed
A Substitute $72 - m$ for d in $d/4$. Write the resulting expression.	$(72 - m)/4$	43%	RecExprProd ^a
B Ann is in a rowboat on a lake. She is 800 yards from the dock. She then rows for m minutes back toward the dock. Ann rows at a speed of 40 yards per minute. Write an expression for Ann’s distance from the dock.	800 – 40x	27%	EngToMathOps ^a + RecExprProd

^aEngToMathOps = English comprehension and translation to math operations, such as $40x$ and $800 - y$. RecExprProd = Recursive expression production, like $800 - 40x$ from $40x$ and $800 - y$.

We should also be alert for decomposition opportunities, where the transfer may not be at the whole problem level (problem schemas), but at the level of intermediate steps (step schemas or knowledge components). The concept of a problem schema, which is emphasized in most studies both in the psychology (e.g., Gentner et al., 2009; Gick & Holyoak, 1983) and educational psychology (e.g., Sweller & Cooper, 1985) literature, mostly ignores the important componential character of the *construction* of human intelligence. Transfer of knowledge to novel situations comes as much or more from the reconfiguration or recombination of smaller pieces of knowledge into new wholes than from the analogical application of larger pieces of knowledge.

Conclusions and Future Directions *Learning With and Without Language*

We have focused on an aspect of learning to think that involves the leverage of symbolic systems or languages to enhance thinking and learning (see Gleitman & Papafragou, Chapter 28). This kind of learning to think is rather indirect because before one can make use of a new language to aid thinking, one must first learn that language. We have construed learning languages broadly to include learning symbolic patterns (syntax, perceptual chunks) and semantic interpretations of those patterns, as is done in many STEM disciplines. A child learning his or her first natural language is the prime example of the fact that the human mind can learn language without knowing any language to support that learning. Let us call the learning processes used in this case *non-language-mediated (NLM) learning*.¹⁰ NLM learning is responsible not only for language acquisition but also for learning of other knowledge components (e.g., How do you know how much salt to put on your food?). Such processes include perceptual learning (e.g., Gobet, 2005), unsupervised statistical learning (e.g., Blum & Mitchell, 1998), and some supervised learning in which the learner imitates or induces from correct examples (Gentner et al., 2009; Hummel & Holyoak, 2003) or gets nonverbal negative feedback from incorrect actions (e.g., Matsuda et al., 2008; VanLehn, 1987).

On the other hand, it seems clear enough, given how much instructors talk, that language is an important part of the academic learning process (cf., Michaels, O'Connor, & Resnick, 2008). Let us call the learning processes used in this case *language-mediated (LM) learning*.

Here are some related questions for future cognitive science research on learning and thinking:

- 1) *NLM learning*: What are the learning mechanisms that humans use to learn a language (at least their first language) without using language? What are the mechanisms behind learning by watching, by doing after watching, or after nonverbal feedback?
- 2) *LM learning*: What are the learning mechanisms that humans use to make use of language in learning other things? What are the mechanisms of learning by listening, by reading, by writing, by doing after verbal explanation, or after verbal feedback?
- 3) *Continued use of NLM learning*: How do NLM learning mechanisms continue to be used by learners after they have acquired the relevant language?
- 4) *Separate or subservient*: Do NLM and LM processes operate independently or do LM learning processes work by calling upon NLM learning processes?

LANGUAGE IMPROVES THINKING

We have evidence for the “language improves thinking” claim in the domain of algebra (Koedinger et al., 2008). We see that students who have learned the language of algebra are much more likely to solve a particular class of complex story problems (which do not absolutely require equations) than students who have not learned the language of algebra.¹¹

Some research has shown that prompting students to think with a symbolic language can enhance learning (Roll, Aleven, & Koedinger, 2009; Schwartz, Martin, & Pfaffman, 2005). In both of these studies, students who were asked to reason using mathematical symbols acquired a more general, transferable representation knowledge than students who were not instructed to use mathematical notations. Other studies have shown that prompting students to explain their reasoning (in English) as they solve problems or study examples helps them acquire deeper understanding of the target knowledge components (Aleven & Koedinger, 2002; Chi, De Leeuw, Chiu, & LaVancher, 1994).

Experimental evidence that language improves thinking has been collected in other domains as well. For example, 3-year-old children given instruction on relational language (e.g., *big*, *little*, *tiny*) make better abstract inferences than children without such symbolic support (Gentner, 2003). Beyond algebra,

others have also argued that human-invented symbol systems, like computer modeling languages, are “literally languages and accordingly offer new cognitive tools” (Goldstone & Wilensky, 2008).

Language-Mediated Versus Non-Language-Mediated Learning, Expert Blind Spot, and Effective Educational Design

A key point of this chapter is that too much instructional design is suboptimal because it is driven by memories of LM learning experiences. It is not driven by memories of NLM learning processes because these processes and the resulting tacit changes in knowledge are hard for learners to reflect upon. In essence, because of NLM learning processes, experts have worked harder and know more than they realize. Indeed, experts often have difficulty describing what they know (e.g., Biederman & Shiffrar, 1987). As illustrated earlier, instructors and educators can have *expert blind spots* whereby their own expertise may lead them to overestimate students’ abilities with the normative problem-solving strategies (e.g., use of algebraic equations). In general, our intuitions about what and how to teach are underinformed. Thus, cognitive task analysis can provide a powerful tool for improving our intuitions and producing more effective instruction (cf. Clark et al., 2007).

More effective educational practice could be achieved through a better understanding of the role of NLM learning in academic learning. The popular (and appropriate) rejection of the “transmission model” of instruction is a step in the right direction. Students usually do not learn simply by being told. Unfortunately, the constructivist alternative (cf., Tobias & Duffy, 2009) is sometimes *misinterpreted* to essentially mean students must teach themselves and instructors need not teach at all! A more sophisticated interpretation suggests that it is the students who should be primarily doing the talking, and the teachers’ role is to get them talking (Michaels, O’Connor, & Resnick, 2008). While there is much merit in this idea, it is driven by intuitions that LM learning is where all the action is. The merits of classroom dialog can be bolstered by a complementary emphasis on the role of NLM learning (example induction and repeated practice with feedback) and its interplay with LM learning.

Knowledge Representation and Transfer

SMALL-BIG IDEAS

The focus on big ideas tends to ignore the importance of *small-big* ideas, that is, *specific* facts,

skills, or concepts that have a very high frequency of reuse. Furthermore, the learning of big-big ideas is often mediated by the learning of external symbols—new ideas are often associated with new vocabulary. For example, new mathematical ideas like the distributive property have concise symbolic descriptions, and learning the syntax of those symbolic descriptions strengthens and may even seed the semantics of the underlying idea. How can we identify the small-big and big-big ideas that are most valuable to pursue toward improving education?

SEARCH FOR APPROPRIATE GRAIN SIZE OF TRANSFER

A related issue is the instructional decision of what level of analog to choose to target. This decision is a nontrivial part of testing the generality of basic cognitive science research in educational contexts. Can we develop empirical and theoretical approaches to identify the ideal level of generality that instructional design should target to best enhance learning and transfer?

DOES UNDERSTANDING (VIA LANGUAGE-MEDIATED LEARNING) OCCUR BEFORE OR AFTER PRACTICE (NON-LANGUAGE-MEDIATED LEARNING)?

Is understanding necessary for transfer, that is, does understanding lead transfer? Or is understanding emergent from transfer, that is, does “understanding follow transfer”? To the extent that much of learning to think is about learning specialized languages, it may be that what it means to “understand” is to develop a “metalanguage” (e.g., words like “term” and “coefficient” in algebra or “conjugation” in second language learning) that one can use to describe and reflect on the language that has been learned, as well as give words and symbols to knowledge components that were acquired via MLM learning mechanisms. This kind of understanding, that is, the development of such metalanguage, may as often be a consequence of NLM learning, rather than a source of it. Here the idea/skill is first acquired in nonverbal form (e.g., students who have learned to remove a “coefficient” in an algebra equation but don’t know the term), and later the student may learn the language to describe what he or she learned. However, other examples suggest the reverse route. For example, asking students to reason with data prior to giving them instruction may facilitate mental representations that support the

subsequent acquisition of procedural competencies (Roll, Aleven, & Koedinger, 2009; 2011; Schwartz & Martin, 2004; Schwartz, Martin, & Pfaffman, 2005).

A Literally Physical Symbol System

Thinking of these pieces of mental function or “knowledge components” as “symbols,” as proposed in Newell and Simon’s (1976) physical symbol system hypothesis, is both helpful and potentially misleading. Cognitive scientists can certainly describe these pieces in symbols, whether we use English or a computational modeling language. However, the cognitive scientist’s symbolic representation of a piece of mental function, like the code that implements a neural network model, is not the mental function itself. Whether the mental pieces *are* symbols we will leave to others (e.g., see Nilsson, 2007). The important claim here is that representing mental pieces or knowledge components in symbolic form, in some language, facilitates thinking on the part of the cognitive scientist or analyst.

Closing

The notion of cultural transmission is suggestive of language, but, while quite powerful, language is not the sole contributor to learning to think. The human brain is built on an animal brain that has perceptually based forms of learning that are effective despite functioning without the use of language (see Penn & Povinelli, Chapter 27). These learning mechanisms, we have argued, are still in use by adult learners with language abilities. It is an interesting and important scientific goal to either disprove this hypothesis or to better identify and understand these NLM learning processes and how they interact with LM learning. Such an endeavor will also have important practical consequences for educational improvement.

Notes

1. That such changes are not directly observable poses a challenge to scientific advance. One way to gain leverage is to create scientific languages to describe these hidden changes, as has been frequently done, for instance, for genes, elements in chemical compounds, or atoms. That is why computational modeling is so important to advance cognitive science and fuel better educational applications.

2. Or, for another example, reading instruction could target learning to decode (sound out) a particular word list (e.g., cat, dog, run, etc.) and the scope of that knowledge, if acquired, might reasonably be reading of those words in the context of

the many sentences in which they might appear. Or, in contrast, reading instruction might use related words (e.g., cat, fat, car, far, etc.) to target particular letter-to-sound mappings (e.g., c, f, a, t, and r), and the scope of that knowledge, if acquired, might reasonably be the reading of the many words that involve those letter-to-sound mappings in the many sentences in which they might appear.

3. Estimates of the number of phonemes vary. See <http://www.spellingsociety.org/journals/j30/number.php#top>.

4. Note that decoding is necessary but not sufficient for comprehension. Good decoders may not be good comprehenders, but bad decoders are bad comprehenders. Furthermore, children have a head start on comprehension through their spoken language experience and decoding opens doors to greater conceptual and vocabulary acquisition that can expand comprehension.

5. The original principle called for a “production rule” analysis, which focuses, in ACT-R terms, on procedural knowledge. We generalize to “knowledge component” analysis (Koedinger, et al., 2010) to include declarative knowledge and to account for declarative as well as procedural transfer (cf., Singley & Anderson, 1989).

6. The point is not that algebra students are unaware of learning algebra in the whole or in the strong sense of implicit learning used, for instance, in paradigms like Reber (1967) grammar tasks. Instead, we mean that there are many details being learned (like the grammar of algebra equations) that are not the result of verbally mediated reasoning. Students have difficulty explaining many of these details and, especially, how they came to know them.

7. We use “physical” here not in the sense of Newell and Simon (1976) of having a physical existence in human minds, but in the more literal sense that the symbols exist, on paper, white boards, computer screens, and so on, in perceptually available spaces.

8. Algebra symbolization is a particularly important area of algebra learning. Today computers can solve algebraic equations and such capabilities are increasingly available even on mobile phones. However, translating the semantics of a problem situation into abstract symbolic form will remain a task for humans for quite a while.

9. This statistically reliable difference ($\chi^2(1, N = 303) = 4.68$, $p = .03$) comes from alternative analysis of data in Koedinger and McLaughlin (2010).

10. Why have we used “non-language-mediated learning” instead of “implicit learning”? Implicit learning is learning that one is not aware of, but it may be possible that one is sometimes aware of the results of NLM learning and thus such learning would not qualify, at least empirically, as implicit learning. It is straightforward to tell when language was not used (by a teacher or in instructional materials) as part of instruction. That’s clearly NLM *instruction*. Pinpointing NLM *learning* is harder as subvocalization and self-explanation may count as LM learning. One form of evidence is when we can create computational models that can learn from examples without being given any verbal instructions and that behaviors of the model match those of human learners (e.g., Matsuda, Lee, Cohen, & Koedinger, 2009).

11. Data from Study 2 in Koedinger et al. (2008) show that when a student correctly solved a complex equation, the student was 82% correct on the matched complex story problem, but when the student failed on the complex equation, he or she was only 44% correct on the matched story problem. That is, symbolic competence enhances reasoning.

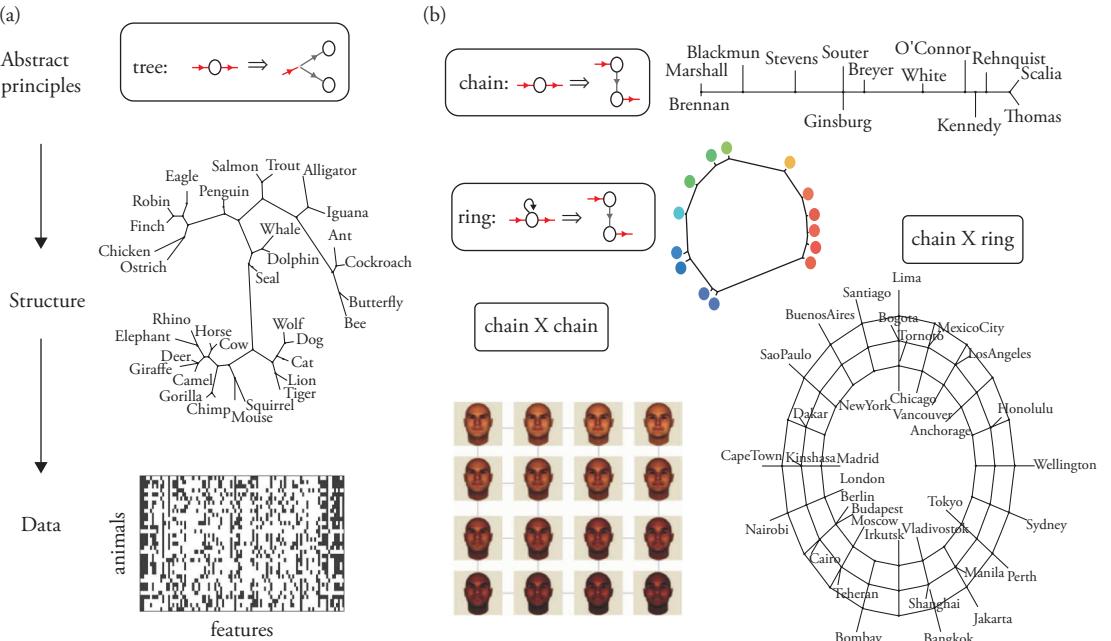

Fig. 3.3 Kemp and Tenenbaum (2008) showed how the form of structure in a domain can be discovered using a hierarchical Bayesian model defined over graph grammars. At the bottom level of the model is a data matrix D of objects and their properties, or similarities between pairs of objects. One level up is a graph describing how properties are distributed over objects. Intuitively, objects nearby in the graph are expected to share properties. At the highest level grammatical rules specify the form of structure in the domain—rules for growing graphs of a constrained form out of an initial seed node. A search algorithm attempts to find the combination of a form grammar F and graph G generated by that grammar which jointly receive highest posterior probability $P(F, G|D)$. (a) Given observations about the features of animals, the algorithm infers that a tree structure best explains the data. The best tree found captures intuitively sensible categories at multiple scales. (b) The same algorithm discovers that the voting patterns of U.S. Supreme Court judges are best explained by a linear “left-right” spectrum, and that subjective similarities among colors are best explained by a circular ring. Given images of faces varying in two dimensions, race and masculinity, the algorithm successfully recovers the underlying two-dimensional grid structure. Given proximities between cities on the globe, the algorithm discovers a cylindrical representation analogous to latitude and longitude.

Multipolymorphic analysis

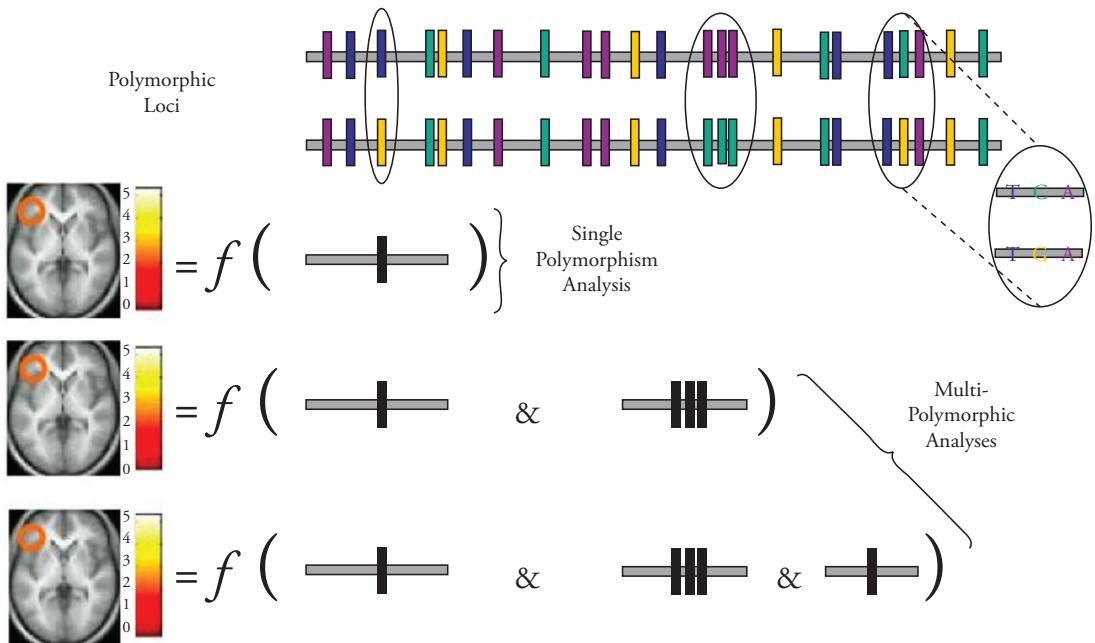

Fig. 7.2 Multipolymorphic analysis. Multiple polymorphic sites in the genome influence a psychological phenotype and its underlying brain activity (brain-based intermediate phenotype). The combined, complexly interactive contributions of these polymorphisms influence neural activity and cognitive function. Most cognitive neurogenetic research to date has focused on variation at individual polymorphisms. These findings are instructive, particularly where only one candidate polymorphism has been implicated by prior findings. However, a growing number of cognitive neurogenetic studies are testing the association of variations at multiple polymorphisms with brain-based intermediate phenotype(s). The figure illustrates a generic multipolymorphic analysis. Polymorphic loci are indicated within two example DNA sequences (where the upper sequence differs from the lower sequence). Brain activity in a region of interest is predicted as a function of one, two, or three of these polymorphisms. Development of multipolymorphic analyses will help construct a better understanding of the complex genetic “networks” that contribute to cognitive brain function and human psychology.

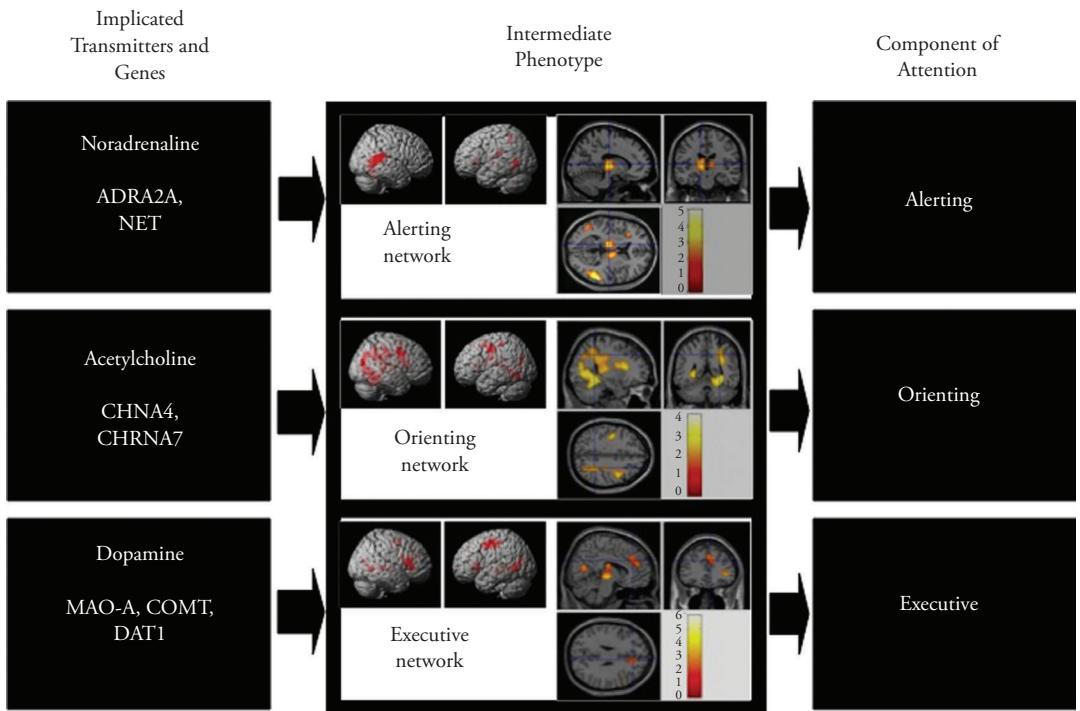

Fig. 7.3 Parsing components of attention in cognitive neurogenetic studies with the Attention Networks Test (ANT). Variations in a set of candidate genes have been correlated with behavioral performance or brain activity for distinct components of attention using the ANT. To generate candidate genes for cognitive neurogenetic studies—in this case for studies on attention—it is important to rely on multiple sources of converging evidence. First, neuroimaging and lesion data pointed to separable neural networks that carry out different aspects of attention. Secondly, pharmacological manipulations demonstrated that noradrenergic modulation can influence the efficiency of the alerting network, while cholinergic modulation and dopaminergic modulation can influence orienting and executive control of attention, respectively. With regard to neural intermediate phenotypes, brain networks were identified where attention-related activity overlaps with patterns of gene expression. It was hypothesized that variation in gene sequence should correlate with individual differences in neural activity associated with components of attention. In the case of executive control of attention, hypotheses of this kind have been supported for brain regions that are targets of dopamine innervation such as the frontal midline, lateral prefrontal areas, and basal ganglia.

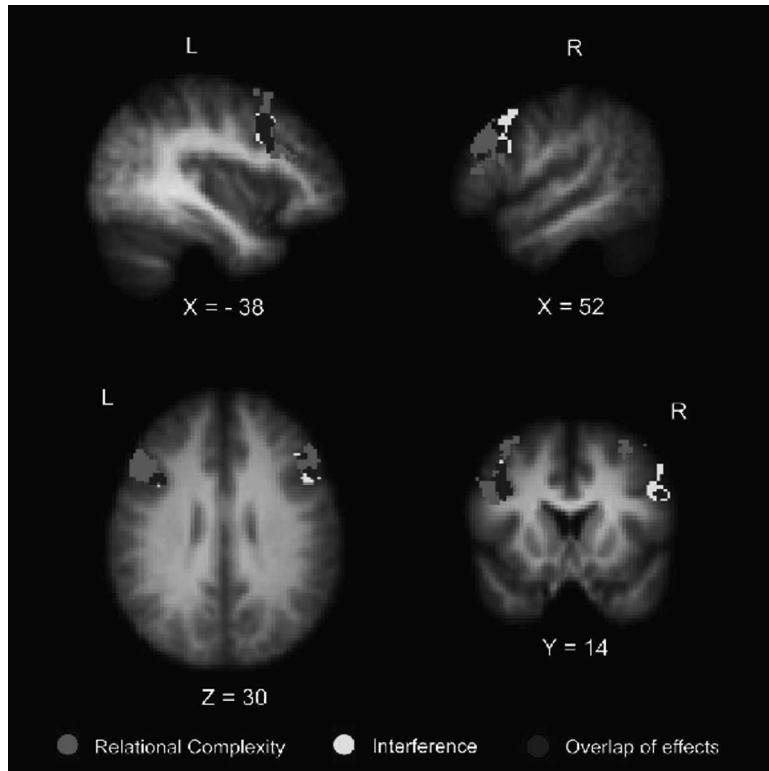

Fig. 13.3 Neuroimaging results from Cho et al. (2010). Regions showing the main effects of relational complexity (shown in red), interference (shown in yellow; small volume corrected, uncorrected cluster-forming threshold $T > 2.3$, corrected cluster extent significance threshold, $p < .05$), and regions where main effects overlapped (blue) within an a priori defined anatomical ROI mask of the bilateral MFG and IFG pars opercularis and pars triangularis. R, right; L, left. Coordinates are in MNI space (mm). (Reprinted by permission.)

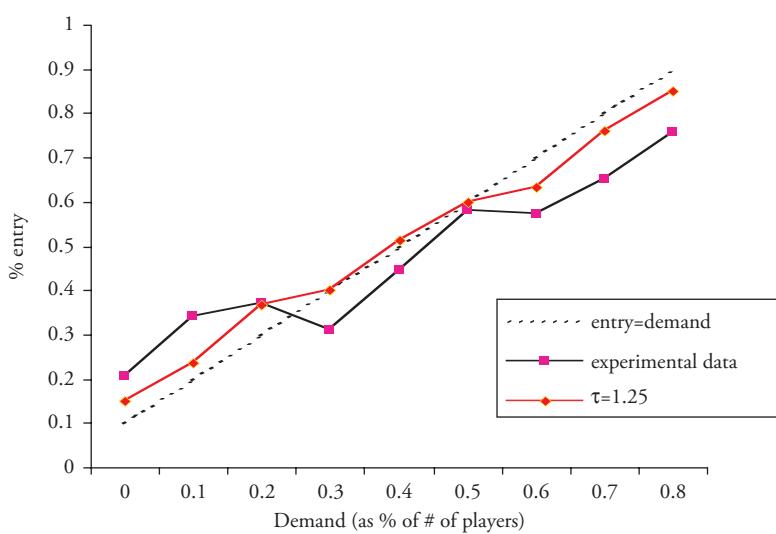

Fig. 18.2 Predicted and observed behavior in entry games.

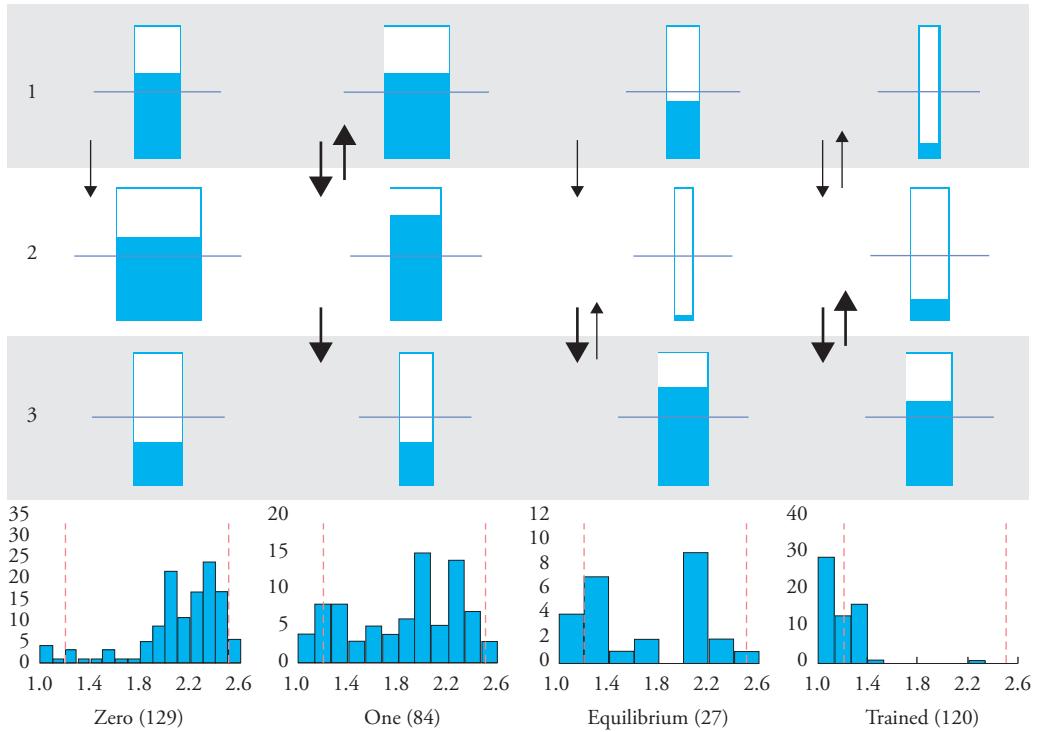

Fig. 18.4 An icon graph of visual attention in three rounds of bargaining (1, 2, and 3) and corresponding distributions of offers. Each column represents a different “type” of person-trial classified by visual attention.

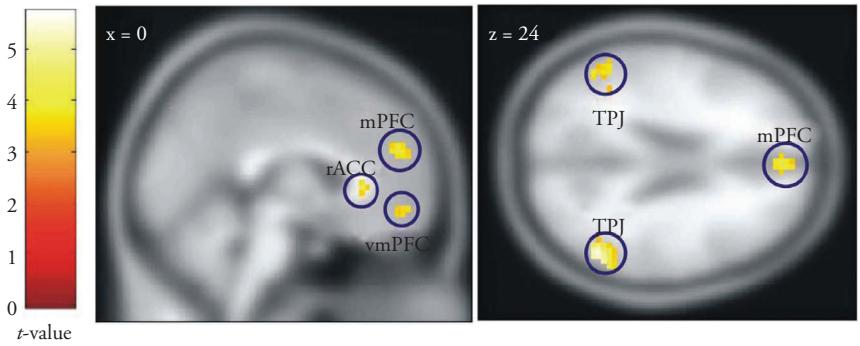

Fig. 18.7 Brain regions more active in level-2 reasoners compared to level-1 reasoners (classified by choices), differentially in playing human compared to computer opponents. mPFC, medial prefrontal cortex; rACC, rostral anterior cingulate cortex; TPJ, temporoparietal junction; vmPFC, ventromedial prefrontal cortex. (From Coricelli & Nagel, 2009, Fig. S2a.)

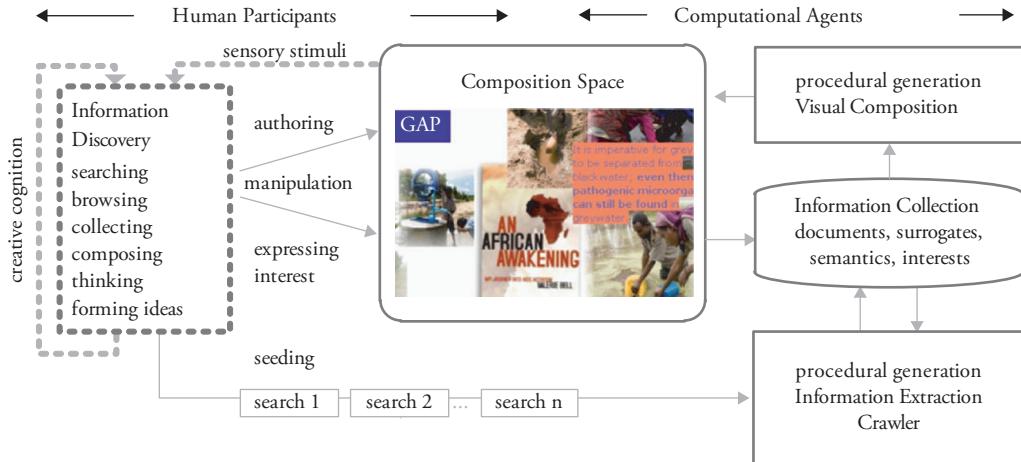

Fig. 23.9 Computational agents support human participants in the combinFormation digital tool for information discovery, which involves browsing through collections returned by search engines and forming navigable compositions of relevant results (Kerne, Koh, Smith, Webb, & Dworaczyk, 2008b). Problems are iteratively reformulated, representations are manipulated, and solutions constructed, often involving integration of multiple information resources (Kerne & Smith, 2004).

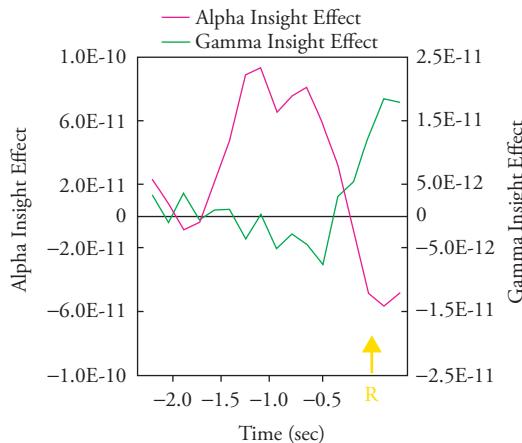

Fig. 24.1 The time course of the insight effect. Electroencephalogram (EEG) alpha power (9.8 Hz at right parietal-occipital electrode) and gamma power (39 Hz at right temporal electrode) for the insight effect (i.e., correct insight solutions minus correct noninsight solutions, in μV^2). The left y-axis shows the magnitude of the alpha insight effect (purple line); the right y-axis applies to the gamma insight effect (green line). The x-axis represents time (in seconds). The yellow arrow and R (at 0.0 s) signify the time of the button-press response indicating that a solution was achieved. Note the transient enhancement of alpha on insight trials (relative to noninsight trials) prior to the gamma burst signifying insight. (Reproduced from open source article by Jung-Beeman et al., 2004.)

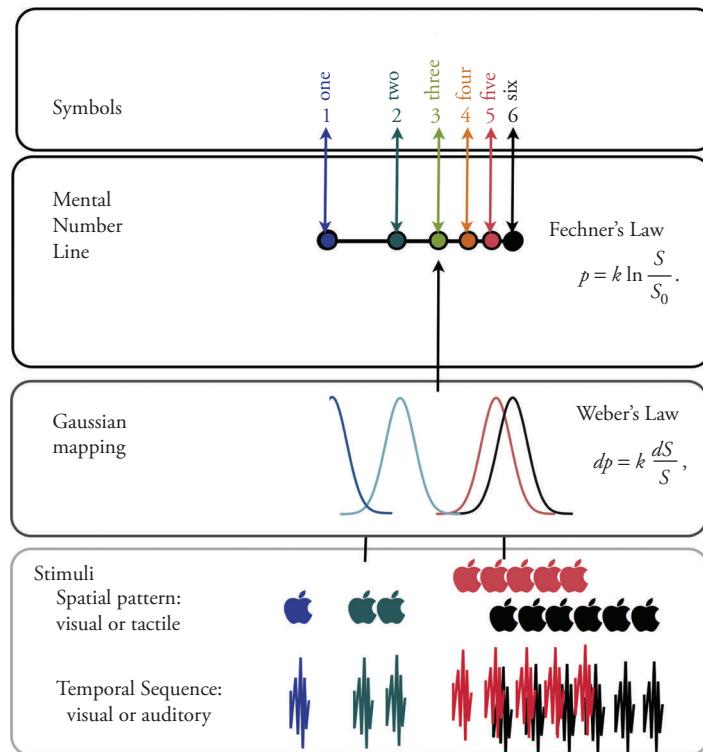

Fig. 30.1 Illustration of a logarithmically-scaled mental number line.
